One teacher students’ answers are highlighting an algebraic solution as optimal. It is stated that the medium tempts the pupils to solve the task geometrically. Already the answer to the first question is, that the pupils must solve the task algebraically. From the third answer it can be inferred that the pupils must be informed about the lure of the medium and that they should be led to an algebraic approach. This shows how fixated this teacher student is on their own solution path.

For answering RQ2, teacher students’ answers to question 3 and 4 were analyzed. The responses on the perceived need for support reflect the previously described levels of professional foundations and tool use. Methodological approaches were also mentioned. These include process-related and content-related support e.g. in a way that the pupils’ explorations are more structured, or the graphical representation should be analyzed in more detail. Four answers state that the task needs to be explained in more detail so that the dependencies are better understood. Content-related support should be given to pupils in the subject-specific basics of linear and quadratic functions and the meaning of parameters. Two answers are interesting which similarly describe that the pupils must first know the solution in order to then set this on the tool. This changes the role of the tool in such a way that it only serves to represent the solution and not to find it. This shows that the potential of the task for independent exploration of the relationships is not recognized or is assessed as non-existent by the teacher students. Another teacher student mentions that there are also solutions where the linear equations are not identical. In a discussion on teacher PD level, it could be mentioned that this can be used methodically so that Lukas and Robert can extend the solution they have found.

The final question on the insights that teacher students take back to their own future lessons is intended to provide information on which aspects cause them to change their way of thinking and

thus perhaps find their way into their lessons. For the case work, it is important that each specific case should contain something generalizable, which is meaningful for their future teaching (Staal Jenset et al., 2024). Unsurprisingly, the answers can again be divided into the areas of subject-specific basics, in particular the explicit repetition of individual content, and the use of the tool. The focus here is on explanations and assistance. The use of the tool is often praised, and it is emphasized that work with it should be intensified. The pupils' work with the tool is described as pure trial and error, which according to some should be better guided, and it would be better not to lose sight of the pupils so that not too much time is lost. At the same time, others positively emphasize that the time for trial and error is particularly important so that the pupils can deal with the mathematics independently. Fortunately, the latter opinion predominates in the teacher students' responses.

The following opinions regard to the task. Five out of 44 responses refer to the fact that the task needs to be explained better, and that pupils' questions need to be clarified before the task is worked on. Three times, the open exploration of the pupils and the associated character of the task was praised. One teacher student even highlights that they would like to use this kind of task themselves. It was emphasized that solving the task as a team was particularly helpful, also to stimulate discussions.

Conclusion

The teacher students perceive the nature of the task as the greatest challenge for the pupils. In addition to the recommendation to better guide the explorations with the tool or to prepare them with structure-like tasks, it is important to them that the pupils are given time to try things out. There is a difference between the perception that trying things out is aimless and praise for persistent exploration. A step-by-step instruction for exploring the relationships would be easier to grasp, particularly through dynamic visualization. Instructions on how to use a slider would be a simple means of using the tool. But it should always be clear that the tool character of the medium is retained, with which the pupils make their explorations and is not used solely for presentation their solution. In a final discussion at teacher PD level, it can be made clear why Lukas and Robert's exploration can be described as systematic experimentation. Perhaps this also changes teacher students' attitude towards the potential of the tool when working on the task. Different approaches include explicit input of parameters, sliders or, in some tools, a drag mode. Those possibilities once again show the potential of this task.

For their own future lessons, teacher students learn how difficult it is to observe the work of all pupils. It is therefore important to create the best possible conditions for independent work. To this end, they state that they would like to discuss tasks thoroughly and use tools continuously in lessons. Step-by-step introduction of various commands and tip cards should support the use of tools in order to reduce barriers to operation. Concluding discussions are intended to bundle the pupils' explorations and uncover difficulties. No one in the study rejected this type of task. The teacher students have become aware of the challenges and even noted that this way of teaching can be a long-term goal.

Synergies and dissonances between designers' and students' perspectives on key features of digital mathematical discussion

Sara Gagliani Caputo[1], Laura Branchetti[1] and Annalisa Cusi[2]

[1]University of Milan, Italy; sara.gagliani@unimi.it

[2]Sapienza University of Rome, Italy

In this paper, we showcase students' perspectives on their experiences with Digital Mathematical Discussion (DMD) and we compare them with the designers' perspectives. After presenting the design of the DMD and the key features of its design in terms of the timing and communication modalities, we report an analysis of the responses given by grade 9 students through online questionnaires following their experience with DMD. We aim at looking for insights into students' interpretations and assessments of how a DMD is structured and operates, potentially revealing areas of strength and opportunities for improvement in future redesign.

Keywords: Digital mathematical discussion, asynchrony, written communication.

Introduction and theoretical background

In recent years, digital technologies have played an increasingly central role in educational environments, particularly by offering new opportunities for extending collaboration and communication beyond the traditional classroom setting (Ball & Barzel, 2018). According to Ball and Barzel (2018), there is still significant, understudied potential in utilising social networks and other communication technologies to connect students learning mathematics from different locations. Moreover, when considering communication through technology, the nature of technology use transforms how students engage with, learn, and think about mathematics (Ball & Barzel, 2018). In this perspective, Digital Mathematical Discussion (DMD) has been introduced to allow students to collaborate, discuss, and co-construct mathematical knowledge also outside the physical space of the classroom (Gagliani Caputo et al., 2023). DMD is framed within mathematical discussion (Bartolini Bussi, 1991) and asynchronous discussion (Wang, 2023). Specifically, DMD relies on the concept of mathematical balance discussion, in which students socialise and evaluate strategies set up in their individual or small-group work on a mathematical problem (Bartolini Bussi, 1991), and it is realised in asynchronous modality with support of specific digital environments that facilitate its unfolding. The discussion is guided by the teacher organising and sequencing excerpts from students' solutions for comparing similar or contrasting strategies (Cusi et al., 2017). The teacher orchestrates the discussion acting as a model of aware and effective attitudes and behaviours (Cusi & Malara, 2013) aiming at making thinking visible to students and at fostering metacognitive reflections.

In this contribution, we consider students' and designers' perspectives on the main features of DMD with the aim of highlighting synergies or dissonances between them. When referring to features, we consider Trouche's (2004, p. 290, footnote 6) distinction between tools' constraint (obliging or impeaching the user), enablement (making the user able to do something), potentiality (virtually opening possibilities), and affordance (favouring particular gestures). In the case of the features of DMD, we interpret Trouche's definitions referring to *constraints* as the norms and rules that shape

how the discussion unfolds, to *enablement* as the conditions or resources that allow participants to contribute effectively in the discussion, to *potentialities* as the range of possibilities that the discussion opens up for participants, and to *affordances* as the features that favour certain types of involvement in the discussion.

Design of Digital Mathematical Discussion and its key features

DMD has been designed by the authors (Gagliani Caputo et al., 2023) and consists of three phases:

1. The first phase involves students in small-group work (4-5 students per group) for developing strategies for solving mathematical problems. The mathematical problems can vary depending on the objectives the teacher aims to achieve through the discussion. This phase takes place over some days (3-4 days in our study) within chats on an instant messaging platform (e.g., WhatsApp). The teacher is present in the group chats but only intervenes if explicitly requested by students. At the end of this phase, one student from each group submits the collective solution to the teacher via an institutional platform (e.g., Google Classroom).
2. The second phase is an asynchronous whole-class discussion orchestrated by the teacher with the aim to guide students in analysing, comparing, and reflecting on the strategies proposed by the groups in the first phase (Cusi et al., 2017). The discussion occurs over multiple days (3-4 days in this study) on a collaborative web platform (Padlet). The teacher structures columns in the Padlet asking questions on selected excerpts from the group solutions (Gagliani Caputo et al., 2023). Students and the teacher can add posts containing text, images, or attachments, and can insert comments and react to posts through upvotes or downvotes.
3. The third phase, following the whole-class discussion on Padlet, is a one-hour in-person discussion in the classroom to summarise and consolidate what emerged on previous phases.

The first two phases of DMD are conducted online and asynchronously as homework over several days. Students are asked to make all thought processes explicit, including problem-solving steps, doubts, new ideas, difficulties, and individual explorations, so that all participants can see the reasoning. Moreover, they are asked to interact on the activity only through the digital environment provided for the discussion (chat and Padlet) taking advantage of the technical features provided by the environments (e.g., sending pictures or attaching documents) and to maintain communication in written form. The digital environment was selected by the designers through an analysis to ensure it closely matched the desired settings for the DMD and could adequately support its implementation.

In this paper, we focus exclusively on the first two phases of DMD, as we are interested in investigating asynchronous modality and written communication. The asynchronous nature of DMD allows participants to engage with discussions at their own pace, affording flexibility that enables students to reflect, process information, and contribute thoughtfully without the constraints of synchronous timing (Wang, 2023). This flexibility is particularly beneficial for accommodating diverse learning styles and schedules, as students can revisit discussion threads, formulate responses over time, and manage their commitments. Similarly, written communication supports clarity and permanence, and provides a transcript of the discussion that can be referenced later (Wang, 2023). Moreover, as highlighted by Santos and Semana (2015), effective communication through writing is crucial for developing a deeper understanding of mathematics. Writing aids students in clarifying and refining their ideas, and in presenting and justifying their problem-solving methods formally.

Asynchrony and written communication can be characterised as key features of DMD as presented in Table 1. The characterisation is based on the design of DMD presented above and introduces the designers' perspective on asynchrony and written communication as key features of DMD.

Table 1: Designers' characterisation of asynchrony and written communication as features of DMD

	Constraints	**Enablement**	**Potentialities**	**Affordances**
Asynchrony	It is required not to interact with others in synchronous modality Time to submit contributions and to refresh to see new contributions	The duration of the discussion is set over multiple days Engagement of participants who feel less comfortable in real-time interaction	Exploration of concepts over time Introduction of ideas that open up new directions for the discussion	Flexibility in participation
Written communication	Impossibility of exploring functionalities that do not involve written communication Lack of body language for non-verbal communication	Making thinking processes explicit for both the one writing a contribution and those who read it Engagement of participants who feel writing as support for developing their reasoning or reflecting on others' contributions	Control over the whole discussion thanks to the availability of its complete transcript and consequent potential activation of metacognitive reflections on the structure of the discussion and on the links between its parts	Encourage structured contributions Encourage the use of mathematical symbols

Context, research question and methods

The study presented in this paper is part of the 2nd and 3rd cycles of a wider design-based research project (Cobb et al., 2003). These cycles involved two Italian science-oriented high schools and took place between February and April in 2023 and 2024. The experiments were conducted with two grade 9 classes and their teachers for each cycle. The mathematical problems students faced during the activities were focused on using algebraic language as a tool to construct proofs in arithmetic.

In this paper, we aim to investigate synergies and dissonances between designers' and students' perspectives on asynchrony and written communication as key features of DMD, in order to highlight relevant aspects of DMD design that should be reconsidered for re-design. The study is guided by the following research question: How do students perceive asynchrony and written communication as key features of DMD in their articulation as constraints, enablement, potentialities and affordances?

In order to answer the research question, we collected students' responses to an online written questionnaire with open-ended questions that highlighted their reflections on the role of the asynchronous modality and written communication in DMD after completing the four activities of the experimentation. The questions aimed to investigate students' perspectives on the challenges they

encountered during the asynchronous phases of the DMD, the usefulness of having access to their peers' written messages, the benefits and weaknesses of working asynchronously, and their reflections on the differences between working in-person and in the different digital environments involved in the DMD. Specifically, to gather students' perspectives on the asynchronous phases of DMD, their reflections were analysed with a focus on the perceived usefulness of having time to read and respond to messages, as well as the value they attributed to accessing written contributions from group members. Although the latter aspect focuses specifically on the availability of peers' written contributions during group work, students' answers were general enough to allow us to analyse their broader opinions about the written communication modality in DMD. We collected 65 students' responses to the questionnaire and we analysed only the 63 responses containing answers to both questions. The analysis of students' answers to the questionnaire is conducted through a thematic analysis. The analysis is conducted reading all students' answers and grouping them according to common themes emerging from the content of their answers with respect to asynchrony and written communication in DMD. The emerging themes are articulated as constraints, enablement, potentialities and affordances recognised by students. In particular, a theme concerns constraints if it highlights students' perceived difficulties or limitations, enablement if it refers to what actually allows them to participate in the DMD, potentialities if it concerns new possibilities DMD offers to students, and affordances if it relates to what students experience in the DMD in relation to their modes of involvement.

Analysis and results

The analysis of the answers given by students to the questionnaire allow us to identify themes of students' perceptions concerning the asynchronous modality and the written communication in DMD as constraints, enablement, potentialities, and affordances. In this section we present the results of the analysis that consist in the identification of themes based on students' reflections and the percentage of answers pertaining to each theme (the total percentage does not add up to 100% because each response may fall into multiple themes).

Concerning the asynchronous modality of DMD, four perceived themes emerged in students' answers: (1) flexibility in work management (22% of answers); (2) availability of time to reflect on one's contribution (60% of answers); (3) availability of time to reflect on others' contributions (18% of answers); (4) lack of pressure to respond immediately (3% of answers).

Students' answers in theme 1 concern how the asynchronous modality supports them at the organisational level both as enablement and affordance. Indeed, they noted that the flexibility in time allows them to effectively taking part in the discussion (enablement) but also that it shapes their time of interaction within the discussion (affordance), as they could choose when to participate in discussions without restrictions on their peers' timing ("I didn't have any problems coordinating with others, and I could write in the group whenever I had time"), and manage their participation alongside other school's activities ("I was able to organise myself better with the rest of my homework") and personal commitments ("With my personal commitments, I wouldn't have always been able to write"). Themes 2 and 3 show students' exploitation of the potentiality identified by the designers of exploring concepts over time. Students reported that the possibility to take their time allowed them

to reason more thoroughly ("[taking my own time] gave me the opportunity to have all the time to reason") both revisiting their own reasoning multiple times before submission ("one can review their ideas more calmly") and reading and understanding others' contributions more easily due to the ample time available ("I had the opportunity to read and understand others' contributions more easily, given that I had a lot of time available [for the activity]"). Theme 4 includes students' interventions who state explicitly that they "didn't have the pressure to respond immediately". Even though theme 4 was identified in only a few students' contributions, it is still relevant to be considered, as it highlights a potentiality of DMD recognized by the students but only partially addressed in the design. With respect to asynchrony, students were generally positive in their comments, nevertheless some have identified some constraints. For theme 1, students noted that the freedom to organise their timing sometimes led to procrastination and close proximity to deadlines ("You could work on the activity whenever you wanted, but sometimes, there was a tendency to always postpone the work, thus delaying it until almost the deadline"), or to forgetting to respond ("Sometimes they [peers' contributions] would arrive while I was working on other assignments, and I needed to focus, and then I would forget to respond"), or losing the line of reasoning ("If you take time to respond you risk losing the line of reasoning, which in turn results in wasting more time").

Regarding the use of written communication, three themes were identified. According to students, written communication in DMD supports: (A) read and reflect on others' reasoning while discussing (25% of answers); (B) compare others' reasoning with one's own (34% of answers); (C) re-read old contributions (42% of answers).

In theme A, students reflected on the enablement of written communication for accessing others' contributions more easily within the discussion. Examples include statements such as "[having access to others' written contributions] was helpful for comparing and seeing the different types of solutions" and "I was able to better understand what my classmates wanted to communicate". In theme B, students noted that having access to written contributions enabled them to revise their own opinions ("I was able to have direct comparisons between my opinions and those of my classmates, and on many aspects that I thought were clear, I changed my mind") and to find new insights ("[others' written contributions] were tools for gaining insights, but it was also challenging to read them and sometimes not understand them"). Theme C concerns students' exploitation of the potentiality identified by the designers concerning the availability of the transcript of the discussion. Students highlighted the possibility to re-read contributions once the discussion has moved on or finished to gain a better understanding of others' interventions ("since they [others' contributions] were written, they could be reviewed multiple times and reflected upon more deeply"), revisit one's own reasoning ("[having access to written contributions was useful] to revisit my reasoning even after days"), avoid forgetting important points during the discussion ("I didn't risk forgetting them [others' contributions]"), recover from missed parts of the conversation ("It was useful because I sometimes lost track of the conversation when others were writing in my absence, but by re-reading the messages, I was still able to understand what had been discussed"), or reconstruct the entire work ("It was easier to trace the development of the work"). However, few students expressed a perceived constraint that was not completely considered in the design, that the challenge to deal with long written contributions ("Having so much written in a single message is really annoying").

Students' comments focus also on combined features concerning asynchrony and written communication, such as the possibility to use the written contributions at their own pace to develop individual reasoning, and the availability of the written transcript of the entire workflow and discussion to all participants at any time. Regarding the first aspect, some students highlighted a potentiality of written communication, stressing that taking their own time to reflect on their own contribution was possible because they were writing their reasoning and that it wouldn't have been possible otherwise, such as using vocal messages ("before sending any message, there is time to review and correct any possible errors (which is not the case when sending a voice message)") or calls ("it was useful because I could respond when I had time. Therefore, it was more convenient than a phone call and offered more flexibility."). Regarding the second aspect, students shared their views on the availability of transcripts in response to the question "Do you think having access to the messages (both on chats and Padlet) even after the activities ended was helpful? Why? Did you find yourself going back to re-read messages (both on chats and Padlet) after the activities ended?". Forty students said that having access to the transcripts was beneficial and that they used them for various reasons: to clarify initially unclear issues ("I found myself going back to re-read the messages at the end of the activity to try to reflect on and understand some questions that were initially unclear"), to support subsequent class work ("In my opinion, keeping the messages was useful because, for example, while we were discussing in class, we could review our written reasoning from the chat"), to review the entire activity ("The messages show the progression of the entire activity, allowing one to 'retrace' it"), or to review parts of the activity when transitioning between phases of the discussion ("I found myself re-reading the passages when we moved from the chat to Padlet to understand our reasoning" or "[it was helpful] to compile the summary of the discussion that I then submitted on Classroom"). On the other hand, 29 students reported that they did not take advantage of the opportunity to revisit the messages. Many of them (21) do not recognise the enablement and affordances of written communication considered in the design, as they declare that having the transcripts was not useful at all ("I did not revisit the messages after the end of the activity because, once the posts were read, the reasoning was understood and memorised, making it unnecessary to go back"). Other 4 students, instead, acknowledged the potential future utility of having all contributions saved ("I did not review the messages after the end of an activity, but it is useful to have them saved in case they might be needed in the future"), even if at the moment they experienced DMD they have not recognised the availability of the transcript of the discussion as a potentiality.

Discussion and conclusion

The analysis of students' answers to the online questionnaire following their experience with DMD allow us to answer the research question by characterising their reflections on the asynchronous modality and the written communication in DMD and highlighting alignment and divergence in how the key features of DMD were characterised by designers. Students' responses reveal a more complex interaction with these features, introducing new insights that were only partially anticipated by the designers. Concerning asynchrony, for designers, flexibility (theme 1) is seen primarily as an affordance, allowing participants to engage in the discussion at their own pace. This feature aligns with students' perspectives, but according to them, flexibility functions as both an enablement and an affordance. It enables participation by allowing students to engage in the discussion according to their

own schedules, making it possible for them to manage their time effectively and participate despite other commitments. This aligns with the designers' intentions but goes further as students perceive it as actively shaping their interaction with the discussion. However, this flexibility also introduces a constraint that was not fully considered by designers: some students experience a loss of control over their work, leading to procrastination, forgotten responses, and difficulties maintaining the flow of reasoning. This reveals a dissonance between the designers' idea of flexibility and the practical challenges students face when this flexibility is not well managed. Moreover, designers emphasised the potentiality of asynchrony for exploring concepts over time. This potentiality is exploited by students, as reflected in their recognition of the benefits of having time to reflect on both their own and others' contributions (themes 2 and 3). Students describe how this extended time allows them to carefully reason, revisit, and refine their ideas before submission, as well as to understand others' contributions more deeply. This alignment between designers' intentions and students' experiences suggests that the potential of asynchrony to enhance reflective thinking is being effectively realised in practice. A key difference between students' and designers' perspectives emerges around the emotional dimension of participation, particularly the lack of pressure to respond immediately (theme 4). While designers considered the emotional aspects of asynchrony only partially, they did not specifically identify this as a significant feature. However, for students, the reduced pressure is perceived as a new potentiality of asynchronous discussions. This emotional benefit, which allows students to engage without the stress of immediate responses, fosters a more relaxed and thoughtful approach to participation, in line with Wang's (2023) vision of online discussion as a "relaxing environment" (p. 3) in which students can participate at their convenience. This aspect adds a new dimension to the designers' understanding of asynchrony and suggests that the emotional impact of flexible timing should be given more consideration in future design iterations.

Concerning written communication, designers identify it as a key affordance that facilitates reflective and structured engagement and thinking within discussions (as in Wang, 2023), but students' experiences introduce additional insights and challenges that were not fully anticipated. Designers characterise the ability to read and reflect on others' contributions (theme A) as an enablement, intending to make thinking processes more explicit. This aligns with students' perspectives, as they view this feature as an enablement that allows them to easily access others' reasoning within the discussion. Also concerning theme B, students' and designers' perspective align since written communication serves as an enablement that supports participants in comparing others' reasoning with their own, fostering deeper understanding and self-reflection. Themes A and B also align with the use of written communication experienced by Santos and Semana (2015) to introduce and justify reasonings in a clearer way to themselves and to others. Designers identify the potentiality of re-reading old contributions (theme C) as a feature of written communication, allowing participants to engage in metacognitive reflection. This potentiality is actively exploited by students, who highlight the advantages of being able to re-read contributions once the discussion has moved on or concluded. However, some students perceive a constraint in managing long written contributions, finding them challenging to navigate, an issue that was not fully considered in the design. This suggests a need for more user-friendly ways to manage extensive written content in future redesign.

Overall, the comparison reveals that while there are significant synergies between designers' intentions and students' experiences, some dissonances and new insights also arise. Students highlight new potentialities regarding the emotional benefits of reduced response pressure, but also new constraints, suggesting that further refinements could enhance the usability and effectiveness of asynchrony and written communication in DMD. Concerning the potentiality of having a transcript of the discussion identified by designers, just some students used it for further work even if most of them recognised the importance of having it for possible future uses. The ability to go back, review, and rethink is an attitude promoted through discussion and students should be taught how to exploit the potentiality of having at disposal the transcript of the discussion. In future experimentations this can be realised asking students to re-read and comment on some excerpts of their previous asynchronous discussion from the transcripts.

Teacher perspectives on textbooks and their role in implementing the mathematics laboratory approach in Italy

Marzia Garzetti[1]

[1]University of Genoa, Department of Mathematics, Genoa, Italy; marzia.garzetti@edu.unige.it

This study examines the use of mathematics textbooks by Italian lower secondary school teachers, focusing on their role in implementing the mathematics laboratory approach of the 2012 National Guidelines. Through a questionnaire completed by 609 teachers, the results show that textbooks are mainly used for exercises, with limited use for promoting laboratory-based, interactive learning. The results provide valuable insights into the role of textbooks for teachers and their relationship to the implementation of the mathematics laboratory. In addition, this study lays the groundwork for more systematic research into how the intended curriculum is implemented in practice.

Keywords: Curricular resources, Instructional change, Role of mathematics textbooks, Laboratory of mathematics.

Introduction

This research addresses the broad issue of curriculum translation from policy to practice. Although many European countries have introduced guidelines emphasizing active, competence-based learning, the implementation of these reforms in day-to-day teaching - particularly through key curriculum resources such as textbooks - often proves difficult (Rezat et al., 2021). The Italian context offers a particularly insightful case study to explore the role of textbooks. The 2012 National Guidelines for the Curriculum of Early Childhood and the First Cycle of Education (MIUR, 2012, own translation) advocate an instructional change towards a laboratory approach to mathematics that promotes exploration and collaborative problem solving reflecting similar shifts in other European education systems. However, unlike some contexts where textbook selection is centrally regulated, Italian teachers enjoy considerable autonomy in choosing the materials they use. This combination of policy-driven instructional change and teacher-driven resource selection makes Italy particularly well-suited to understand the dynamics influencing the use and role of textbooks in the relationship between policy and practice. By focusing on textbooks as the primary dimension of investigation, this study deliberately narrows its scope. Other relevant factors, such as teacher training, available infrastructure and classroom dynamics, while important, fall outside the scope of this work. Through a questionnaire administered to secondary mathematics teachers, the research explores how textbooks are used and adapted to support the laboratory approach. By providing descriptive insights into textbook use and its alignment with policy goals, these findings lay the groundwork for subsequent, more in-depth qualitative explorations - through planned focus groups - that aim to enrich understanding of the relevant dimension of resource use that influences the relationship between policy and practice.

Theoretical framework

Travers and Westbury (1989) distinguish between intended, implemented and attained curriculum, where intended curriculum is what is prescribed in official guidelines, implemented curriculum is what happens in the classroom and attained curriculum is the results achieved by students. As outlined

by Rezat et al. (2021), curriculum resources, that can be textbooks, multimedia resources or other teaching materials, are considered instruments of educational change. They mediate between the theoretical aims of curriculum documents, the intended curriculum, and the practical realities of classroom teaching, the implemented curriculum. These resources can either facilitate or hinder the implementation of educational reforms. Furthermore, they can be adapted to embed new pedagogical ideas and thus become objects of change themselves (Rezat et al., 2021). Rezat and colleagues (2021) highlight three key areas that are influenced by curriculum resources: mathematical content, instructional practices and vision of mathematics. This study focuses specifically on how textbooks affect instructional practices.

The role of textbooks as educational resources has been extensively explored across various educational contexts. Fan and colleagues (2021) highlight that the usage of textbooks can vary significantly among different groups of teachers, influenced by factors such as experience, training, and national context. They also highlight that the organization of teaching, instructional strategies, and the selection of explanations and exercises are heavily influenced by textbooks. Haggarty and Pepin (2017) discovered that less experienced or non-specialist teachers tend to rely more heavily on textbooks due to a lack of time for lesson planning, confirming that the teacher's level of experience is a critical factor in how textbooks are utilized as educational resources. However, literature reports conflicting results about the role of textbooks as facilitators or barriers in the teaching process. While some studies, like that by González-Martín et al. (2018), indicate that textbooks can be useful tools for sequencing and presenting content, others, like Matić & Gracin (2021), have shown that they can also limit the adoption of more innovative and interactive instructional approaches. In the Italian context, the investigation of textbooks as curriculum resources and teachers' perspectives on them remains underexplored, except for a few studies, mainly focused on primary schools (e.g. Sbaragli, 2020).

To contextualize this research, it is necessary to make a brief reference to the Italian school structure. In Italy, lower secondary school, serves as the second cycle of compulsory education and accommodates students aged 10 to 14 (grades 6 to 8). It lasts three years and is open to all pupils who have completed primary school. The National Guidelines (2012) outline the general learning objectives and competences expected at the end of the cycle. In particular, the national indications emphasise the importance of promoting the mathematics laboratory, described as

> […] both as a physical place and as a moment in which the pupil is active, formulates his own hypotheses and checks their consequences, plans and experiments, discusses and argues his choices, learns to collect data, negotiates and constructs meanings, brings the construction of personal and collective knowledge to temporary conclusions and new openings. (MIUR, 2012, p. 49, own translation)

The laboratory approach is defined in this research as an instructional practice, using the terminology of Rezat and colleagues (2021). Italian textbooks are not subject to any institutional review or approval process for use in schools; they are selected directly by the teachers of each school. However, they sequence the learning objectives and activities across the three school years and are owned by both students and teachers. Textbooks usually divide each topic into two parts, one to

introduce the theory and the other to practice, which typically consists of exercises focused on repetition and reinforcement.

Given the significant role of textbooks in structuring educational content and teacher practices, alongside the National Guidelines' emphasis on the mathematics laboratory as a central instructional practice, the teacher's perspective on the resources at their disposal for the laboratory are fundamental in determining how effectively they can implement the intended curriculum. Despite the guidelines advocating for an active, laboratory approach, there is limited understanding of how these recommendations are actualized in classroom practices through the mediation of textbooks. This gap raises the questions: (RQ1) How do teachers integrate textbooks into their instructional practices, and which specific textbook features or characteristics do they find valuable? (RQ2) To what extent do teachers find textbooks useful in implementing the mathematics laboratory? Acknowledging this viewpoint can shed light on the ways in which textbooks influence the implementation of the intended curriculum.

Methods

To quantitatively assess the variables of interest, a questionnaire was developed and distributed to a large sample of 2332 secondary school teachers in January 2024. This paper specifically focuses on the analysis of responses from 609 lower secondary school teachers, providing insights into this subgroup's educational practices and perspectives in relation to textbooks and the mathematics laboratory. The questionnaire consists of 14 questions, divided into 31 items, designed to analyse the use of textbooks, their role in promoting the laboratory approach and the resources available to teachers for such educational activities.

Each section of the questionnaire addresses different aspects of educational practices. The initial questions (Q1 – Q3) gather background information about the respondents.

The second section of the questionnaire concerns the adoption and use of the textbook (Questions Q4-Q7): question Q4 is an open-ended question that identifies the textbook adopted by the teachers; question Q5 a multiple-choice question exploring the utilization of the teacher’s guide associated with the textbook; Question Q6 examines the frequency of textbook usage in the classroom for five specific activities, selected based on the work of Sbaragli et al. (2020) and Fan et al. (2021). Respondents are asked to specify how often they engage in each of these activities. Question Q7 is a multiple-choice question that quantifies the overall frequency of textbook usage at school.

The third section of the questionnaire deals with the Evaluation of textbook characteristics (Questions Q8-Q9): question Q8.1 - Q8.10 employ a Likert scale to collect teachers’ opinions on ten different textbook attributes. Items were defined looking at Sbaragli and colleagues (2020) categorization of teachers answer to open ended questions about book satisfaction. Question Q9 requests a holistic evaluation of satisfaction with the textbook, rated on a scale from 1 to 10.

The last section of the questionnaire is dedicated to the mathematics laboratory (Questions Q10-Q14)**:** questions Q10 and Q11 assess the frequency at which open-ended problems are presented and laboratory activities are conducted, respectively. Question Q12 is a multiple-choice question that asks teachers to indicate the resources they use as a reference for designing and conducting lab activities, such as textbooks, websites, etc. Question Q13 is an open-ended question that invites teachers to

provide specific details about the resources they use for lab activities. Question Q14 utilizes a Likert scale to measure teachers' satisfaction with the resources available for mathematics laboratories and their accessibility. At the end of the questionnaire the participant is asked to leave an e-mail if he/she is available for a follow-up interview.

The questionnaire was distributed electronically to ensure wide reach. Teachers from various educational institutions across different regions participated, enhancing the generalizability of the findings. Participation was voluntary. Data from the questionnaire were analysed using statistical techniques suitable for the distribution of the data and the research questions addressed.

Results and discussion

The sample includes mainly experienced teachers: 43.8% of the respondents have more than 15 years of teaching experience and including those with more than 10 years of experience reaches 58.6% of the total. The respondents come from the different Italian regions, with a predominance for Northern Italy, where the number of schools is higher. Regarding the adoption and use of the textbook, in secondary schools, the daily use of textbook is widespread: 507 out of 609 teachers, 83.3%, say they use it every lesson, 79, 13%, use it weekly, 12, 2%, use it once a month and only 11, 1.8%, never use it (question Q7). However, it appears that the use of the book (question Q6, Figure 1) is mainly for exercises, with 95.6% of the teachers stating that they often or always use the book for exercises. The textbook therefore seems to be seen more as an exercise book than as a reference book for theory or for introducing topics, which is confirmed by the fact that about 70% of the teachers say that they never or hardly ever use the book to introduce or review content. Regarding mathematics laboratory, 53% of the respondents say that they often or always carry out the laboratories suggested in the book. 62.5% of the teachers rarely or never use the multimedia content of the textbooks. From this question, it appears that there is a general tendency to prioritize the use of the textbook for exercises, with less emphasis on its use as a reference for theoretical content or for supporting laboratory activities.

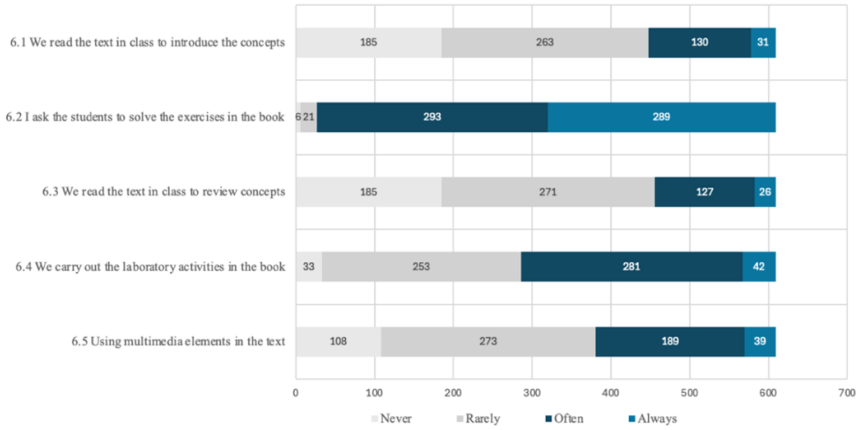

Figure 1: Answers distribution to question Q6 on the use of the textbook at school.

The evaluation of textbook characteristics indicates that, although the book is not typically used to introduce theory or serve as a handbook, it is generally recognized as having the qualities of a good handbook. According to responses to question Q8 (Figure 2), 83.7% of teachers consider it well-structured (item 8.1), 78.1% view it favorably as a tool for lesson planning (item 8.2), and 87.2% find that the instructions for the activities are clear (item 8.5). These results suggest that the limited use of

the book as a textbook is not due to dissatisfaction with its content, but rather to conscious teaching choices. Another interesting aspect concerns the perspective on the laboratory activities included in the textbooks. 73.5% of the teachers recognise in the book the presence of laboratory and problem situations useful for the development of mathematical competences, but the agreement drops to 61.1% for the promotion of argumentative practices and to 50.9% for group work. The textbook appears to be less effective also in areas such as multimedia integration (49.8% agree on item 8.7) and the provision of real-world modelling activities respectively (57% of teachers agree on item 8.10). This suggests that although the textbook is well-regarded for supporting individual activities and exercises—as evidenced by the generally positive responses in question Q8—it may not provide sufficient resources for more interactive and collaborative teaching. The data also implies that the concept of 'laboratory' perceived by the respondents might focus more on the mathematical content and task than on instructional aspects such as argumentative practices or peer collaboration and confrontation. Furthermore, it is possible that teachers are supplementing the textbook with their own methods to implement these interactive aspects of laboratory work, indicating a possible adaptive use of the textbook's content to fit more collaborative educational models.

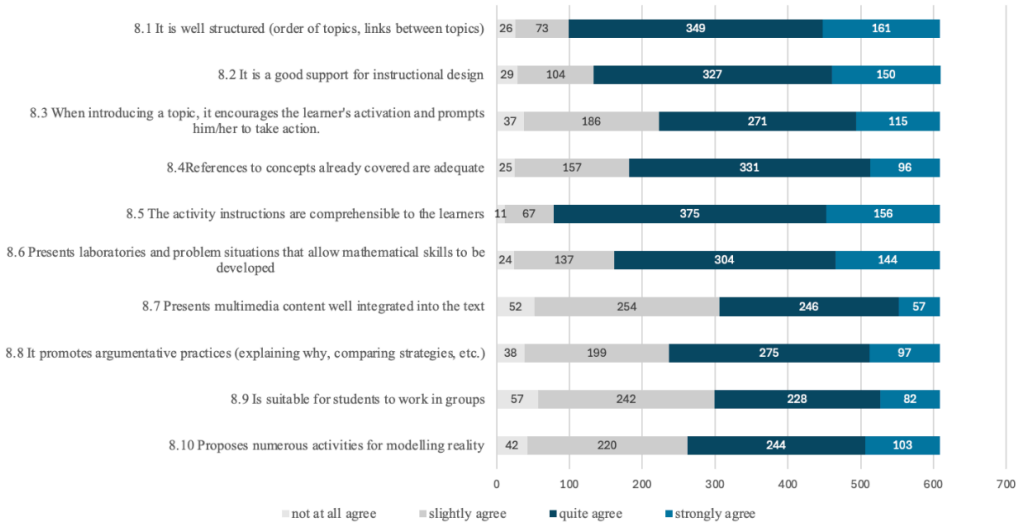

Figure 2: Answers distribution to question Q8. Respondents are asked to agree to statements on the textbook they use.

The analysis of satisfaction with textbook usage across different years of teaching experience reveals a clear trend of increasing satisfaction correlating with longer teaching tenure. The mean satisfaction scores demonstrate this progression, with teachers having 1-5 years of experience reporting an average satisfaction of 6.62, which gradually rises to 7.59 for those with more than 15 years of experience. This upward trend in satisfaction was further validated using the Kruskal-Wallis test, a non-parametric method selected due to the violation of normality assumptions in the data, as indicated by the Shapiro-Wilk test ($p < .001$). The Kruskal-Wallis test highlighted statistically significant differences in textbook satisfaction among groups of teachers with different years of experience ($\chi^2 = 35.4$, $df = 3$, $p < .001$). This result suggests that perspectives on the quality and effectiveness of the textbook vary significantly with the accumulated experience of the teachers. These findings provide evidence that the duration of teaching experience impacts teachers' satisfaction with textbooks, with

more experienced teachers generally reporting higher satisfaction. This could reflect greater familiarity with the textbook's content and features or possibly a more developed skill set in integrating the textbook effectively into their teaching practices.

Regarding the mathematics laboratory, among the respondents, 59.1% reported regularly proposing open problems—problems without a single, predetermined outcome—at least monthly: 25.9% weekly and 33.2% monthly (Figure 3). This indicates that proposing open problems is a common practice among the participating teachers. Furthermore, a significant 80% of respondents engage in laboratory at least once a month, with 51.6% conducting these activities weekly (Figure 3). This highlights the prevalence of laboratory teaching among the study's participants.

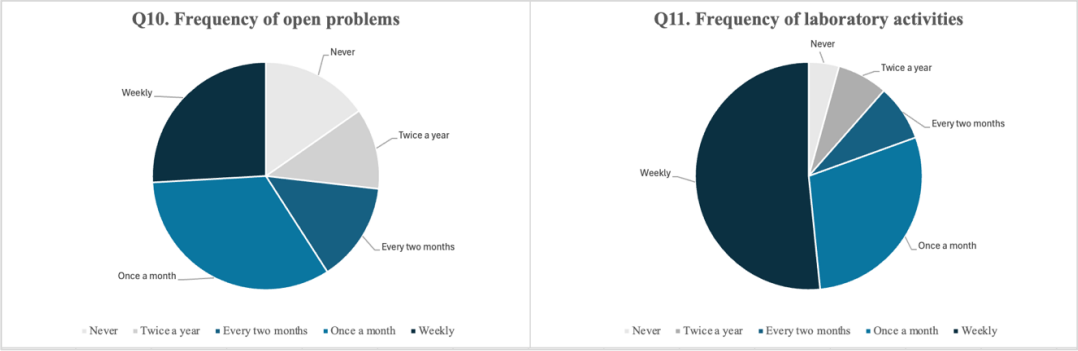

Figure 3: On the left the distribution of answers for question Q10, on the right question Q11.

However, the relationship between conducting laboratory activities and proposing open problems is not strictly one-to-one, as it is made visible comparing the two graphs in Figure 3. For instance, among the 314 teachers who conduct weekly laboratory activities, 39% also propose open problems weekly. Conversely, 35% teachers engage in weekly laboratory activities but only present open problems monthly. Additionally, 8% teachers propose open problems every two months, 7% biannually, and 11% never propose open problems despite weekly laboratory activities. This highlights a possible disconnect between the national indications ‘definition of a laboratory in mathematics and the teachers’ definition of a laboratory. There may be a disconnect between the concepts of open-ended problems and laboratory activities.

Another significant finding concerns the resources used by teachers for mathematics laboratory (Q12). 28.6% of teachers say that they use the textbook as their main reference for these activities. However, a similar percentage, 28.6% of teachers, rely mainly on online resources, while 26.3% design the activities themselves. This suggests that although the textbook is used for laboratory activities, teachers tend to look elsewhere for additional materials and inspiration, perhaps due to a perceived incompleteness or inadequacy of the content in the books themselves, or the need to adapt the resources to meet specific classroom needs. Question Q14 shows that 67.1% of teachers indicated that they spend a lot of time searching for suitable materials for laboratories (Figure 4, item 14.1), with an even higher percentage (76%) of teachers with less than 5 years' experience. These data highlight that materials for mathematics laboratory are not always readily available and accessible, especially for less experienced teachers, who may find it more difficult to adapt or design appropriate activities without external support. To analyse the factors influencing the performance of laboratory activities by teachers, the responses to question Q11, which inquired about the frequency of the

mathematics laboratory, were transformed into a dichotomous variable. This variable categorizes teachers into two groups: those conducting mathematics laboratory at least once a month and those conducting them less frequently. The correlation between this dichotomous variable and the responses to items in question Q14 was then examined. The analysis revealed statistically significant correlations ($p < .001$) with items 14.1 and 14.3, indicating that the frequency of laboratory activities is associated with the availability of adequate resources.

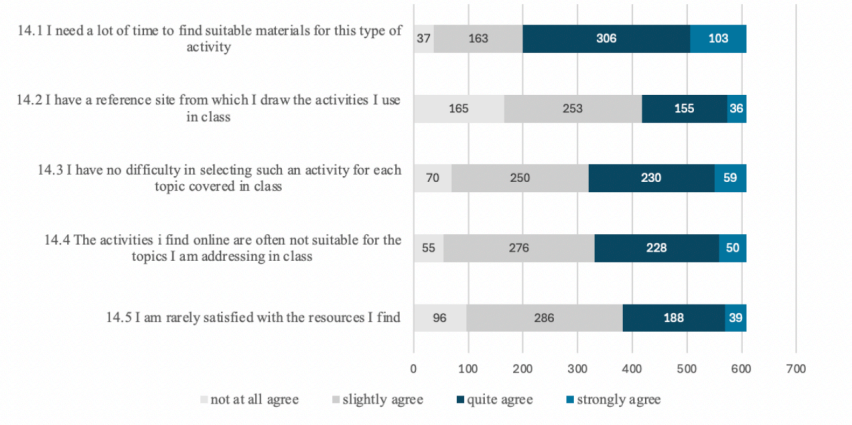

Figure 4: Question Q14. Respondents are asked to agree to statements on laboratory resources.

The observed differences may reflect variations in instructional choices or the availability of suitable materials. Teachers who infrequently conduct such activities might be constrained by the absence of appropriate resources or might choose different teaching methodologies for other pedagogical reasons.

Conclusions

This study underscores the important role textbooks play in Italian lower secondary mathematics education, particularly in relation to the implementation of the mathematics laboratory approach advocated by the National Guidelines. Drawing on the theoretical framework proposed by Rezat et al. (2021), which positions curricular resources as mediators between the intended and implemented curriculum, the findings allow to answer question RQ1, highlighting how textbooks are integral to teaching and learning practices, being used in every lesson by 83.2% of respondents. However, their use tends to be concentrated on exercises rather than fostering laboratory-based activities or promoting collaborative and argumentative practices. As noted in the literature (Fan et al., 2021), textbooks heavily influence lesson planning and the organization of classroom activities. This study supports these findings, revealing that 95.6% of teachers rely on textbooks primarily for exercises. However, a substantial portion of teachers report using external resources for laboratory activities, with 28.6% using online materials and 26.3% creating their own resources. Only 53% of teachers report regularly using laboratory activities found in textbooks, reflecting the mixed findings in the literature regarding the role of textbooks in supporting innovative practices (González-Martín et al., 2018). Teacher experience also seems to influence textbook satisfaction, aligning with the findings of Haggarty and Pepin study (2017). This may be due to greater familiarity with additional resources or different teaching practices, as teachers with over 15 years of experience began teaching before the National Guidelines were introduced and may employ distinct methods. The answer to RQ2

emerges from several trends observed in the data: teachers who infrequently conduct laboratory activities may be constrained by the lack of appropriate resources, as suggested by responses to question Q12 and Q14. Although textbooks are used for laboratory activities, teachers often turn to other sources for supplementary materials (Q12), which can be time-consuming (Q14). Focus groups will be conducted to explore the reasons behind these trends. Key areas of investigation include understanding how teachers interpret the concept of a mathematics laboratory, as there appears to be a gap between the national guidelines and classroom practice. Additionally, the focus groups will examine why many teachers supplement or replace textbooks with external resources for laboratory activities. Lastly, the influence of professional experience on textbook use and perspective will be analysed, particularly the differences between experienced and less experienced teachers. In conclusion, while textbooks remain essential tools for structuring mathematics education, their current use does not fully support the implementation of the mathematics laboratory approach, particularly in its collaborative and argumentative aspects. This article presents only the initial findings and mainly descriptive analyses of the questionnaire; further in-depth study is still required to explore these issues more comprehensively.

Exploring the use of digital textbooks in classrooms: focusing on automated feedback

Dubravka Glasnović Gracin, Goran Trupčević and Katarina Širanović

University of Zagreb, Faculty of Teacher Education, Zagreb, Croatia; dubravka.glasnovic@ufzg.hr

Automated feedback is a significant potential of digital tasks in e-textbooks that supports learning. This paper examines the types of automated feedback present in digital textbook tasks in Croatia and how they are utilized in the teaching process. The study focused on the geometry chapters of the three most widely used mathematics textbook sets in Croatia for grades 5 to 8, as well as a multiple case study involving six middle-grade teachers. The findings reveal that automated feedback is most prevalent in simple digital tasks, primarily in the form of verification, while the exploration tasks often provide hints. However, in classroom observations, these digital textbook tasks were mostly used in whole-class teaching, limiting the full potential of automated feedback.

Keywords: Digital textbooks, automated feedback, use of resources, mathematics education.

Introduction

Over the past several decades, digital textbooks have become important resources in mathematics classrooms which can introduce new potentials such as dynamics, automated feedback, and personalization (Choppin et al., 2014; Glasnović Gracin & Krišto, 2022). These new digital features have the potential to transform mathematics education by enhancing the understanding of mathematical concepts and their relationships.

Feedback, a crucial component of teaching and learning, is defined as "information about the gap between the actual level and the reference level of a system parameter which is used to alter the gap in some way" (Ramaprasad, 1983, p. 4). Schute (2008, p. 154) described formative feedback as "information communicated to the learner that is intended to modify his or her thinking or behaviour for the purpose of improving learning". Van Der Kleij et al. (2015) classified feedback types into knowledge of results (verifying the response correctness), knowledge of correct response (providing the correct response), and elaborated feedback (providing additional information, such as strategic hints, etc.). Findings from their meta-analysis (Van Der Kleij et al., 2015) showed that elaborated feedback is more effective for learning than the other two categories. This categorization also applies to the digital environment and automated feedback. Automated feedback on student solutions is one of the most prevalent digital features of e-textbooks, with the potential to support learning and change and improve instruction (Rezat, 2021). Therefore, we found it important to investigate the types of automated feedback present in digital textbook tasks and how they are used in classroom practice.

The use of digital textbooks, along with their content and features, has the potential to transform educational processes and "bring about new educational dynamics" (Pepin et al., 2017, p. 799). As noted by Remillard (2012), teachers develop a *mode of engagement* with resources over time, shaped by their experiences, which influences how they approach a new (digital) textbook. Consequently, teachers' established practices in using printed textbooks may also shape how they interpret and apply automated feedback in digital resources. Furthermore, the use of textbooks in classrooms inherently

involves questions on their authority, including the teacher's role as a mediator between textbooks and students (Pepin & Haggarty, 2001). Since school textbooks represent authorized versions of knowledge, they carry a certain authority. This extends to automated feedback provided by digital textbooks, whose authority remains an underexplored area of study.

These considerations highlight important questions regarding the design and implementation of automated feedback in school settings. To our knowledge, the relationship between the (educative) features of automated feedback in digital textbooks and its use has not yet been the subject of research. Investigating these issues could contribute to a deeper understanding of the role of automated feedback as a tool for educational transformation and improvement. In our study, we explored these questions within the Croatian context.

In Croatia, textbooks can be printed and electronic, and are mandatory educational resources approved by the state board. The Ministry of Science and Education's (2019) Textbook Standard outlines specific requirements for digital textbooks, including dynamics, simulations, and various types of interactions. The student-content interaction in digital textbooks serves both for evaluation (interactive quizzes with feedback) and learning (didactic games, etc.). This aspect of the Textbook Standard highlights the need for automated feedback in digital textbooks and the following research questions: (1) What types of automated feedback appear in digital textbooks? (2) How is automated feedback from digital textbooks utilized in classroom practice and why?

Theoretical framework

Shute (2008) classified feedback types according to their complexity, including categories such as no feedback, verification, correct response, try again, error flagging, elaborated feedback, attribute isolation, topic contingent, response contingent, hints, misconceptions, and informative tutoring. Building on Schute's (2008) classification, Glasnović Gracin and Krišto (2022) developed a framework for analysing tasks in digital textbooks (see Table 1). This framework forms the foundation for the study presented in this paper.

Table 1: Automated feedback types (Schute, 2008; Glasnović Gracin & Krišto, 2022)

Feedback type (code)	Description
No feedback (F1)	A student responds in a digital space, but no feedback is provided
Verification (F2)	Returning a simple right/wrong response
Correct response (IF1)	Provides the correct answer, with no additional information
Try again (IF2)	Trying until the correct answer is given
Error flagging (IF3)	Highlighting incorrect answers in the task, but without offering the correct answer
Elaborated (IF4)	Explaining why a specific response was correct or incorrect

Hints/cues/prompts (IF5)	Guiding students in the right direction by giving examples or recommendations on what to do next, for instance, but the correct answer is not explicitly given
Other	Other types of automated feedback

According to Van Der Kleij et al.'s (2015) classification mentioned in the introduction, feedback types of verification, try again, and error flagging (Table 1) are categorized as feedback on the knowledge of results, while elaborations and hints/cues/prompts belong to elaborated feedback.

Regarding the use of automated feedback in classrooms, we applied the types of teacher resource utilization identified by Brown and Edelson (2003). These include offloading (where teachers heavily rely on curriculum materials such as textbooks), adapting (where teachers use and modify parts of the curriculum materials), and improvising (where teachers do not depend on textbook content). Based on Brown's Design Capacity for Enactment Framework, Pepin et al. (2017) developed a model for teacher design capacity while interacting with digital resources. It comprises the goal of design (resource accordance with the curriculum and the teacher's aims), design principles (robust and flexible concepts of teaching when digital resources are used), and reflection-in-action (teacher decisions during the instruction). Flexible principles may refer to accepting and using educative features of automated feedback in the classroom.

Methods

In this study, which is part of a broader investigation into the analysis and use of digital textbooks, a mixed-method approach was employed. To address the first research question, document analysis was conducted, focusing on the digital versions of the three most widely used mathematics textbook sets in Croatia for grades 5 to 8. The analysis included all digital tasks within the geometry chapters (1,381 tasks in digital textbook set A, 1,250 in set B, and 363 in set C). The instrument for analysing these digital tasks was based on the framework presented in Table 1, with the addition of a new feedback type found during coding, Worked solution (code WS), where the automatic feedback provides an elaborated solution. The codes for feedback types are not mutually exclusive. The coding process was carried out by the second author, while the first author analysed 10% of the items, achieving a high level of agreement in coding (99%). The coded data were then analysed using relative frequencies for each type of feedback.

To answer the second research question, a multiple case study was conducted involving six middle-grade mathematics teachers. This study included observations of 29 geometry lessons and supporting semi-structured interviews. The observations included the following questions: *Is automatic feedback used in this activity? If so, describe what types are used and in what way*. The interviews aimed to gain a deeper understanding of the participants' views, experiences, and reasons for utilizing automatic feedback. Key questions included: *In your opinion, what are the benefits of using digital textbooks and automated feedback in geometry education? What challenges and drawbacks do you encounter? Please explain.* The observation notes and transcribed interviews were analysed using qualitative content analysis, with the resulting categories subsequently grouped into larger thematic clusters.

Results

Automated feedback in digital textbook tasks

The tasks found in the geometry chapters of digital textbooks were categorised into those requiring a closed answer (simple tasks) and those designed for exploration activities. The results indicate that the number of closed tasks with feedback (Table 2) greatly surpasses the number of exploration activities (Table 3). In closed tasks, automated feedback is predominantly utilized for basic performance checks (verification, error flagging), while largely overlooking formative assessment and the transformation of learning within a digital environment. While other types of feedback are rarely present in digital textbooks A and B, textbook C offers knowledge of correct response (IF1) as feedback and provides some hints for solving the closed tasks. Excluding verification, closed tasks rarely provided a combination of more than one type of feedback (1,1%).

Table 2: Automated feedback in tasks with closed answer

Dig. textbook	No feedb. (F1)	Verification (F2)	IF1	IF2	IF3	IF4	IF5	WS	Other
A (1270)	0.1%	99.9%	0.4%	1.7%	34.0%		2.2%	0.2%	0.1%
B (1187)	0.3%	99.7%	0.3%	0.3%	48.1%		1.1%	0.1%	
C (257)	1.2%	98.8%	17.9%		33.9%	0.8%	11.3%	0.4%	0.4%

Textbook tasks involving exploration activities (Table 3), primarily made in GeoGebra, had a focus on the student's exploration within the applet rather than providing a specific answer to a question. As a result, verification as a form of feedback is less common compared to Table 2. Conversely, these tasks frequently offer students hints (IF5) and occasionally provide worked solutions (WS) and correct answers (IF1). Moreover, hints are often given together with correct answers and worked solution. These findings imply more educative features of automated feedback.

Table 3: Automated feedback in tasks involving exploration activities

Dig. textbook	No feedb. (F1)	Verification (F2)	IF1	IF2	IF3	IF4	IF5	WS	Other
A (111)	7,2%	21.6%	10.8%		1.8%	0.9%	53.2%	20.7%	0.9%
B (63)	6,3%	6.3%	30.2%	1.6%			55.6%	30.2%	
C (106)	5,7%	12.3%	78.3%				87.7%	2.8%	

These results offer a deeper understanding of the educational potential of automated feedback in analysed digital textbooks. The focus is primarily on simple knowledge of results, which is inadequate for fostering the comprehensive development of geometric thinking. However, in tasks involving exploratory activities, feedback plays a supportive role, aiding students in developing a deeper understanding of geometric concepts.

Use of automated feedback in the classroom

The 29 observed lessons included altogether 150 activities with digital textbooks, 44 of which included using tasks with automated feedback. Other activities involved using textbook content that did not provide interactions in the digital space, but merely static images (PDF of a printed textbook). The observations identified two types of automated feedback usage in the observed classrooms: (1) direct use of automated feedback from the digital textbook tasks (offload), and (2) modified use of automated feedback (adaptations).

Direct use of automated feedback. This type of use occurs when, after answering a question, the feedback button is clicked. In the observed lessons, this approach was employed by students during individual work (16 activities) and by teachers or students in frontal instruction (13 activities). It is important to note that all activities related to students obtaining individual feedback occurred during a single lesson, where the students were brought to a computer classroom and each student sat at their own PC workstation (T1L2A1–16 means: teacher T1, lesson 2, activities 1–16):

> Observation T1L2A1–16: Students individually work with a digital textbook on the topics of supplementary and alternate angles. They complete each activity and solve all the tasks from these two topics, utilizing the automatic feedback provided. To log in, they use their student IDs. The teacher walks around the classroom, helping and engaging in discussions with the students.

Teacher T1 explained that these activities provided each student with automated feedback, enabling them to practice at their own pace. This approach can be interpreted as a form of didactical flexibility in her use of digital textbooks. Still, the teacher expressed satisfaction with the feedback which primarily offered *knowledge of results* at both the task and lesson levels. She noted, “they receive feedback on whether their answers are correct or not. (...) Additionally, they are shown the total percentage of all tasks they have completed”. Satisfaction with knowledge of results implies robust and traditional principles in her teaching design while using automatic feedback.

Thirteen observed activities involved teachers presenting the digital tasks to the entire class on the smartboard. In this approach, automated feedback was utilized as part of the frontal teaching.

> Observation T6L2A3: Direct teaching to the entire class. The teacher presented a GeoGebra applet from the digital textbook (topic: area of a parallelogram) to demonstrate an animation that explains how to derive the formula for the area of a parallelogram using the area of a rectangle. Discussion with students throughout the activity. The applet included buttons that provided feedback in the form of hints and the final area formula. The teacher clicked on these buttons and used hints to drive discussion. Additionally, the teacher derived the formula on the board.

Here, automated feedback had elaborative elements used in the classroom as a part of interactive discussion (flexible principles in teacher’s design). Still, the robust principles refer to the teacher’s

control over the process because she decided to click on the feedback buttons, not the students, because "I always try to make it an interaction between me and them so that we come to a solution together" (T6). The other reason participating teachers clicked on feedback in the frontal setting was the limited availability of PCs for all students.

> T5: If we had an IT classroom at our disposal like we used to, then each student could try a lot of things (including feedback) on their computers.

Furthermore, observations of teacher T3's lessons revealed an interesting issue related to students' use of automated feedback. Namely, the students entered the correct solution (estimation) but became confused by the negative automated feedback:

> Observation T3L1A6: The teacher used a GeoGebra applet from the digital textbook (topic: finding a central-symmetric point). Two students came to the smartboard and, using their finger, estimated the position of the symmetric point. Automated feedback was used (by students), but because the GeoGebra applet was set to a very high accuracy level, the student received an "incorrect" response, even though the estimation was satisfactory. The teacher encouraged them by saying their estimations were well done.

This illustrates a problematic aspect of automated feedback and serves as an example of *reflection-in-action* regarding feedback. In such cases, the teacher creates connections or guiding actions that may not be immediately apparent but emerge and take shape during the teaching process. Within this context, the feedback provided directly by the teacher holds greater authority over the students than the automated feedback they receive after completing the task.

Modified use of automated feedback from tasks. In 15 cases, the use of automated feedback from digital textbooks was modified. In some observed activities, the digital tasks were presented to the class, but the automated feedback was ignored, as teachers decided to provide feedback personally. This is an example of teachers prioritizing their authority over automated feedback, sometimes overlooking its potential and instead relying on familiar practices as robust principles. For example:

> Observation T2L1A2: A quiz from the digital textbook is displayed on the classroom board. Students work on the quiz tasks in their notebooks. Afterward, they exchange notebooks in pairs and read each task aloud along with their answers. The teacher types in the answers into the quiz via laptop and provides feedback on the screen, deliberately ignoring the automated feedback. At the end, each student counts their correct answers, and the teacher types the scores in her Excel table, followed by a discussion about the students' achievements.

In the interviews, teachers offered several reasons for preferring to provide feedback themselves rather than relying on automated feedback. These included the ability to offer better explanations and facilitate further discussion (T1), the presence of incorrect answers in the automated feedback (T5), and technical issues with the smartboard that prevented the use of interaction buttons required for automated feedback (T2).

The observations also included several activities where teachers combined automated feedback with their own feedback, depending on the student's correct or incorrect responses (reflection-in-action):

> Observation T2L3A6: The teacher introduces a practice task from the digital textbook to the class (topic: supplementary and alternate angles, 11 computer-generated subtasks). She selects a student to provide the angle magnitude, then she inputs the response. If the answer is correct, the teacher provides feedback herself, disregarding the automatic feedback. However, when a student gave an incorrect answer, she allowed the automated feedback to deliver the response.

In this instance, the output "incorrect" provided by the automated feedback acted as both an authority and a catalyst for classroom discussion (elaborated feedback with the teacher).

Discussion and conclusions

The study presented in this paper investigated the extent to which automated feedback is incorporated into tasks within digital textbooks and how it is utilised in mathematics instruction. The study found that automated feedback is indeed present in Croatian digital textbooks, primarily as simple verification, while elaborations are more commonly found in exploration activities. The use of automated feedback in observed lessons revealed both flexibility (using automated feedback from digital textbooks) and robust design principles (teachers' control and providing their own feedback). Sometimes teachers disregarded automated feedback because of the frontal teaching, issues with IT, or because it did not provide elaborated information, so further classroom discussion was needed.

Although automated feedback is recognised as a digital potential that can support learning and enhance instructional practices by taking responsibility from the teachers, so they are not the only ones providing feedback (Rezat, 2021), the results of this study suggest that it was not fully utilized in this way. At times, participating teachers chose to disregard automated feedback and provide their own when they believed it could not fully realise its potential. This may be related to a strong tradition in Croatia of whole-class instruction and the use of printed textbooks in mathematics education (Glasnović Gracin & Krišto, 2022). The influence of automated feedback was shaped not only by the available technology but also by the robust pedagogical intentions and personal preferences of the participants, who ultimately determined whether and how to incorporate feedback into their instruction. Previous studies suggest that teachers often adhere to one or more familiar activity formats in the classroom and prefer using materials that do not require completely new approaches to activities (e.g., Monaghan, 2004). Their mode of engagement (Remillard, 2012) with printed textbooks may have influenced the design principles in their lessons.

These findings highlight the issue of the *authority* of digital textbooks and their potential, such as automated feedback, and the authority of a teacher as a mediator between textbooks and students (Pepin & Haggarty, 2001). In our study, the presence of automated feedback in digital textbooks led to a kind of "battle of authorities" during the observed activities: the participating teachers chose to disregard the automated feedback in favour of providing their own feedback to students or combining them within reflection-in-action. Additionally, instances where the automated feedback was incorrect necessitated teacher intervention. It seems that the full pedagogical potential of automated feedback should be further examined and described, including an examination of the students' perspectives, such as their perceptions of automated feedback compared to feedback provided by teachers.

Upper-secondary school mathematics teachers' use of a topic-centered research-based teacher guide

Marcus Gustafsson

Karlstad University, Department of Mathematics and Computer Science, Karlstad, Sweden;
marcus.gustafsson2@kau.se

This paper reports on an exploratory study in which upper-secondary school mathematics teachers used an experimental research-based teacher guide for the topic of quadratic equations as a supplement in their planning and teaching practice. A survey and semi-structured interviews were used as data-generating instruments. Building on data from six teachers, a map of the use was constructed qualitatively. From this map, categories of affordances and constraints perceived by teachers in relation to the teacher guide content features, and types of mobilizations were constructed. The main finding on this use is that lesson activities that were perceived as having a variety of affordances were mobilized to a greater extent than other features. The role of research and context for this use is discussed.

Keywords: Teacher guide, research-based, upper-secondary, quadratic equations

Introduction

Teachers need access to relevant research to plan research-based mathematics instruction. However, Swedish teachers' access to such findings is limited, as few teachers have the habit or know-how to find research and schools are typically not organized to support teachers' planning practice (Nordgren et al., 2019). The notion of knowledge brokering by providing research summaries (e.g., Rycroft-Smith & Stylianides, 2022) could be a fruitful way to help teachers gain access to research. If centered around curriculum topics, such summaries could constitute curriculum resources (CR). This paper aims to contribute to research by combining research on design, mathematics, and user studies of CR (Rezat, 2024), through exploring how research summaries for a specific mathematical topic designed into CR could be used by teachers in their planning practice.

When planning and teaching, teachers select, modify and create new resources (Trouche et al., 2020). Through this use, they perceive and mobilize the resources available to them to design instruction (Brown, 2009). Most Swedish teachers, despite their autonomy in choice and use of resources, conform culturally to the common classroom practice of a teacher-led instruction, the Swedish *genomgång* (e.g., Andrews & Larsson, 2017), followed by individual work in the textbook (Boesen et al., 2014). For upper-secondary school, the student textbook still plays a major role in planning and teaching, and teacher guides are typically not used, despite availability of other resources. (Gustafsson et al., 2024). The prevalence of research and external support in planning in this teacher practice can therefore be assumed to be low.

This paper presents the first cycle of a design research study (Bakker, 2018) within a larger project aiming at understanding how research-based teacher guides could be designed to support teachers in their planning and teaching practice. This exploratory phase investigates how Swedish upper-secondary mathematics teachers interact with an experimental research-based teacher guide on the

topic of quadratic equations (QEs), made available within their usual practice. The aim is to describe how Swedish upper-secondary mathematics teachers within their cultural context perceive and mobilize content from a research-based teacher guide.

Theoretical framing

In this study, planning teaching is in accordance with Brown (2009) a design activity, in which teachers perceive and mobilize resources in designing instructional activities – using their pedagogic design capacity. The focus in this paper is not to evaluate different teachers' capacities, but to use the terms perceiving and mobilizing as a lens for describing teachers' resource use. Elements of perceiving CR include reading, interpreting and evaluating, both in preparation for teaching and in enactment (Remillard, 2019), and this study focus on preparation in planning. When a teacher perceives an affordance within a resource, this may lead to a mobilization of this resource into designed instruction, while a perceived constraint, both within a resource and in the context, can hinder such mobilization. Elements of mobilization can be seen in terms of different degrees of artifact appropriation, which Brown (2009) termed offload, adapt and improvise. The meaning of these terms, stemming from socio-cultural roots, corresponds to the amount of agency in deciding on instruction that is given to an artifact, from using an artifact as it is (offload), modifying the suggested design (adapt), or to fully deviate from the original intended use to create something new (improvise). A teacher guide can be seen as an artifact, with the intention to enable action in a specific way. Even though the teacher guide in this study is designed with some intentions (see Method), it is here the teachers' perceived affordances and constraints using the guide as a resource in planning teaching that are in focus, and not the fidelity in following the intentions of the designer.

Method

Six Swedish upper-secondary teachers (T1-T6), who received a designed teacher guide for QEs prior to planning and teaching the topic, were surveyed and interviewed on their use. They all had at least three years teaching experience and had taught the topic before. Geographically, they were spread out over four different schools from three different cities. Before part-taking, they were informed that the guide was based on research on the teaching and learning of QEs, including types of content that could be supporting for teachers. Part-taking meant to use as much or as little (even nothing) within their normal planning and teaching practice.

The questionnaire included qualitative open answer items, as well as fixed items that for example let teachers grade the extent to which they had used different features, how they had used these, the time spent working with the guide, as well as rate the usefulness and how they valued different features. An interview guide for semi-structured interviews, organized around the different content features, and adapted to the outcome of the individual teacher's use was constructed, aiming to obtain insights regarding reasons to why the guide and its different features was perceived and mobilized in the specific ways.

The content of the experimental research-based teacher guide

The teacher guide was experimental, designed for this project by the author, with the intention to support teachers by informing and giving suggestions, rather than to impose any particular type of

teaching or classroom practice. It consisted of three main types of content features: an expository text on the teaching and learning QEs, one document with lesson activities, and one document with supplementary mathematical tasks. These types of content were chosen as research on educative features of CR (e.g., Davis et al., 2017) and findings from the context from upper-secondary school teachers planning (Gustafsson et al., 2024) indicated that these might be useful for teachers. The notion of 'research-based' therefore acts on at least two levels: the material contains a research summary and the content features are informed by research.

The expository text contained a research summary synthesized from a literature review on the teaching and learning of QEs. The summary included mostly qualitative findings on important mathematical concepts for learning QEs, common student (mis)conceptions and mistakes with possible reasons and implications for teaching. Sub-sequent sections contained teacher narratives from experience, aligning with the research summary, and final suggestions of how to handle different issues in teaching. Included was also a description of the Swedish curriculum context for QEs, including the curricula standards, how QEs are treated in three common curriculum materials and how it was historically tested in national exams.

The first appendix consisted of four lesson activities (A1-A4), all aiming to address some of the issues raised from the expository texts. Each activity had a text describing the rationale of the activity to provide transparency for the teacher, as well as suggestions on how to modify the activities, in line with educative features (e.g., Davis et al., 2017). A1 and A4 aimed to build student conceptual understanding, by students sorting and grouping different mathematical objects, while also opening up for different types of procedural exercises. Support for teachers summarizing the issues in whole-class discussions were included. A1 addressed student difficulties of differentiating between mathematical expressions, equations and functions, identifying if these were quadratic or linear in nature, and offering practice in rewriting sorted QEs into equivalent forms. A4 addressed awareness of how different types of solution strategies are useful for different types of QEs. A2 had the same aim as A4, and provided equations to solve after first consulting with a student colleague. A3 aimed at discovering the relationship between the discriminant and the number of solutions to a QE, through a suggested pathway. A2 and A3 were in a sense more traditional, and less elaborate in their design.

The second appendix contained a collection of mathematical tasks to use without explicit guidance, previous national exam tasks on QEs from publicly available tests (NT), tasks constructed around fictional student solutions with common mistakes (CM), challenging tasks for students (CT), a quick reference for different solution types of QEs (QR), and tasks in the form of exit tickets (ET).

Analytic procedure

The data material consisted of the survey answers and audio-recorded transcribed interviews (~60 minutes each) of each of the six participating teachers. Using a qualitative content analysis approach (Kuckartz, 2019), the answers from the questionnaire were used to create an initial map on the use and evaluation of the guide's content features. From the semi-structured interviews, reasons of use or not use, and ways of perceiving was generated. Being an explorative study, the interviews were quite open in letting teachers talk about what was important to them. Expressions regarding the content features therefore emerged in various places in the interviews. Different features also got different

focus from different teachers. Passages from the transcriptions (as well as the occurring open-ended questionnaire answers) about the different content features were coded deductively. This updated the initial map. For each part of the explored map, types of reasons and use were created as categories of perceptions or mobilizations. These categories were not necessarily exhaustive, but representatives of some patterns. A choice of using offload and adapt (Brown, 2009) as categories for use of tasks and activities deductively was made. Finally, the map was adjusted by going through all transcripts, until a reasonably accurate map was obtained (presented in Figure 1). From the map, the categories for reasons were interpreted in terms of teachers' perceived affordances and constraints and the uses in terms of mobilizations.

Findings

All the teachers stated they normally use student textbooks, colleagues and official documents in terms of the curriculum and the national exams as their main resources for designing instruction. None of the teachers expressed having used a teacher guide before. They all refer to their genomgång in describing parts of their practice, and through the interviews there were several expressions about allocating lesson time for students' individual work.

The interaction with the expository texts

As seen in Figure 1, the research summary impacted teacher the most of the expository texts (1). This was emphasized by the positive evaluations and that the issues mentioned by teachers in interviews, stemmed mainly from this section.

The majority of presented categories of reasons for evaluations as important (2) corresponded to perceived affordances related to research or to teacher preferences. First, research played a big role, corresponding to the guide being perceived as research-based, and that teachers trusted it due to the institutional setting of a researcher from a university providing it. This was connected to the guide being perceived as well-written and accessible, and that findings were summarized (quotes translated from Swedish by author):

T1: I think that if one gets a well-packed and well-presented material, I trust that there is some research. \...\ I think I have to trust what implications someone has found

T3: I have trusted this [guide] more than if I just had found one, considering it is research-based. \...\ I trust that those who have constructed the teacher guide also have done a good survey of the research

Second, reasons within teacher preferences reflected value in that the texts were focused on students and learning, that they resonated with teacher experience, and contained previous teacher experience. The main perceived constraint was that the expository text was too long for teachers to read given the time constraints of their planning situation (3). All teachers read the research summary, but few read further into the expository text. In particular, the section containing the connection to Swedish curriculum was expressed as redundant (4); it did not add any value as teachers were already familiarized with the curriculum of QEs.

The mobilizing influence of the expository texts on teachers from reading, interpreting and evaluating the texts can be divided into two main categories. One category (5) was that the guide enabled teachers to focus on important issues in planning, exemplified by mentions of picking up on common

student mistakes or misconceptions, or the important student skill of being able to choose suitable solution methods based on the identification of type of QE. Even though the issues mentioned by teachers covered many of the issues presented in the expository text, some issues were not mentioned at all. A second category (6) captured the confirmation teachers expressed regarding their professional experience, as their own experience was in line with the issues presented in the teacher guide. Reading it was expressed as a way to reactivate and be reminded of what they already knew, but also to add small new insights:

T1: For me, it confirmed much I had experienced and I was strengthened by it
T5: It is a security for me that when I read it, it confirms things I already know, but also that I can learn some things

The focus on important issues made teachers plan specific parts of teaching, such as their genomgång, or the use of activities or tasks. As can be noted in Figure 1, the issues mentioned by teachers being picked up in the expository texts (7) to a large extent coincide with teachers using activities or tasks that targeted those particular issues, especially for A1, A2, A4 and CM.

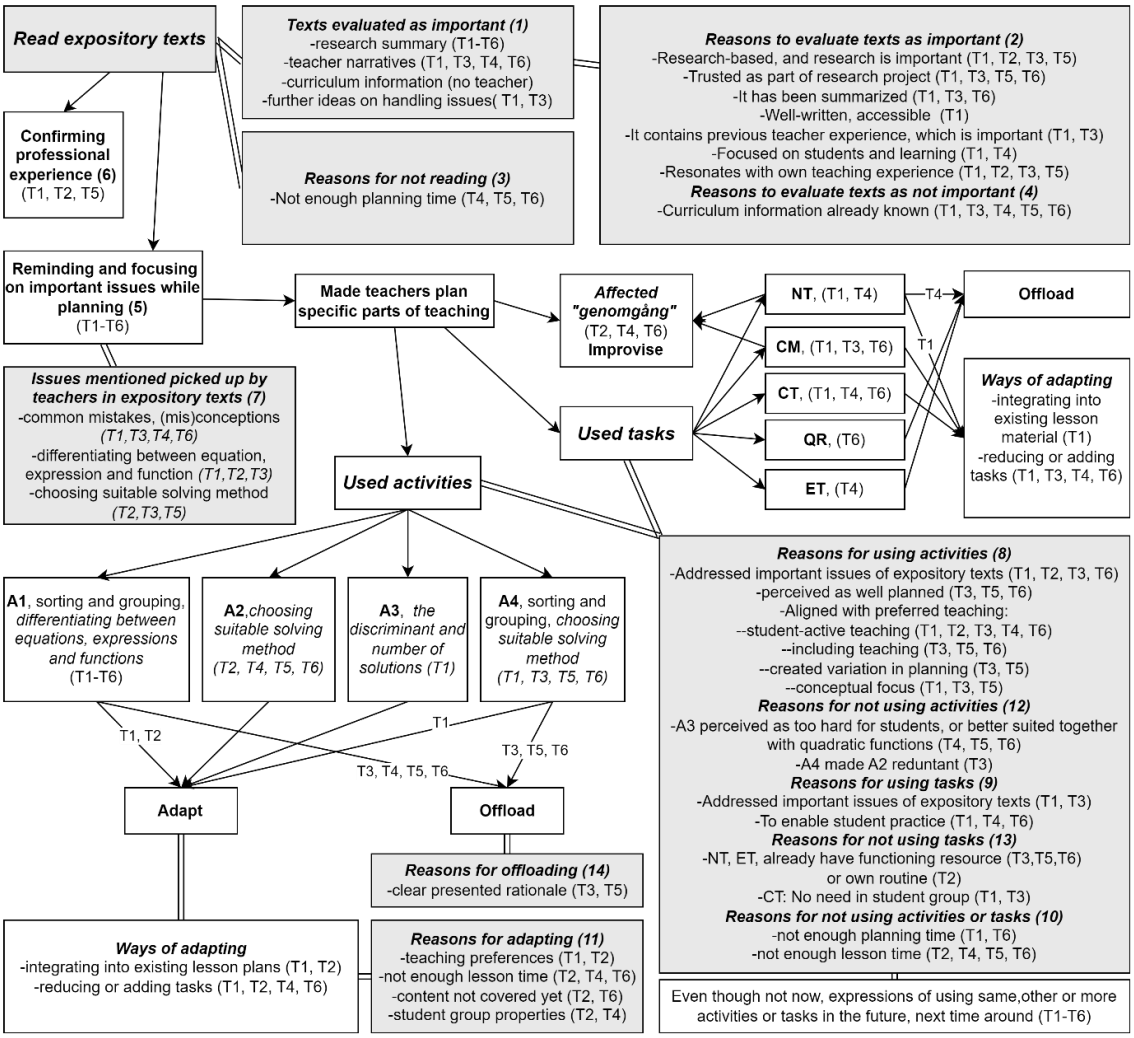

Figure 1. Aspects of teacher perceptions (grey) and mobilization (white) of the content features.

The interaction with activities and tasks

Activities that were student-centered (A1 and A4) were used to a greater extent than other activities or tasks. The majority of presented categories of reasons for use (8) corresponded to perceived affordances that were related to usefulness or to teaching preferences. First, the activities were perceived as well-planned, and a way to handle the issues teachers picked up from the expository texts. Second, they aligned with ideas on how teachers wanted to teach. For instance, having conceptual focus, students being active instead of teachers talking, students discovering instead of teachers telling, and every student being able to part-take:

> T3: One reason was that I was made aware that there is a need in students in general, after reading the teacher guide.. \..\ I also like how the activity is built, so that no matter if you are a high- or low achieving student you can contribute. That is something I think is problematic in other situations when one wants students to work together or in activities. That is also a reason why I used that activity. Also, I rather let the students be active, than listening to me, so it aligns good with my vision of teaching. That's why I used it.

Usefulness could also be seen an affordance in enabling students' practice (9), through national exam (NT) or common mistakes (CM) tasks being solved and discussed in genomgång, which can be seen as a form of improvising. They were also put in worksheets, as also in the case for exit tickets (ET), challenging tasks (CT) and the quick reference (QR).

Perceived constraints in relation to using activities and tasks were related to time, students, or the teaching context. First, lack of lesson time and planning time were categories of reasons for not using tasks and activities at all (10), or adapting by removing mathematical tasks to make the activity shorter to fit lesson-time constraints (11). Not using activities (A2 and A3) were related to that the aim of A2 overlapped with A4, so given lesson-time constraints both could not be used, and A4 was perceived as the better (12). Second, categories such as the lack of need in the student group to use CT (13), or that not using A3 was due to that it was deemed too hard for students (12) showed student-related constraints. Third, that A3 was expressed to be better suited together with the topic of quadratic functions, as the number of solutions could be better connected to the graphical view of x-intercepts, or that content was adapted because content was not yet covered yet (11) was example of constraints within the teaching context. Related to this, already having a functioning resource made teachers not use tasks, being more of a "non-affordance" than a constraint, expressed as reasons for not using NT and ET (13). Even though these constraints existed in the teachers' current planning situation, expressions were made that activities and tasks that were not used now were to be used in the future.

In terms of mobilization, the majority of the teachers reported planning and enacting activities (especially A1 and A4) in line with the description in the teacher guide – offloading, relating to that the activity had a clear presented rationale (14). Some adaptation took place, besides adaptations already mentioned in relation to constraints, with small modifications being organizational, such as organization in pairs, or in groups of four, to fit different classroom management practice. One teacher (T1) adapted activities and tasks to a large extent, by integrating it into existing lesson plan documents that the teacher already had, for example by cutting and pasting tasks. The general use of the tasks could be seen as a mix of offloading, adapting and improvising, as they did not have the same detail of suggested use as the activities.

Discussion

In this study, it was found that issues from the research summary that was also targeted in the activities were mobilized to a larger extent than the issues without a "solution". The main perceived affordances by teachers in their interaction with the teacher guide seems to be the proposed lesson activities, for reasons that they were well-planned, handling an important mathematical learning issue from the expository text, had conceptual focus, and were student-active and student-inclusive. The role of the research summary in the expository text, besides being perceived as valuable for teachers, acted as a way to prime teachers on certain issues. The main expressions made by teachers on these issues were to a larger extent overlapping with the issues handled in the proposed lesson activities. This indicates that as a whole, the lingering ideas from teachers when reporting in the survey and interviews post-teaching and planning, are the issues targeted both by the research summary and the activities. A research summary in itself is therefore not necessarily enough to mobilize action for teachers, if one wants to design a teacher guide resource that induces change of practice. Which, without such a specific intention, the guide in this paper to some extent did.

The teachers in this study can be assumed to be representatives of the Swedish cultural context for upper-secondary mathematics teachers in terms of the reported common textbook use, genomgång and individual student practice (Boesen et al., 2014). However, when presented a teacher guide, all teachers were able to perceive some affordances leading to mobilizing some content features into different kinds of instruction. Even though there were individual differences in offloading and adapting behavior, reflecting individual teachers' pedagogical design capacity (Brown, 2009), teachers utilized support for lesson design, mainly through the proposed activities. This can be seen as filling a gap for which teachers not already had an external resource (see Gustafsson et al., 2024). Using a teacher guide, even though it is a new practice, did therefore not seem to be culturally challenging, except for the required planning time. Despite their teaching context, these teachers seemed to have aims and goals in line with more reform-mathematics education (Boesen et al, 2014). Presenting and supporting teachers with proposals of lesson activities, intended to handle important issues from research, with a clear rationale, made teachers perceive those activities as important and allocate time for them.

Planning time affected teachers in that they did not have the time to read the entire guide; the majority of teachers stated they did not have the time to read everything, so they only read the things that "came first" in the guide, and the rationale for activities they planned on using. Available lesson time seemed to be a larger constraint than the available time for planning, as it in many cases seemed to be the reason for not mobilizing certain activities at all, or adapting them to take shorter time. Consequently, when we think about time as a constraint for teachers, we need to separate planning and lesson time.

This study can be seen as a systemic approach to the mathematics, the teachers, and the CR (Rezat, 2024). The findings also contribute to the field of teachers' use of research summaries (e.g., Rycroft-Smith & Stylianides, 2022). In this study, the role of research acted in several ways. First, the fact that the teacher guide summarized research findings on the topic of QEs was expressed as valuable by most teachers, as it was perceived as an affordance to access findings in a digestible way and

trusted from the researcher backing. Second, as the research summary findings for many of the teachers aligned with their teaching experience, teachers expressed a feeling of being strengthened in their professional experience through the reading of the teacher guide. Third, the perceived link between the research summary findings and the goals of the activities seemed to act motivational for mobilizing that specific content feature.

Down-to-earth mathematics: transforming curriculum and teaching on function transformations

Yosep Dwi Kristanto[1,2] and Zsolt Lavicza[2]

[1]Sanata Dharma University, Yogyakarta, Indonesia; yosepdwikristanto@usd.ac.id

[2]Johannes Kepler University Linz, Austria

The present study proposes and evaluates a digital task sequence aimed at transforming the curriculum and teaching of function transformations by promoting productive meanings of these transformations and integrating mathematics with other domains, specifically climate science. The findings of this study show how students' envisioning of a graph in terms of what is made (a trace) and how it is made (covarying quantities) supports their construction of productive meanings of function transformations. Furthermore, this study also highlights challenges experienced by students during the learning process, which can be used to improve future instruction.

Keywords: boundary crossing, DNR, emergent graphical shape thinking, function transformations.

Introduction

Function transformations are often taught by first introducing a parent function and treating other functions as transformations of this parent shape. While this approach can enhance students' fluency in applying function transformations, researchers (Moore & Thompson, 2015) argue that it may not fully support students' understanding of what they are transforming—specifically, representations of covarying quantities. This study proposes and evaluates a digital task sequence aimed at transforming the curriculum and teaching of function transformations by promoting productive meanings of these transformations and integrating mathematics with other domains, specifically climate science. The task sequence incorporates emergent graphical shape thinking (EGST) as a boundary object, providing students with opportunities to navigate between the domains of mathematics and climate science within a DNR-based instructional context.

In the following sections, we first describe the theoretical frameworks that informed the design of the digital task sequence. We then detail the structure and rationale behind the task sequence, illustrating its role in supporting students' understanding of function transformations as transformations of covarying quantities.

Positioning EGST within DNR and Boundary Crossing Frameworks

Our design integrates two frameworks: DNR-based instruction in mathematics (Harel, 2008) and boundary crossing (Akkerman & Bakker, 2011), along with its associated learning mechanism, particularly reflection. We draw on DNR's principles of duality, necessity, and repeated reasoning to inform the design of our digital task sequence. Drawing on the principle of duality, the task sequence focuses on both developing meanings of function transformations and using EGST as a way of thinking. Drawing on the principle of necessity, we designed the task sequence to include problems that ignite students' intellectual needs. Drawing on the principle of repeated reasoning, we structured the task sequence to provide opportunities for students to use EGST repeatedly throughout the tasks.

Building on the boundary crossing framework, we design the task sequence to support students in reflecting, through taking and making perspectives on both mathematics and climate science, in order to develop meanings of function transformations. We hypothesize that EGST can serve as a boundary object, facilitating students' perspective-taking and perspective-making across the domains of mathematics and climate science. This aligns with previous studies showing that graphical reasoning is an important tool for understanding both mathematics and science concepts (Paoletti et al., 2024; Stephens, 2024).

From both frameworks, EGST plays an important role: as a way of thinking to construct meanings of function transformations and as a boundary object bridging the domains of mathematics and climate science. We refer EGST as "envisioning a graph in terms of what is made (a trace) and how it is made (covarying quantities)" (Moore & Thompson, 2015). Paoletti et al. (2023) argue that for students to engage in EGST, they must engage in both situational and graphical reasoning. We integrate these forms of thinking and reasoning throughout our digital task sequence, which is described in the following section.

Digital task sequence

Our digital task sequence is titled "Down-To-Earth Mathematics: How Hot Is Our Earth?". The phrase "down-to-earth mathematics" was chosen for two reasons: first, to make mathematics more relatable and realistic for students, and second, to use the context of the Earth to raise awareness about the real and urgent challenges related to global temperature trends. We designed the task sequence in Desmos, and it is publicly accessible at https://s.id/down2earth-math.

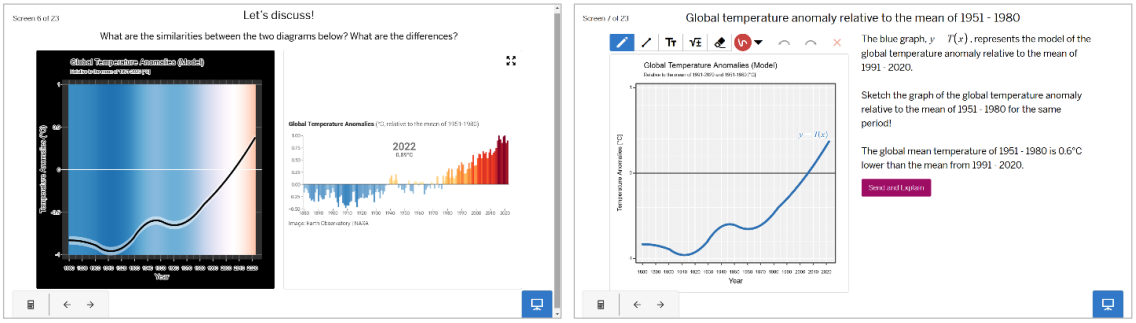

Figure 1: Sample screens from Task VT

The task sequence guides students in using perspectives from climate science to interpret global temperature anomalies over time, and then making mathematical perspectives to construct meanings of function transformations from contextualized problem situations. This understanding of function transformations is subsequently applied to taking mathematical perspectives on function transformations, allowing students to make connections in climate science and predict future global temperature anomalies. This approach highlights the opportunities for students to reflect on both mathematics and climate science through the processes of perspective-taking and perspective-making. Building on this approach, the blueprint of the task sequence is outlined in Table 1.

Table 1: Blueprint for the digital task sequence

Task	Description
MT	**Modeling global temperature anomalies.** Students watch a video animation showing global temperature anomalies (relative to the 1991–2020 average) from 1880 to 2022, featuring both a heatmap and warming stripes. They record what they notice and wonder about the animation. Then, they sketch a graph to model the global temperature anomalies over time.
VT	**Building meanings of vertical translation.** Students compare and contrast a model based on the 1991–2020 average with another graphical representation using a different baseline (1951–1980 average) for global temperature anomalies. Using the information that the 1951–1980 average is 0.6°C lower than the 1991–2020 average (see Figure 1), they then sketch a graph modeling global temperature anomalies relative to the 1951–1980 average. Finally, students relate the resulting model to the previous one to develop an understanding of vertical translation, both visually and algebraically.
HT	**Building meanings of horizontal translation.** Students are presented with a problem of "seeing the y-axis," requiring them to modify the previous model so that it starts from $x = 0$ (the domain of the previous model is from 1980 to 2022). They watch an animation illustrating the construction of the new model alongside the previous one (see Figure 2). Finally, they connect the new model to the previous one to develop a visual and algebraic understanding of horizontal translation.
VS	**Building meanings of vertical shrinking/stretching.** Students sketch a graph of a new model where global temperature anomalies are measured in °F, based on the previous model in °C. They then connect the new model to the previous one, developing a visual and algebraic understanding of vertical stretching/shrinking.
HS	**Building meanings of horizontal shrinking/stretching.** Students watch a video animation demonstrating a strategy for adjusting the x-axis scale to match the y-axis scale. The video illustrates the construction of a new graph alongside the previous model. Students then connect the new model to the previous one, developing a visual and algebraic understanding of horizontal stretching and shrinking.
PT	**Predicting future global temperature anomalies.** Students predict the trend of future global temperature anomalies by extending the graph of the previous model. They then observe the intersection of the graph with $x = 2.25$. Using their understanding of function transformations, they identify the year corresponding to $x = 2.25$.

The design of the task sequence presented in Table 1 follows DNR's instructional principles of duality, necessity, and repeated reasoning (Harel, 2008). First, it addresses both the meanings of function transformations and the use of EGST as a way of thinking. EGST is incorporated in two ways: (a) by asking students to sketch a graph based on a given situation (MT, VT, and VS, see Figure 1), or (b) by having students watch an animation of the graph's construction (HT and HS, see Figure 2). Second, the task sequence creates intellectual needs for students to develop their understanding of function transformations: (a) changing the baseline of temperature anomalies for vertical translations; (b) "seeing the y-axis" problem for horizontal translations; (c) converting temperature units for

vertical stretching/shrinking; and (d) adjusting the x-axis scale for horizontal stretching/shrinking. Finally, throughout the task sequence, EGST is repeatedly incorporated to build students' fluency.

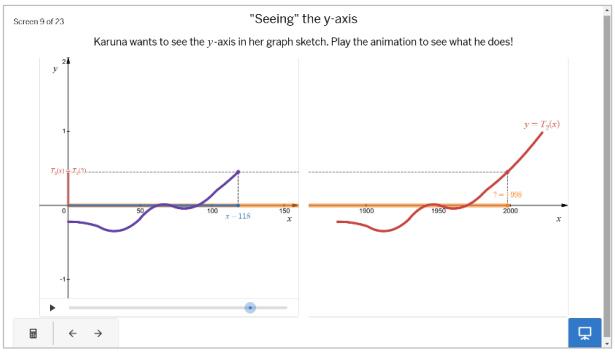

Figure 2: A sample screen from Task HT

Research questions

While the DNR and boundary crossing frameworks inform the design of the task sequence, the EGST framework plays a crucial role in guiding the design. Therefore, this study narrows its focus to investigating the opportunities the task sequence provides in promoting EGST to support students in constructing meanings of function transformations. The research questions guiding this evaluation are: How, and to what extent, do students develop their meanings of function transformations through the use of EGST?

Methods

This study is part of a larger design research project aimed at transforming curriculum and instruction related to change and relationships. Specifically, it presents a lesson case showcasing the implementation of a digital task sequence on function transformations. The participants were 22 first-year undergraduate students enrolled in an algebra and trigonometry course at a private university in Yogyakarta, Indonesia.

Prior to these lessons, the students had already engaged with EGST in interpreting and constructing graphs, as reported elsewhere (Kristanto et al., 2024). The lessons were conducted in two sessions in early October 2023. The first author, who also served as the teacher-researcher, was the regular course instructor. At the beginning of the first session, the teacher explained temperature anomalies, including their definition and how they are calculated, as this was an essential prerequisite for the tasks. Students worked in groups of two or three, resulting in nine groups. In the first session, they completed Tasks MT, VT, and HT; in the second session, they worked on Tasks VS, HS, and PT. During the sessions, the teacher facilitated productive mathematics discussions by allowing students to work in groups while monitoring their progress, purposefully selecting and sequencing groups' work for presentation, and connecting students' approaches and the underlying mathematics (Stein et al., 2008).

Students' work on the digital platform Desmos was recorded. Additionally, the teacher's Desmos dashboard was recorded to provide supplementary data on students' progress. To analyze how students developed their meanings of function transformations, we coded their works and video

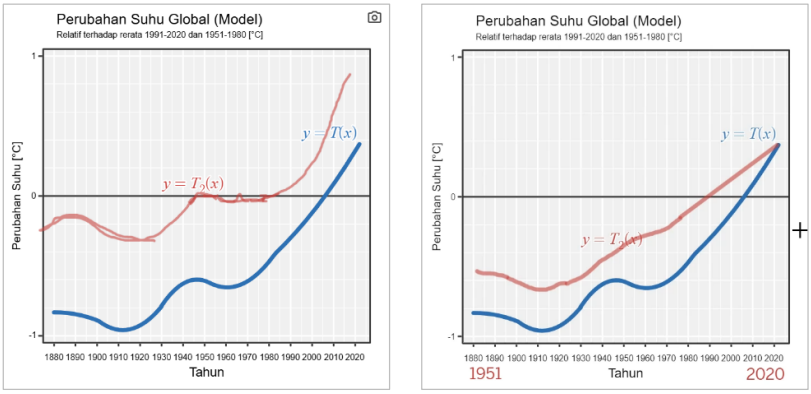
recordings of the teacher's dashboard using the EGST framework (Paoletti et al., 2023). The codes comprised situational quantitative and covariational reasoning (MS), reasoning with graphical representations of covarying quantities (MR), and emergent graphical shape thinking (ME). To assess the extent of their understanding, we focused on evaluating students' answers to Tasks VT, HT, VS, and HS, as these tasks align directly with the research questions guiding this study. Using the rubric presented in Table 2, we analyzed their responses to these tasks, where students were asked to (1) represent their new model algebraically and (2) explain their reasoning.

Table 2: Rubric

Mark allocated	Description for algebraic representation	Description for reasoning
0	No answer or incorrect solution.	No answer or incorrect solution.
1	Correct solution.	The answer demonstrates a conceptual understanding of the problem, as reflected in the mathematical approach used. However, no evidence links the reasoning to the problem's context exists.
2	–	The answer demonstrates a complete understanding of the problem, is accurate, and includes clear reasoning that is well-connected to the context of the problem.

Results

We begin by qualitatively examining how students develop their meanings of function transformations. Next, we quantitatively assess the extent to which they have developed these meanings.



How students develop their meanings of function transformations

Nearly all groups accurately sketched continuous graphs when tasked with modeling annual global temperature anomalies in Task MT. Only one group, Group 9, plotted discrete points but followed the correct trend. This suggests that all groups demonstrated meanings of MS and MR, while one group did not engage in ME as they did not account for all possible points.

In Task VT, six groups adopted a strategy to shift the graph upwards by 0.6 units when the baseline was changed from 1951–1980 to 1991–2020 in their initial sketch. The reasoning from these groups was similar. One group explained their approach as follows:

> Due to the difference in the average global temperature anomalies, the period from 1950 to 1980 differs by 0.6 degrees from the average global temperature changes between 1991 and 2020. This causes the entire temperature comparison graph to shift upwards, indicating that temperatures are getting hotter (Group 7, translated from Indonesian).

Group 7's reasoning indicates engagement with MS, MR, and ME. They appeared to conceive each point of the previous model (with the 1991–2020 baseline) as representing a co-ordination between years and global temperature anomalies, treating each point as a multiplicative object. Using this meaning, they sketched a new model (with the 1951–1980 baseline) by shifting all points of the previous model upward by 0.6, see Figure 3(a). This demonstrates that they developed a meaning of what the y-coordinates in each model represent—specifically, the global temperature anomalies based on the 1991–2020 and 1951–1980 baselines, respectively.

(a) (b)

Figure 3: Sketches from two groups for Task VT

Group 1 employed a different strategy by initially plotting the graph from 1951 to 1980 and then extending it to cover 1880 to 2022, as shown in Figure 3(b). This group likely had an incomplete meaning of the baseline in calculating temperature anomalies. Two other groups drew a new graph by shifting the old one downwards. Their rationale for this strategy was the same: the average temperature from 1951–1980 was 0.6°C lower than from 1991–2020. This suggests that the groups lacked a comprehensive meaning of ME, particularly regarding the concept of temperature anomaly and its relationship to the baseline.

In Task HT, all groups arrived at the correct answer, $T_3(x) = T_2(x + 1880)$. One group used the explanation of a "shifted reference point" as follows:

> This is because Karuna assumes that the year 1880 represents zero, so the intervals for subsequent years start from 1880 as the reference point (Group 5, translated from Indonesian).

For Task VS, while all groups successfully sketched the transformation graph, only a few accurately explained their strategies. For example, one group explained it as follows:

> If we assume that 0°C corresponds to 0°F, then if Celsius increases to 1°C, Fahrenheit will rise by 9/5 or 1.8 units. This means the graph shifts approximately 1.8 units downward (if Celsius is negative) or upward (if Celsius is positive) (Group 9, translated from Indonesian).

In Task HS, eight groups wrote $T_5(x) = T_4(71x)$, but only three groups provided accurate reasoning. One group explained it as follows:

The graph of $T_5(x)$ is derived from the graph of $T_4(x)$ by compressing the input (x) by a factor of 71 (Group 4, translated from Indonesian).

In summary, students' meanings in MS, MR, and ME supported their development of function transformation meanings. Students who understood function transformations as transformations of covarying quantities envisioned each point on the graph as a multiplicative object, which helped them relate it to the new graph. For example, in Task HS, they observed that each y-coordinate in the new model corresponded to the y-coordinate at 71 times the x-coordinate in the previous model.

To what extent did students develop meanings of function transformations?

Figure 4 shows the distribution of group scores across four tasks (VT, HT, VS, and HS). The students performed best in Task VT, where most groups scored 2, indicating they made correct algebraic work with sound mathematical reasoning but did not connect their reasoning to the context of changing the temperature anomaly baseline. In contrast, Task VS saw lower scores, with most groups receiving a score of 1. While these groups demonstrated correct algebraic work, they did not provide reasoning to explain their approach.

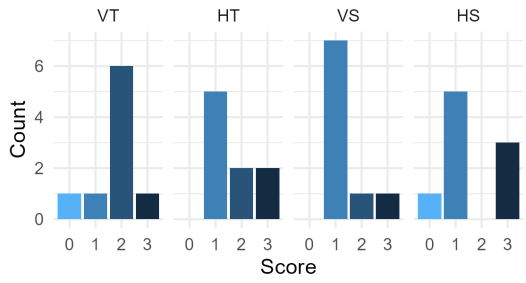


Figure 4: Frequency of group scores across tasks, with scores ranging from 0 to 3

Discussion and conclusion

The findings of this study highlight the potential of the proposed digital task sequence in supporting students in developing productive meanings of function transformations. The qualitative data analysis revealed that EGST supports students in understanding the relationship between a function and the result of its transformation, both algebraically and visually. The results of the quantitative data analysis further reinforce this finding. The findings of this study reveal that some students still demonstrated an incomplete understanding of the baseline used in temperature anomaly calculations. These misconceptions hindered their ability to fully develop mathematical concepts, particularly concerning vertical shifts in functions. This insight highlights areas for improvement in refining the digital task sequence for future iterations. Additionally, an interesting case emerged with Group 1. Their sketch in Task MT provided evidence of their meanings of MS, MR, and ME. However, their incomplete understanding of a critical quantity, i.e. temperature anomaly, prevented them from succeeding in Task VT, which required a proper understanding of this concept.

In refining our task sequence, we plan to incorporate a strategy from cognitive load theory to minimize the extraneous cognitive load associated with understanding the concept of temperature anomaly (Chen et al., 2023). Specifically, we will redesign the sequence to include an initial phase

where students learn how to calculate temperature anomalies using a given baseline, followed by opportunities to practice these calculations independently. We hypothesize that this approach will help reduce their cognitive load when working on Task VT.

While this study focuses on how students construct meanings of function transformations through EGST, it does not extensively analyze how students navigate disciplinary boundaries between mathematics and climate science. Future research could explore how integrating real-world contexts, such as climate change, fosters or hinders students' meanings of function transformations.

Examining the paths of reasoning presented in the topic of 'patterns' in Norwegian mathematics textbooks

Magdalini Lada, Iveta Kohanová, Birgit Pepin

Norwegian University of Science and Technology, Trondheim, Norway; magdalini.lada@ntnu.no

This paper presents the findings of a textbook analysis of two commonly used Norwegian mathematics textbooks for grades 8 and 9. We examined how these textbooks operationalize the national curriculum (LK20)'s competence aims related to the generalization of patterns. The analysis revealed two main differences: whereas Book A has a strong numerical focus, Book B adopts a more figural approach. Additionally, Book B incorporates reasoning processes that encourage proving through generic examples, whereas Book A involves only processes related to making generalizations. These differences appear to stem from the lack of clear conceptualization of mathematical reasoning in LK20, which has led to varied interpretations in textbook design. Clearer guidance on reasoning in the curriculum could help textbook developers, teachers, and professional development providers align instructional practices with curriculum aims.

Keywords: Textbook analysis, paths of reasoning, patterns, generalization, curriculum change

Introduction

Despite the fast-evolving development of digital resources in mathematics education (Pepin et al., 2024), textbooks remain the most frequently utilized resource by mathematics teachers across several European countries, including Norway (Çakıroğlu et al., 2023). Designed to help teachers organize their teaching in terms of both pedagogy and content, textbooks play a key role in shaping what school mathematics becomes for teachers and students (Johansson, 2003). At the time of mathematics curriculum reforms, especially when new topics or perspectives on mathematics are introduced, textbooks play an even more crucial role for teachers, who may lack experience or knowledge on how to approach these new topics. Over the past five decades, Norway has undergone six major mathematics curriculum revisions. The most recent update, the 2020 curriculum (LK20), introduced a competence-based structure for grades 2–10, specifying 10 to 13 competence aims per grade. Each aim consists of a verb indicating a specific competence (e.g., "explore," "describe," "argue") and a noun phrase outlining a particular mathematical domain (e.g., "relationships between the length of the sides in triangles") (Directorate of Education, 2019, p. 14). Alongside these aims, LK20 introduced six process-oriented *core elements* that emphasize how students should learn and engage with mathematical concepts. These core elements act as overarching "umbrellas" that apply across all topics and grades. One such core element, *Reasoning and Argumentation*, focuses on developing students' ability to evaluate mathematical reasoning and justify their conclusions. Processes related to mathematical reasoning (as defined by Jeannotte and Kieran, 2017) are also integrated into other core elements (such as *Abstraction and Generalization*), reflecting LK20's increased focus on reasoning compared to previous curricula. However, as Valenta and Enge (2020) highlighted, the competence aims often remain general and lack detailed explanations or examples. For instance, they noted that "it is not made explicit in the curriculum whether what is arrived at should be validated" (p. 14), and called for an examination of "how proof-related competencies are addressed in textbooks

and schools" (p. 16). Vague competence aim formulations can create a gap between the curriculum and textbooks, posing challenges for teachers in interpreting and effectively implementing these aims (Ochieng & Kamina, 2022). Given LK20's focus on reasoning and the call of Valenta and Enge (2020), it is important to examine how textbooks, as one of the primary resources for teachers, support this aspect of the curriculum. To be able to provide a detailed and focused analysis, we have chosen to concentrate on the topic of 'patterns', due to their potential to engage pupils in multiple reasoning and argumentation processes (Orton, 2005). In LK20, competence aims related to patterns are listed among the aims for the 8th and 9th grade:

- For 8th grade: "describe and generalize patterns in one's own words and algebraically",
- For 9th grade: "describe, explain, and present structures and progressions in geometric and numerical patterns" (Directorate of Education, 2019, p. 12 - 13).

Given the pivotal role textbooks play in 'translating' curricular policies, such as the emphasis on reasoning, into classroom practices, they are regarded as the potentially implemented curriculum (Valverde et al., 2002). Our study is guided by the following research question: *How do two commonly used mathematics textbook series operationalize the Norwegian National Curriculum's competency aims related to the generalization of patterns?*

Theoretical background

In this section we explain how we understand the different terms used: patterns; and generalization.

Mathematics is often described as the study of patterns. The term 'pattern' is not a well-defined mathematical concept and has been associated with different meanings. As a result, curriculum developers and textbook authors have adopted diverse approaches regarding the topic (Carraher et al., 2008). While a complete classification does not appear to exist, a variety of types of patterns, have been used at different grade levels and mathematical topic areas (Orton, 2005; Rivera, 2013).

Tasks involving generalization of patterns are rich in reasoning processes. Jeannotte and Kieran (2017) include "identifying a pattern" and "generalizing" in those mathematical reasoning processes related to the search for similarities and differences, and Stylianides (2008) places identification of patterns under the broader category of "making mathematical generalizations". Not all generalizations are related to mathematical reasoning. Stylianides (2008) relates *structural generalizations* of definite patterns to mathematical reasoning, as opposed to *empirical* ones. Similarly, Radford (2006) distinguishes *naive induction,* a trial-and-error process through which a pupil guesses a rule, from *generalization.* He defines *algebraic generalization* as "grasping a commonality noticed on some elements of a sequence S, being aware that this commonality applies to all the terms of S and being able to use it to provide a direct expression of whatever term of S" (p. 4). Note that the definition is formulated particularly for sequences and in what follows we consider this type of patterns that comprises the main body of the relevant literature.

Grasping the commonality, or in other words identifying the pattern, entails discovering the rule under which the sequence is built. This rule can be either *recursive* or *explicit* (Lannin et al., 2006). In addition, when a number sequence is illustrated with figures, the generalizing process can be either *figural* or *numerical* (Rivera & Becker, 2005). Last, by focusing on how students express generality,

Radford (2006) identified three types of generalizations: *factual, contextual,* and *symbolic*. The first two are pre-symbolic generalizations with the difference that while factual generalizations operate in the concrete level, enabling the solver to express a particular term of the sequence (e.g. figure nr 100), contextual generalizations belong to a higher, abstract level, from where the solver is able to view and discuss the general term of the sequence (*the* figure).

The choices students make in identifying, generalizing and expressing patterns have consequences for succeeding in a task. Lannin et al. (2006) found that students had difficulties moving from recursive rules to explicit formulas, whilst Rivera and Becker (2005) concluded that figural mode leads to more successful generalizations, so teachers should use activities that de-emphasize numerical generalizations. Examining how these reasoning processes are treated in textbook tasks enables us to identify (a) the *paths of reasoning* promoted, regarding generalization of patterns, and (b) possible differences in the operationalization of the related competence aims between different textbooks. Our paths of reasoning include processes from the whole spectrum of mathematical reasoning processes (Zeanotte & Kierann, 2017) and are therefore an extension of Even and Silverman's (2024) 'paths of justification' that include only processes of mathematical reasoning related to validating.

Methods

The Norwegian education system is centralized, with the Ministry of Education developing the national curriculum. However, schools and teachers can freely choose textbooks, as there is no government approval process for instructional materials, allowing for local flexibility and autonomy in how the curriculum is taught. Given our focus on competency aims related to the generalization of patterns, we selected 8th and 9th grade mathematics textbooks from two of the largest publishing houses with the most commonly used textbooks: Aschehoug (referred to as Book A in this study) and Cappelen Damm (referred to as Book B, with Book B9 denoting the 9th grade textbook). Both books were updated according to LK20.

The textbook analysis was restricted to the textbooks' sections related to the competence aims regarding generalization of patterns. These were identified by the explicit mention of the term 'pattern' in the title and/or in the learning goal(s), whenever those were listed. We initially classified inductively all the patterns found in the relevant sections according to their type. The resulting categories are summarized in Table 1. Then, we investigated the reasoning processes connected to each task involving a pattern, identifying its path of reasoning. This was conducted in three steps: a) identifying the parts of the task related to *identification* of pattern, *generalization* of pattern, and *expression* of the general term, as in Radford´s (2006) definition; b) further categorizing *identification* as either *recursive* or *explicit* (Lannin et al., 2006)*, generalization* as either *numerical or figural* (Rivera & Becker, 2005)*,* and *expression* as either *factual, contextual* or *symbolic* (Radford, 2006); and c) categorizing the processes related to proving as either *generic example* or *demonstration* (Stylianides, 2008). The tasks were coded independently and differences in coding were resolved by discussion leading to agreement.

Findings

The various types of patterns that were found in the textbooks are described in Table 1, along with the frequency they occurred. The largest category, *sequence,* consists of sequences of mathematical objects which are either numbers, or figures, the latter being further divided into *repeating* and *growing*. Figures 1 and 2 provide solved examples involving figural growing patterns. An example of a pattern occurring within *natural number properties* is presented in the task shown in Figure 3. Few tasks discuss patterns in *arrays,* like symmetries in the Pascal triangle or the multiplication table. Last, a pattern occurring when investigating a problem posed verbally, such as modelling of a real-life situation, was coded a *word problem*. Note that although patterns in the last three categories may also be expressed sequentially, it is the solver who must identify the regularity in the task to produce the sequence, and they are therefore coded separately.

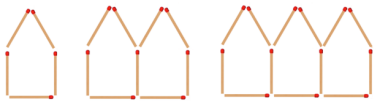

Table 1. Types and frequencies of patterns included in the textbooks

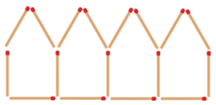
Type of pattern	Frequency			
	Book A8	Book A9	Book B8	Book B9
Sequence	**43**	**23**	**28**	**23**
Number sequence	35	0	7	0
Figural sequence	6	23	21	23
Repeating	0	6	0	0
Growing	6	17	21	23
Natural number property	**8**	**0**	**1**	**12**
Array	**1**	**0**	**0**	**2**
Word problem	**1**	**0**	**0**	**2**

While most of the patterns offered in both textbook series are sequences, differences occur both in the type of sequence and in the ways generalization is dealt with. In particular, Book A includes mostly number sequences in grade 8, while Book B only a few in grade 8. In addition, Book A contains a few repeating figural sequences, while this type is absent from both grades in Book B.



In Book A the process of pattern generalization is introduced gradually. The tasks initially involve only identification of a pattern, which is most often recursive, and then progress to tasks that require algebraic generalization of the identified patterns. The generalizations are mainly numerical and typically result in a symbolic expression. Only one task is categorized as inviting for a contextual generalization. The symbolic expression is sometimes used to determine a far term in the sequence. This path of reasoning *identification/recursive → generalization/numerical → expression/symbolic* is illustrated in the solved example in Figure 1.

Look at the pattern the figures form when you answer the task.

a) Draw figure number 4, and state how many matches this figure has.
b) Explore the pattern and find how many matches each new figure increases by.
c) Find a formula that describes the number of matches in the n-th figure.
d) Use the formula and find the number of matches in figure number 10.

Solution

a) There are 17 matches in the fourth figure.
b) The increase is 4 matches for each figure.
c) The total number of matches increases by 4, and the first figure has 1 more match. Therefore, the number of total matches in figure number 1 can be written as: 4 . 1 + 1. The total number in figure number 2 can be written as: 4 . 2 + 1.
The formula then becomes: $F_n = 4n + 1$
d) We insert $n = 10$ and calculate.
$F_n = 4n + 1$
$F_{10} = 4(10) + 1 = 41$
There are 41 matches in the tenth figure in the pattern.

Figure 1. Solved example with typical reasoning path in Book A9

A near generalization (Rivera, 2013) is asked for in a) (Figure 1), solved by drawing and counting. The open question "explore the pattern," which could allow for various strategies, is narrowed by focusing on how each new figure is built from the previous one, leading to the discovery of the *recursive* rule. Parts a) and b) were therefore coded as *identification of pattern/recursive.* In c) the *symbolic* expression is generated from the *generalization* of the numeric expressions of the first two terms, without using the figures in the reasoning. The mode is therefore *numerical*, and this part is coded as *generalization/numerical.* Part d) of this task is not coded in terms of reasoning paths as it is a mere application of the formula that the solver is instructed to perform.

Book B, on the other hand, offers mostly figural sequences that gradually increase in complexity. The grade 8 textbook presents various strategies and includes tasks related to all types of identifications, generalizations and expressions. While there is no clear dominant reasoning path followed, there appears to be a tendency towards a figural mode of generalization. This is evident in tasks where pupils are asked to describe figures and the use of distinct colors to highlight parts of the figures. Additionally, symbolic expressions are often produced after factual or contextual ones. Textbook B9 focuses on breaking down complex figures into simpler components. Then the symbolic expressions of the parts are combined to construct the one for the original figure. This approach is demonstrated in the solved example in Figure 2, where the path of reasoning is: *identification/explicit* → *generalization/figural* → *expression/contextual* → *expression/symbolic*.

To divide figures into smaller units

[…] The orange chips illustrate the rectangular numbers. The number of orange chips in figure nr. n is thus $n.(n+1)$.
The blue chips illustrate "the previous triangular number". The total number of blue chips in figure nr. 2 is the triangular number 1, the total number of blue chips in figure nr. 3 is the triangular number 2, etc.
We therefore replace n with n-1 in the algebraic expression for the triangular numbers. The number of blue chips in figure n is thus $\frac{(n-1)n}{2}$.
The number of chips in figure nr. n is $n.(n+1) + \frac{(n-1)n}{2} = [\ldots] = \frac{3n^2+n}{2}$

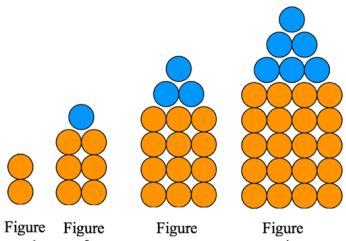


Figure 2. Solved example from Book B9

The process of identification of this pattern starts by decomposing it into two simpler ones, where each one is handled separately, and their formulas are in the end composed to produce the symbolic expression of the original pattern. The rule observed in the identification of both simpler patterns is *explicit* and while for the case of the rectangle numbers, the formula can be used as it is, in the case of the triangle numbers it needs to be adapted as the general term contains "the previous triangular number", a formulation that can be linked to a *contextual* level of expression. The statement is supported by exemplifying it using the two first terms of the sequence. The contextual expression is then used to describe the *symbolic expression* of the blue part of the pattern. The different colors used for the two parts of the figures are also used in the two parts of the formula helping pupils understand the connection between the figural pattern and its symbolic expression. This technique is commonly used in this textbook illustrating the focus it has on the *figural mode* of generalization.

The next significant category of patterns found in both textbooks contains patterns related to *natural number properties* and operations between them. The properties investigated are similar in the two books, but in contrast to Book A Book B moves beyond making mathematical generalizations and invites the pupils to engage with proving and in particular providing generic examples. A typical task is discussed in Figure 3, with the following path of reasoning: *identification* → *generalization* → *proving/generic example*.

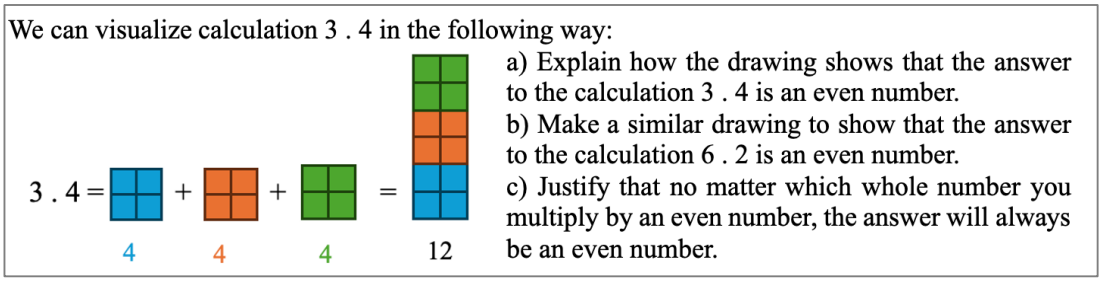

Figure 3. Natural number properties task from Book B9

The pupils have already seen earlier in the textbook that any even number can be represented as a tower of pairs of blocks, and any odd number as a tower of pairs of blocks plus an additional one at the top. The pattern that they must identify and generalize here is the visual argument that will support the statement in c). The cases a) and b) are therefore used to identify and generalize this pattern. The argument is coded as generic as it seems natural here for the pupils to use the particular cases to argue for the general. We note that the same task is included in Book A8, formulated as an open question prompting the pupils to explore products of odd and even numbers and identify the patterns.

Discussion and conclusions

In this study, we explored how two commonly used mathematics textbook series in Norway operationalize the competency aims related to the generalization of patterns that are outlined in the LK20 curriculum. Our findings highlight two main differences in how these textbooks approach pattern generalization, which may have significant implications for how reasoning and argumentation are fostered in the classroom. The first one regards the strong numerical focus Book A has, manifested by the choice of patterns, which are mostly number patterns in grade 8, and the mode of generalization, which is mostly numerical, compared to the more figural approach Book B

adopts. The second one is related to the reasoning processes promoted by the textbooks in the sections about generalization of patterns. In Book B, patterns occurring as natural number properties and operations between them are used to guide the students in proving using generic examples, while in Book A tasks centered around this type of pattern involve only processes related to making mathematical generalizations (Stylianides, 2008). We contend that these differences may be a result of the vaguely formulated competence aims, which, in addition, include terms that have been associated with different meanings in the mathematics education literature. It appears that there is no clear conceptualization of mathematical reasoning in LK20, with reasoning processes spread in different core elements. However, our study has limitations, the tool used to study reasoning processes is topic-specific and would need to be adapted for broader application across different mathematical content areas. Further research could extend the analysis to other mathematical topics, different textbook series or involve classroom studies.

As a general conclusion, we argue that, although there has been a significant change towards including processes of reasoning and argumentation in the recent LK20 curriculum (compared to the previous national curriculum), the competency aims with respect to reasoning were left rather vague, as also suggested by Valenta and Enge (2020). This is not an uncommon feature of national curricula, but it leaves the challenge for textbook authors and teachers to interpret the competency aims and to operationalize them in the classroom. Given the role of textbooks as the potentially implemented curriculum (Valverde et al., 2002), textbook developers, teachers, and professional development providers would benefit from a clearer conceptualization and understanding of reasoning and argumentation processes in the curriculum. This would help teachers plan and enact lessons aligned with these processes, enhancing the effectiveness of reforms.

In this paper we investigate how place value concepts are presented in selected German and Australian workbooks used by Year One students. Place value is an important concept that provides the foundation for further mathematical learning. Analysis of student workbooks is limited, especially in relation to the topic of place value. Student workbooks are a useful indicator of the opportunities for learning that students are provided. A cross-country analysis of the similarities and differences in the extent to which various concepts are addressed is useful to identify gaps that need to be addressed in student materials, and in the work we do as teacher educators.

Keywords: Place value, comparative textbook analysis, mathematics workbooks, role of zero.

Introduction

A poorly developed concept of place value is one of the main reasons for difficulties in mathematics. A substantial body of evidence identifies that understanding place value is central to the success of students in primary school mathematics (e.g., Kortenkamp & Ladel, 2013; Yuan et al., 2019). However, research also suggests that students struggle to master place value concepts (e.g., Yuan et al., 2019). Place value involves the learning of several "big ideas" (Van de Walle, 1998) and fundamental to these is the integration of early experiences of counting, grouping, and bundling amounts in tens (and in tens of tens, and in tens of tens of tens, and so on). Building upon the prerequisite knowledge of counting, grouping, bundling, and part-whole, is the concept of positional notation, which comprises the sub concepts of i) the value of the place (that is the value of the bundle unit); ii) the value of digits (based both on the symbol and on its position), and iii) the value of the number (that is the application of the part-whole concept to each of the digits in a number) (Ladel et al., 2023).

Given that textbooks and student workbooks[1] frame the teaching activities and learning opportunities provided to students (Sievert et al., 2021), and have an enormous influence on teaching and learning, we now provide a short analysis of research regarding their use.

Literature regarding textbook/workbook analysis

Textbooks have drawn considerable research attention and are regarded as the main resource used by teachers and students (Rezat, 2022). According to Jäder et al. (2020) more than 50% of students in secondary school in countries such as Australia, Finland, Singapore, Sweden, South Africa, and Canada are taught in classrooms where the textbook is the basis of instruction. We regard workbooks as a mediator between the intended and the implemented curriculum. In taking this position, we are

[1] In this article textbooks refer to sources of tasks which teachers can modify/adapt, and students answer elsewhere, and workbooks present tasks for students that are completed as prescribed.

not arguing that student workbooks and textbooks *should* be a key component of children's experience of mathematics but do acknowledge that these artifacts *are* a part of many children's mathematics learning experiences and are therefore worthy of analysis. Our view is that an analysis of student workbooks will get us closer to the implemented curriculum than if we had analyzed textbooks, as the student workbooks more closely indicate the tasks that the students will complete. Comparisons between countries (see Jäder et al., 2020) can assist in determining the quality of textbooks in their individual countries.

Our review of recent literature indicates that there has not been an analysis of how place value is presented in textbooks or student workbooks; therefore, the aim of this article is to present our analysis of Year One student workbooks from Germany and Australia regarding place value. Although in our larger project we have reviewed workbooks from four countries (Germany, South Africa, Japan and Australia), for the CERME audience we felt it most appropriate, and within the scope of the paper, to only discuss the German and Australian workbooks. Importantly, these two workbooks provide a good contrast regarding how place value is taught. Our research question is

What is the extent and nature of place value coverage evident in tasks in the selected German and Australian workbooks?

Methods

Methodologically, textbook analysis is a form of content analysis, whereby researchers make replicable and valid inferences from the text (in our case student workbook examples) they are evaluating. By its nature, this will involve making inferences based on the content and the contexts in which the texts were written, with the goal being to assess the likely impact of the text on the students. Following van Zanten and van den Heuvel-Panhuizen (2018), in this research the unit of analysis was any task that demanded a response from the student. Where we could see that a task included significant subtasks (that comprised work at about the level of a normal task in that workbook), these subtasks were treated as a task and coded accordingly. We acknowledge that there is no guarantee that any task, if it is completed at all, will be completed in the order presented and thus "all textbook analyses, irrespective of the approach adopted, are probabilistic" (p. 218).

Selection of workbooks

Both Germany and Australia have a system of Federated States (Länder) or Territories, each with responsibility for education and this results in textbooks/workbooks within each country varying greatly; indeed, in the Australian context there are workbooks written specifically for one state (e.g., the series NSW Targeting Mathematics workbook is advertised as being "fully aligned to NSW K-10 Syllabus"). Given this context, it was not possible to determine the most popular workbook in the Australian context. The selected workbook was chosen because i) it is published by a reputable educational provider in the Australian/New Zealand market; ii) is representative of the types of workbooks that students in Australia use; and iii) the entire student activity book could be accessed online. In Germany the three biggest publishers of workbooks were asked which mathematics workbook for primary school had the highest usage in Germany and based on their response, a workbook was chosen for analysis. Although there is variability between different workbooks in different countries, we are confident that the two workbooks chosen are indicative of the work that

students in these two countries are learning. As much of the conceptual work in place value occurs in the early years, we have chosen to evaluate Year One workbooks for students in Year One, where students in both countries are first introduced to place value concepts.

Analysis process

In the first step of coding the data, the team met and reviewed a sample of tasks from each workbook to ensure that we would evaluate place value prerequisite knowledge and place value sub concepts presented in the workbooks in a consistent manner. Each task was mapped to key place value concepts (See Ladel et al., 2023), including pre-concepts (counting, (decimal) part-whole, grouping and bundling) and place value sub concepts (bundling [Base Ten], the decimal part-whole concept, value of the place and positional notation) as these are critical for flexible place value understanding (Ladel & Kortenkamp, 2014). For this analysis we excluded the prerequisite knowledge of counting single ones, cardinal number, and part-whole as these aren't exclusive to the development of place value understanding. In addition, as we are only interested in this article in Base Ten - we also excluded the concepts of "different possibilities to group due to the group size" or "different possibilities to bundle due to bundle size" as these concepts are only relevant if we are using a range of bases.

Grouping and bundling are related yet different concepts with the difference largely a matter of what language is used to describe the sets that can be formed. While both concepts require groups of amounts, bundling results in a group of objects being recognised as a new object with its own identifier (i.e., name or label). For example, ten objects are initially referred to as a group of ten ones but then are bundled and labelled as one ten. Likewise, a group of ten tens can be bundled again and labelled as one hundred. Maximal grouping and maximal bundling occur when no further groups or bundles can be formed. For example, the number 123 can be represented as 12 bundles of ten and three ones or one hundred and 23 ones; however, these examples are not maximally bundled as the 12 tens can be bundled again into one hundred and two tens or the 23 ones can be bundled again into two tens and three ones. We require maximal bundling when representing amounts using standard notation.

In the second step of coding, as with the approach used by Sievert et al. (2021), each workbook was analyzed by two pairs of team members and workbook tasks that were considered to potentially develop place value understanding were identified. Tasks that passed this initial screening were then assessed to determine whether the place value concepts were present. In the final step of coding, all authors met to resolve the coding of any contentious tasks.

Scoring of items.

Every task in each workbook that was considered as potentially developing place value knowledge was coded as either a "0" (not explicitly developed) or a "1" (explicitly developed). As a task could be coded against multiple concepts, the total number of concepts being developed in each workbook is greater than the number of tasks. This scoring process led to the analysis of each task yielding a sequence of ones or zeros, according to the presence or absence of each concept in that task.

Results

We examined the workbooks in terms of four clusters – decimal part-whole, grouping, bundling or place value sub concepts. The data indicated that decimal part-whole was developed in every place value task (as might be expected) and, as this finding does not add any new knowledge, we have not presented this data. The data for the other three clusters is presented in Tables 1, 2, and 3.

Table 1: Distribution of Grouping prerequisite knowledge within Workbooks

Country	*Australia (N of tasks = 36)*		*Germany (N of tasks = 66)*		*Combined (N of tasks = 102)*	
Concepts	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*
Counting groups of ten and single ones	15	40.54	10	15.15	25	24.51
Maximal grouping	10	27.03	4	6.06	14	13.73
Grouping Cluster	*25*		*14*		*41*	

Table 2: Distribution of Bundling prerequisite knowledge within Workbooks

Country	*Australia (N of tasks = 36)*		*Germany (N of tasks = 66)*		*Combined (N of tasks = 102)*	
Concepts	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*
Counting bundles of ten and single ones	19	52.78	11	16.67	30	29.41
Maximal bundling	19	52.78	9	13.64	28	27.45
Bundling Cluster	*38*		*20*		*58*	

Table 3: Distribution of Place Value sub concepts within Workbooks

Country	*Australia (N of tasks = 36)*		*Germany (N of tasks = 66)*		*Combined (N of tasks = 102)*	
Concepts	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*	*N of tasks developing concept*	*% of tasks developing concept*
Value of place	33	91.67	56	84.85	89	87.25
Standard Partitioning	32	88.89	49	74.24	81	79.41
Role of zero	12	33.33	59	89.39	71	69.61
Value of digit	29	80.56	18	27.27	47	46.08
Value of number	29	80.56	24	36.36	53	51.96
Place Value sub concepts Cluster	*135*		*206*		*341*	

As the workbooks only provide numbers up to 100 in Australia and up to 20 in Germany, there is no opportunity for the related concepts of repeated grouping or repeated bundling (i.e., ten groups of ten make one larger group of one hundred or ten tens are equal to one hundred). Consequently, these two

concepts were not included in Table 1. Although it is possible to demonstrate different possibilities to group or bundle with numbers less than 100 (e.g. 25 objects could be grouped as 10 objects, 10 objects and 5 single objects or 10 objects and 15 single objects or bundled as 2 tens and five ones or 1 ten and 15 ones - i.e., non-standard partitioning), there were no examples of this flexibility of bundling in the Australian workbook. In the German context, it is not possible to demonstrate different possibilities to group or bundle with numbers less than 20, and consequently these two related concepts were not included in Table 2. In our view the lack of opportunities for repeated grouping or bundling limits developing place value understanding and is a direct consequence of curriculum design, which limits students' initial exposure in Australia (Year 1) and Germany (up to Year 2) to numbers to less than 100. This is compounded in the German context by the design of the Year 1 workbook, which only provides students with place value opportunities up to 20 (the only exception being the two final pages that include working with tens up to 100).

Discussion, limitations, and conclusion

In this section we discuss the impact of workbook design decisions on how students learn place value. It is important to note here that we are not attempting to determine whether one workbook is better than the other, as to do so would be to ignore a whole range of other factors that impact upon how students learn place value. Rather we discuss how the decisions regarding what content appears in each workbook offer advantages and disadvantages for learning place value. Both workbooks have interesting, but different, ways of scaffolding students' progress. In the Australian workbook, "call out text bubbles" direct the students to notice conceptual and/or mathematical connections. In the example below (Figure 1; left), the callout text (in green) encourages students to move beyond grouping ten objects and five single objects and ten objects and three single objects to the bundling of 10 objects into 1 group of ten by noticing that the first digit in each number is a 1 (i.e., one group of ten). In the German workbook, students are accompanied by a frog called Mini, and a dog called Max, who accompany their learning (See Fig 1; right). The structure is always the same as Mini and Max scaffold each activity by completing a sample task and discussing it. Analysing these prompts were necessary for accurate coding as they indicated whether a task was a place value task or not.

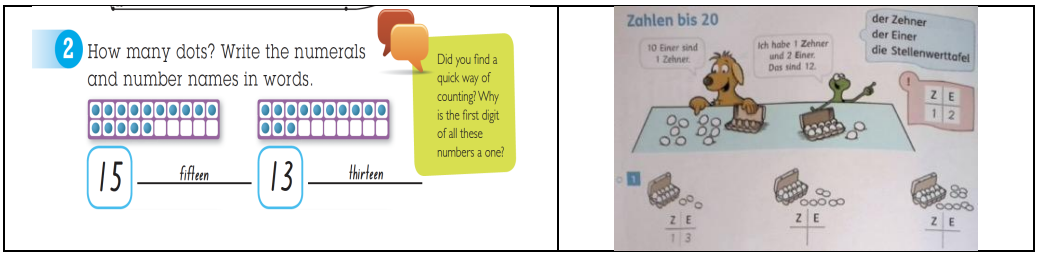

Fig 1. Examples of scaffolding in Australian (left) and German (right) workbooks

We now turn to a discussion of the descriptive statistics with the combined data suggesting a wide variability in the number of opportunities that students have to develop pre-requisite place value knowledge as compared to the number of opportunities for the development of place value sub concepts. Overall, the 102 tasks in the two workbooks offer 440 opportunities for students to engage with the place value concepts identified earlier. By far the least developed concepts are those related to grouping tens and single ones/maximal grouping (41 instances) and bundling tens and single

ones/maximal bundling (58 instances) with less than 30 percent of tasks across both workbooks developing these four concepts. This is most likely influenced by the number ranges - up to 100 (Australia) and up to 20 (Germany) - as these ranges limit opportunity for working in groups or bundles of tens. Given that bundling and unbundling is a fundamental prerequisite to understanding place value, we view this as a missed opportunity for students. The five place value sub concepts (value of place, standard partitioning, role of zero, value of number and value of digit) are more strongly represented (341 instances) with the first four of the five sub concepts being developed in over 50% of the tasks. Most regularly presented to students are the concepts of value of place and standard partitioning (87% and 79%).

Of importance to us is how place value knowledge is developed respectively in each workbook. There are two important comments to note here. Firstly, the German curriculum allows for students in Year One to be working in the number range up to 100, and it is therefore a publishing decision to limit the number range to 20. Secondly, as we indicated earlier, we are not making a judgment on whether one workbook is better for student learning as we have no empirical performance data to make such a claim. An initial difference between the workbooks is the relative weighting of concepts developed per task. Although the German workbook presented close to double the number of tasks (66 vs 36) and overall, more opportunity to engage with concepts (236 vs 198), the tasks in the Australian workbook included an average of 5.50 concepts per task, as opposed to 3.58 concepts per task in the German workbook. Given the connected nature of place value concepts, this might provide additional scope for Australian teachers to highlight the relationship between place value prerequisite knowledge and/or place value sub concepts when several of them are present in the one task.

In terms of the specific emphasis on individual concepts, the pattern of development differs markedly. In relation to Tables 1 and 2, the Australian workbook provides students with greater opportunity to develop two concepts related to grouping, namely counting in groups of ten and single ones (40.54% of workbook tasks include this concept) and maximal grouping (27.03% of tasks) when compared with the German workbook with (15.15% and 6.06 %) respectively for these concepts. Likewise, the Australian workbook provides greater opportunity for the related concepts, counting bundles of ten and single ones (Australia 52.78%, Germany 16.67%) and maximal bundling (Australia 52.78% and 13.64%). As we have described, grouping and bundling are very similar concepts and so we might expect that the relationship between the percentages of the concepts is similar, and this is indeed the case (counting in groups of tens/bundles of tens: Australia 40.54% & 52.78% and Germany 15.15% & 16.67% respectively). However, this relationship does not hold true when grouping and bundling (maximal grouping/bundling: Australia 27.03% & 52.78% and Germany 6.06% & 13.64%), where in both workbooks the opportunities to maximally group are less than to maximally bundle. The difference in allocation of tasks between maximal grouping and maximal bundling reflects the emphasis in both workbooks in representing amounts in the standard partition, whereby the focus is on naming the number of tens or ones in each place, which requires maximal bundling rather than maximal grouping. The lower percentage of tasks in the German workbook in both cases is again a consequence of the design decision to only use numbers up to 20.

There are also noticeable differences in the opportunities for students to develop place value sub concepts (Table 3), and here we focus on three, firstly the related concepts of the value of digit and

the value of number and then the separate concept of the role of zero. In relation to the two concepts - value of digit and value of number, our data suggests that these two concepts are closely connected in tasks in both workbooks (Australia - 80.56% & 80.56%; Germany - 27.27% and 36.36%). This data indicates that i) both concepts share the same or similar emphasis respective to each other in the separate workbooks; and ii) they are less often presented to students in the German workbook. The second observation is again accounted for by the design decision of only going to 20, which offers less variability in representing the value of digit, as any digit other than 1 only has one value, that is, students only ever encounter the digits 2-9 in the ones and thus encounter less tasks overall as the tasks would become repetitive; or the value of number, as it is likely the case that the ordinal nature of numbers is used by students to complete tasks. It is likely easier for students to just count, and not see these numbers as parts of ten and ones (e.g., 12 is just one more than 11 or 16 is one more than 17). This could be considered as a missed opportunity for Year One students in Germany to develop their early place value knowledge.

A final point of interest for us involves the emphasis on the role of zero, and we come at this point from two perspectives. Firstly, both workbooks depart somewhat from their respective national curriculums. In our earlier research into the respective curriculums (see Westaway et al., 2023) we discussed the lack of emphasis on the role of zero and identified this as a limitation of both. However, contrary to the curriculum, in both workbooks, the place value role of zero is emphasised. We see this as a strength but acknowledge that this could be problematic for teachers who are tasked with delivering the national curriculum. Secondly, there is a marked difference in emphasis between the two workbooks in highlighting the special nature of the zero (Australia - 33.33%; Germany 89.39%). A possible explanation is that there is a strong emphasis in the German workbook on combinations bridging through ten, highlighting the special nature of a 10 (See Fig 2.).

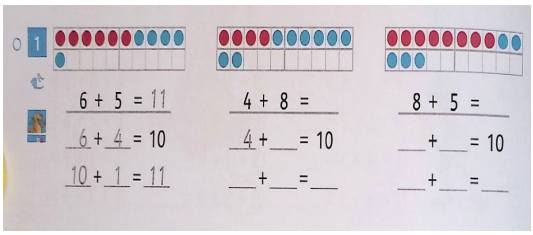

Fig 2. Examples from German workbook supporting knowledge of the role of zero

In many examples such as these, the students encounter that the symbol 10 means one ten and zero ones and this understanding is supported by the use of the ten frames that again indicate a bundle of tens and some, or indeed no, number of ones.

Conclusion

This conference paper has presented a component of a larger program of research where we investigated workbooks from four countries. It serves as an initial attempt to understand the implications of workbook design on how students are presented with tasks developing place value concepts. We argue that only offering initial exposure to small number ranges (i.e. up to 100) can limit opportunities for students to develop the important prerequisite knowledge related to repeated grouping and bundling of tens, as well as opportunities to investigate the value of digits within a

number. Given the increasing reliance by teachers on prepackaged materials, it is important that we better understand how place value concepts should be presented to students. In terms of progressing our work further, we have learned that we need to develop a mechanism for examining more closely the pattern of how prerequisite knowledge and place value sub concepts are presented together in tasks, beyond what we could say in this paper regarding the density of concepts per task. Pedagogically, it might be appropriate in our ongoing research to compare workbooks across number ranges (i.e. up to 100) rather than across age ranges where curriculums differ between countries.

This paper presents a case study that aims to explore how a teacher with low mathematical knowledge for teaching, in a class with an average level of students' socioeconomic status, manages to establish high instructional quality in the lesson with the support of a lesson plan that draws on variation theory. The analysis shows how patterns of variation, such as contrast, generalisation, and fusion helped students in an upper primary school class to discern critical aspects of fractions. The study highlights the need for lesson plans that provide teachers with structure while supporting their flexibility, to modify instruction based on real-time student feedback and needs.

Keywords: Variation theory, lesson plan, high-quality mathematics instruction, fractions.

Introduction and aim of the study

The quality of mathematical instruction is influenced by a complex interplay of various factors that together shape the effectiveness of teaching and the learning outcomes of students. Much effort has been put into investigating factors that concern the individual teacher, such as teachers' MKT (Ball et al., 2008) and/or views of what constitutes high-quality mathematics instruction (Munter, 2014). Another group of studies focuses on student characteristics, showing that what constitutes instructional quality (in terms of positive effects on student achievement) depends on factors such as students' age and socioeconomic status (SES) (Broer et al., 2019). A third group of studies brings up the role of educational resources for the quality of mathematical instruction, both theoretically (Remillard & Heck, 2014) and in effect studies (Jackson & Makarin, 2018). Teaching based on well-structured teaching materials can potentially reduce the relative impact of the teacher compared to other factors within a classroom learning community (Shechtman et al., 2010). In this study, we will focus on educational resources, while also taking into account factors at the teacher and student level. More specifically, we explore how a teacher with low MKT, in a class with an average level of students' SES, manages to establish high instructional quality in the lesson with the support of a lesson plan that draws on variation theory (VT) (Marton, 2015).

Educational resources constitute an important link between curriculum and teaching practice. The teacher and the educational resource, such as a textbook, form "a dynamic inter-relationship in which both are active participants and contributors to instructional outcomes" (Charalambous & Hill, 2012, p. 449). However, for instructional material to be the educational resource it is intended to be it must provide structure and guidelines for the teacher (Charalambous & Hill, 2012) and questions and instructions should be close to everyday life in the classroom so that the teacher can immediately see its relevance and implement them in their classroom practice (Davis & Krajcik, 2005). Indeed, there is a risk that a lesson plan can instrumentalise a teacher's work in the mathematics classroom. Strongly structured lesson plans

may leave little room for teacher autonomy, restricting their ability to adapt instruction based on students' immediate needs, interests, or understanding (Remillard, 2005). Hiebert and Morris (2012) argue that, while structured lesson plans can offer consistency, they often limit teachers' ability to modify instruction based on real-time student feedback and needs. The hypothesis of the present study is that a lesson plan that follows the principles of VT (Marton, 2015) can balance between structure and flexibility, noting the importance of allowing teachers to make instructional decisions based on student interactions and understanding.

Variation theory as an instructional design principle

The VT has proven accessible and useful for teachers to design and implement well-organised and structured lessons that provide students the opportunity to engage with and explore important ideas in different mathematical areas (Kullberg et al., 2017; Mason, 2017; Ryve et al., 2013). The theory emphasises variation as a necessary condition for learners to be able to discern new aspects of an object of learning (Kullberg et al., 2017). VT entails *holism*: People learn through experiencing differences and similarities. Nothing has one aspect only: "We cannot grasp just one meaning; it takes at least two. We can only find a new meaning through the difference between meanings. The difference between meanings thus becomes visible against a background of invariance in other respects" (Marton, 2015, p. xi).

VT spells out two conditions of learning: 1) that learning entails discerning necessary aspects of the object of learning and 2) that discernment cannot happen without the learner having experienced variation (Kullberg et al., 2017). For instance, it would not be possible to notice the colour red if there was just one colour. One must be exposed to variations in colours, such as green, blue or yellow to experience something as red or, to make sense of the concept colour(s) in general. It is the structure of an exercise as a whole, not the individual items, that promotes mathematical sense-making. Tasks that are carefully sequenced are generally likely to result in progress in ways that unstructured sets of tasks do not. In the words of variation theory, "to make the (critical) aspect possible to discern, the teacher must open up the aspect as a dimension of variation (Kullberg et al., 2017, p. 560). The variation theory describes three patterns of variation for structuring teaching that promotes discernment, i.e., learning (Marton, 2015):

Contrast: To experience something, we need to compare it with something else. For instance, in order to understand that triangles are geometrical objects with three vertices, we must experience geometrical objects that have not three vertices, such as a rectangle or any other geometric shape (Kullberg et al., 2017).

Generalisation: To fully understand what constitutes a triangle, we must also experience varying appearances of a triangle. Generally expressed, generalisation means that it is necessary for us to grasp the focused aspect of a phenomenon (e.g. features defining a triangle) and separate it from irrelevant features (e.g., the thickness or colours of the lines to illustrate a triangle). In teaching practice, this means that different (irrelevant) aspects are systematically varied while keeping the focused aspect invariant.

Fusion: If there are several critical aspects of a phenomenon that a learner has to take into consideration at the same time, they must all be experienced simultaneously. In the case of a

triangle, this could imply the simultaneous discernment of three vertices, that each vertex corresponds to an angle, and that the sum of the three angles is 180°.

Method

We follow the methodology of a case study and, particularly, that of a paradigmatic case (Flyvbjerg, 2006). In case study methodology, a paradigmatic case serves as an exemplar to illustrate a particular phenomenon in a clear and representative manner. In the present study, we are interested in how an educational resource (a lesson plan) that follows the principles of variation theory can support a teacher in establishing a lesson in mathematics with high instructional quality. To increase the probability of detecting this, we wanted to reduce other factors that could also explain the quality of instruction. Therefore, the selection of the lesson was based on the fact that a) the educational resources that informed the lesson showed principle from variation theory, b) the instructional quality was high, c) teacher level factors (e.g., MKT; Training in VT) were low, and d) student level factors (e.g., SES) were at or below average.

Concerning a), the lesson in this study is conducted in the context of a national-scale professional development program (PDP) for mathematics teachers in Sweden – Boost for Mathematics (BfM). During the PDP teachers, among other things, study PD materials (e.g., texts, video) available on a digital platform and, together with their colleagues at the respective schools, plan a teaching activity (usually a lesson to conduct). The lesson analysed was such a teaching activity, focusing on fractions. The PD materials, forming the basis of the teachers' joint work, did not explicitly articulate VT. That the lesson plan follows VT principles comes from our reading of the PD material and from the observation of how sequences of tasks were presented on the pre-planned PowerPoint, through which the teacher led the teaching. So, when referring to the lesson plan in the present analysis, we refer to the organised sequence (plan) of tasks through which the teacher led the teaching.

Concerning b)-d), it is important to note that our pragmatic case is part of a dataset for a larger research project that involves a large data set, including video recordings of ~170 mathematics lessons conducted during BfM as well as teacher interviews (~50 teachers). Some of these data have been coded within the research project and serve as a basis for the selection of our case. For example, concerning b) instructional quality, different aspects of instructional quality of the mathematical lessons have been rated using the UTeach Observation Protocol (UTOP) (Walkington & Marder, 2018), an observation instrument that has been shown to have high correlation between observation score and student achievement (Kane & Staiger, 2012) and that rests on dimensions of instructional quality corresponding with ambitious mathematics instruction (Walkington & Marder, 2018). The pragmatic case is a lesson that was known to be of high quality (UTOP-score in the upper percentile of the sample). Concerning, c) teacher level factors, teachers' MKT has been captured using interview questions derived from Empson and Junk (2004), and teachers' views of what constitutes high-quality mathematics instruction has been captured using an established survey (Swan, 2006). The teacher in our case had low MKT (MKT-score in the lower percentile of the sample) as well as a view of high-quality mathematics instruction that leans more toward viewing the teachers' role as either 'chalk and talk' or as a facilitator, rather than a knowledgeable other. Finally, concerning d) student-level factors,

students' SES (measured in terms of the proportion of students who have at least one parent with tertiary education), was in line with the average value for our sample.

UTOP captures a wide range of mathematical quality of instruction and to provide a detailed analysis of all these dimensions is beyond the space limitation of the present paper. In this paper, we focus on how a lesson plan that follows the principles of variation theory can enhance the quality of instruction according to the dimensions Lesson Structure and Mathematics Content and their relationship. Lesson Structure assesses the teachers' plans for the organisation of the lesson and includes items such as the sequencing of the lesson, the resources employed, and the opportunities and/or methods used to gauge student understanding. Mathematics Content assesses the quality of the mathematics content enacted during the lesson and includes items regarding, for example, the teachers' communication of the content and the content significance.

We analysed the lesson through the lens of VT (Marton, 2015). We first discerned episodes where aspects of fractions were enacted during the lesson. We then took a closer look into these episodes. In particular, we examined how the aspects came through in patterns of variations, mediated by the lesson plan, through which the teacher led the lesson.

Analysis and Results

The sequencing of activities kept students engaged in the content, had a clear sense of purpose, and allowed students to engage with mathematic concepts for most of the class period. There were, however, some activities in the lesson that appeared a bit difficult for the students to follow. The lesson included several opportunities and/or methods for the teacher to gauge student understanding by using multiple examples. Most of the time, the teacher made clear attempts to involve all students in the lesson, and several attempts were made for formative instruction by displaying different student solutions. The teacher used appropriate digital (Smartboard) and non-digital (small whiteboards) resources for interaction and visualisation, with some missed opportunities in using the resources. The teacher frequently used questioning techniques to encourage and maintain participation. Next, we elaborate on how the enacted lesson plan, following principles of VT, provided structures to the lesson to achieve these qualities. All names referred to are synonyms.

The overall object of learning was the part-whole relationship of fractions. The object was structured in two related critical aspects, constituting the foreground of the lesson structure. One was that fractions can be ordered according to variations in the numerator when the denominator is kept constant, and the other was that fractions can be ordered according to variations in the denominator when the numerator is kept constant. These two aspects were captured in a number string of fractions (Figure 1) where the students were asked to suggest a fraction that was smaller than, but as close to 1 as possible. The number string was structured according to a pattern of contrast *within* pairs of fractions, where the denominator is given in the first fraction and the numerator is given in the second fraction in each of six pairs of fractions. The number string was also structured according to a pattern of generalisation, taking place *between* each pair of fractions. That is, the contrast between the fractions with an eight in

the denominator and an eight in the numerator was generalised in the subsequent five pairs of fractions.

Before the lesson turned into working with this number string, the teacher articulated, ”We will try to find a fraction that is as close to one as possible, and then we must first ask: What is one then when you have fractions?” Hence, she moved the lesson forward by contrasting close to one, with one. One student voiced, “One whole”, which the teacher confirmed by revoicing.

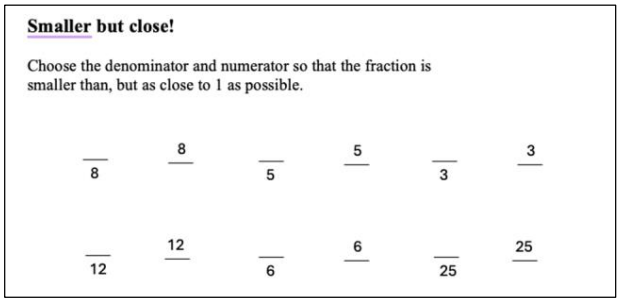

Figure 1: Number string on smaller but close

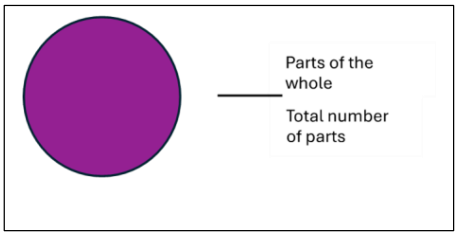

Figure 2: Circular disc (text translated)

The teacher switched the display on the smartboard to a circular disc filled in purple, together with a fraction line to the right of the circular disc (Figure 2). The teacher used the display to prompt students to investigate and make sense of how to express 1 as a fraction. The prompts were structured in a pattern of generalisation, where she asked students to add the numerator and the denominator in a pre-planned sequence of filled circular discs. The form and the size of the disc were kept constant and, so was the symbolic representation of the fraction form. What varied was the number of the equal parts a disc was divided into. This variation pattern turned the students to focus on the number of parts making up a disc and how to link this to a symbolic representation of a fraction. However, the variation was also important for making explicit to the teacher the difficulty some students had in making sense of a filled disc in the form of a fraction. After two introductory examples, the teacher showed a filled disc divided into three equal parts. She then asked the students to answer on their small whiteboards what the numerator and denominator should be. Most students answered 3/3 but, some students answered 1/3 and some 3/1. The teacher selected one board of each and showed them to the class. The selection of answers was not random but followed variation theory. The teacher used 3/1 and 1/3 to support the learning of 3/3. In other words, she helped students recognise the link between the disc and 3/3 by noting why the disc cannot be linked to either of the other two fractions. In achieving this, she utilised the possibility for visualisation on Smartboard. In practice, she pulled two of the thirds away from the disc, to prompt the students to make sense of 1/3. It was easier for students to link 1/3 to the Smartboard display, now visualising the circle sector 1/3, and, in the means of variation theory, by understanding 1/3 the students were in a better position to understand what it is not.

The teacher turned the lesson back to the number string (Figure 1) and the task to find a fraction smaller than but as close as possible to 1, given the numerator or the denominator. The teacher constantly used the former activity, making sense of a 1 in the form of a fraction, as a questioning technique, based on the pattern of contrast, to support students in discerning a fraction smaller than 1. What then contributed to the quality of the lesson was that she deviated

from the pre-planned structure of the number string. Instead of dealing with one pair at a time, the class first worked through all the fractions with the denominator being given. In terms of variation theory, instead of contrasting the fractions within each pair, she developed a pattern of generalisation along the fractions with given denominators. She kept as constant that the denominator was given through all six fractions. The values of the denominators varied. This helped the students to see the pattern that the numerator should be one number less than the denominator for the fraction to be smaller than, but as close to 1 as possible. When the last fraction of the six first fractions was done (24/25), the teacher asked; "What pattern can we see here?" Several students raised their hands and Lucas answered, "That it is one more in the denominator". The teacher revoiced, "That it is always one more in the denominator". The use of "always" can be seen as an act, adding to the pattern of generalisation. What then added to the high quality of the lesson, was that Lucas filled in the teachers' re-voicing by, "or one lesser in the numerator". This act by Lucas added to the quality in two respects. Firstly, it confirmed that several students discerned the connection between the numerator and the denominator in fractions. Second, it contributed to enacting the variation pattern fusion; two ways of discerning the pattern were enacted simultaneously.

Next, the lesson turned to the string with the numerators being given. The teacher asked, "So, how are we supposed to think here [pointing to the Smartboard]?". Peter replied, "One more". The contrast within each pair of fractions was made explicit on the Smartboard. For instance, the eight was kept constant in the first pair of fractions, while its position as a denominator and a nominator varied. The teacher completed the number string of fractions, asking different students to voice what denominator to add to each fraction. The completion of the number string ran smoothly.

Discussion

The present study shows how a teacher with low MKT (Ball et al., 2008), in a class with an average level of students' SES (Broer et al., 2019), manages to establish high instructional quality in the lesson with the support of a lesson plan that draws on VT (Marton, 2015). Teachers' MKT and students' SES are not objects of study. Instead, we refer to these two contextual factors to provide for generalisations from the case study. For instance, a case-to-case generalisation builds on the assumption that, if something worked or happened this way here, it might also work or happen in a similar situation elsewhere. Teachers' MKT and students' SES can play a key role in determining the similarities between instructional contexts. Moreover, the combination of a teacher's low MKT and students with an average SES suggests that the instruction is not reliant on exceptional conditions. This indicates that many teachers, guided by the theory of variation, could achieve similar teaching outcomes.

One of the key outcomes observed in this study is the balance between structure and flexibility provided by the VT principles. Overly structured lesson plans might inhibit teacher adaptability (Hiebert & Morris, 2012; Remillard, 2005). In the present case, the structured lesson plan gave the teacher a clear framework to follow, guiding students through critical aspects of the object of learning—fractions—while still allowing room for teacher autonomy. The teacher could respond to real-time student needs by deviating from the pre-planned sequence in meaningful ways, such as focusing on generalising patterns before addressing individual pairs of fractions.

However, the analysis also calls for further investigations on the balance between structure and flexibility, connected both to VT and to the teacher's design capacity (Remillard & Heck, 2014). We observed some students found it hard to make sense of a filled disc in the form of a fraction. In all cases, the teacher started with a filled disc. Acting flexibly, she could have tried to start with a blank disc and then fill up its parts, linked to corresponding fractions, until the entire disc was filled. On the one hand, the educational resource (the Smartboard) allowed for such flexibility. On the other hand, however, it was not part of the pre-planned sequence of tasks to start with a blank disc, which potentially restricted the teacher from making proper changes to real-time students' needs.

While the study focused on a single case, the findings offer valuable insights for broader educational practices. The analysis suggests that a lesson plan following VT can potentially reduce the relative impact of the teacher compared to teacher-level factors (e.g., MKT) and student-level factors (e.g., SES) in a classroom learning community (cf., Shechtman et al., 2010). This raises important implications for teacher education and professional development, particularly in designing resources that allow for a combination of structured guidance and instructional flexibility for all classrooms.

Use and perception of differentiated scaffolding by primary school students involved in mathematical tasks

Caterina Papa and Agnese Ilaria Telloni

University of Macerata, Dep. of Primary Education, Cultural Heritage and Tourism, Macerata, Italy; cp.caterinapapa@gmail.com

In this paper, we focus on scaffolding elements provided in a sequence of four geometrical tasks to support primary school students' activity and overcome potential difficulties. Using a qualitative method, we analyze 18 3rd-grade students' performance and their answers to a survey aimed at investigating their use and perception of scaffolding elements, and their impact on the subsequent activity. In particular, we focus on the reasons preventing students from proper use of scaffolding elements, intended as a form of formative feedback. The results of the data analysis allowed us to identify four distinct categories of students' behaviours regarding the use, the perception, and the impact of the scaffolding elements on the subsequent work. These categories reflect different ways of interiorizing and translating the acquired information into action.

Keywords: Feedback, scaffolding, primary school students, task design.

Introduction

Scaffolding is a fundamental part of the teaching-learning process. Providing scaffolding means giving students suitable support to solve problems, perform tasks, or achieve formative goals beyond their unassisted efforts (Bakker et al., 2015). The effectiveness of a scaffolding action can be defined in terms of responsiveness (Koole & Elbers, 2014), i.e. based on the extent to which it benefits the receiver. This is related to the scaffolding intended as a form of formative feedback (Shute, 2008), i.e. as a piece of information clarifying the students where they are in the learning process, where they are going, and what steps should be taken to go forward. As highlighted by some research, feedback needs to be understood and actively used by students to be effective, and this is not always the case (Jonsson, 2012; Withey, 2013). Although many studies have been devoted to the effective use of scaffolding and feedback by secondary school and university students (Cusi & Telloni, 2019; Winstone et al., 2017), there is little research on this topic in primary school (Antoniou & James, 2014; Hargreaves & Flutter, 2019). This study should contribute to this lack of research, focusing on the use and perception of scaffolding by primary school students involved in mathematical tasks.

Theoretical framework

Scaffolding is described as a process where an expert supports a learner in completing a task. A particular feature of scaffolding with respect to other forms of support is that it should be progressively faded, i.e. gradually reduced and possibly eliminated so that students' competencies and autonomy increase (Bakker et al., 2015; Sharma & Hannafin, 2007). In this study, we focus on scaffolding elements we designed and provided within mathematical tasks as forms of formative feedback (Shute, 2008). In particular, the scaffolding elements are intended as triggers of

facilitative feedback, i.e. not providing an answer to the tasks, but guiding the students to organize the solving strategy. In tune with Hattie and Timperley (2007), these elements should be easily accessible but not immediately visible, to allow children to think about possible solutions before recurring help. Moreover, they should contain a limited quantity of information, preferably content-specific (Shute, 2008). Scaffolding actions and the triggered feedback can be regarded as two-way communicative events (Nicol, 2010). Consequently, their effectiveness depends on the fluency of the dialogue and, specifically, on the students' capacity to participate in it (Winstone et al., 2017), deciding when seeking scaffolding elements to support their activity. Relying on the mentioned studies about the design of scaffolding that generates effective feedback (Alessio & Telloni, 2024; Nicol, 2010; Sharma & Hannafin, 2007; Shute, 2008; Winstone et al., 2017), we structured mathematical tasks with scaffolding elements such that: a) take into account the specific difficulties afflicting the learning of the topic at stake; b) are of different kinds, content-specific and envisaged the differentiation of cues so that different learning needs could be supported; c) are easily accessible and not immediately visible; d) are student-driven, i.e. the students could receive them only if they decide to require these elements; e) contain a limited quantity of information to provide a sustainable cognitive load; f) are provided informally; g) progressively faded. Although some research highlighted a generally positive perception of scaffolding as a form of formative feedback by students, with different preferences for different kinds of feedback (Hargreaves & Flutter, 2019), unfortunately, they often do not take advantage of it. This could depend on cognitive, metacognitive, or affective factors within the learning (Jonsson, 2012; Rakoczy et al., 2013). Winstone et al. (2017) identified four main barriers preventing students from effectively using feedback: a) difficulties in decoding feedback content and purpose; b) poor knowledge of suitable strategies and theoretical elements addressed by the feedback; c) sense of disempowerment and difficulty in translating feedback in actions; d) lack of receptiveness and engagement. In particular, students often lack awareness of their difficulties and monitoring control, so meta-scaffolding is needed (Pea, 2004). Within wider research about the use of scaffolding as a form of formative feedback by students at different grades (Alessio & Telloni, 2024; Cusi & Telloni, 2019), in this study, we investigated if and how primary school students choose to use specific scaffolding elements aimed at supporting their solving process of mathematical tasks.

Context and method

The participants in the study are 18 third-grade primary school students, attending a school located in a semi-rural area in central Italy. The class has been chosen for the students' differences in learning rhythms, typical approaches to solving tasks, and their sense of self-efficacy in mathematics; indeed, all these aspects could influence the use and perception of scaffolding elements. The authors designed and developed a sequence of four geometrical tasks of increasing difficulty, provided with scaffolding elements, also called *hints*, to support the students' work, and *queries* to guide students in choosing the most suitable hint for their possible difficulty. After the students solved the sequence of tasks, they answered a semi-structured survey about their use and perception of the hints. In particular, the participants were invited to explain if and how they used the hints, what suggestions they considered more useful and what improvements they would

suggest to structure more effective feedback. Moreover, concerning perception, students were asked how the presence of potential help influenced their solving process. One of the authors was in the classroom as an observer during the activity. The specific research questions addressed in this study are: 1) Did students use the hints in case of difficulty? How did they use them?, and 2) What factors prevented students from requesting hints and/or taking advantage of the feedback they received?

The data collected are the field notes of the author who was present in the classroom, the students' answers to the survey, and their solutions to the submitted tasks. Using a qualitative approach (Cohen, 2017), the authors made a cross-analysis of the data. They individually compared the field notes with the students' productions, highlighting the moments in which the students were in difficulty, their choice of using the hints or not in those moments, the consistency between the kind of difficulty and the chosen hint, and the effects of the use of the hints on the subsequent work. Moreover, the authors individually analyzed the students' answers to the survey, identifying and coding the excerpts concerning the students' motivation for using or not the hints and their perception of the provided support. This allowed the researchers to define categories of behaviours, in tune with the model elaborated by Winstone et al. (2017), based on the factors preventing students from properly seeking, using the hints, and acting upon the related feedback. In the following we describe the design of the tasks with the hints and queries provided.

Design of the tasks and the scaffolding elements

The authors designed a sequence of four tasks to be solved in a paper and pencil environment, concerning elementary geometry, three multiple-choice and one open-ended. Each task is provided with hints addressing different aspects, i.e. a) theoretical concepts; b) strategical aspects, possibly counter-examples; c) guiding questions to foster the procedural steps. All the hints are student-driven. Indeed, they are provided by a system of folded and glued paper: the hints are glued on the back of the sheet, they remain hidden, and the paper is folded until students opt to access them. The choice to recur to hints subsumes the students' will to invest resources and time in decrypting feedback, processing information, and modifying the solving strategy accordingly. The hints are preceded by specific queries, fostering the students' monitoring of the solving process and guiding the choice of the hints, as a form of meta-scaffolding (Pea, 2004).

Design of the four tasks and description of the survey

The first task of the sequence requires students to recognize the definition of "polygon" by selecting one or more possible options: a) shape bounded with straight sides, b) shape bounded with lines, c) shape bounded with closed lines, d) shape with equal sides. The right complementary options are a) and c). Specific hints are provided, associated with the single options, and aimed to give feedback based on counter-examples. For instance, the hint associated with the first option shows a rectangle with a missing line and the question "Is this a polygon or is something missing?". The second task shows a series of five shapes and requests to find the isoperimetric ones. Two of them are the same polygon but rotated, other two were shaped differently but isoperimetric. Different hints are provided. The first one, introduced by the query "I do not remember what the perimeter is", is theoretical and gives the definition of "perimeter"; the second hint, introduced by the query "How

can I find the length of the sides?", is procedural, and shows how to find a side. The third and fourth hints are strategic and have been designed considering the possible difficulties the students could encounter. The queries "Do similar shapes have the same perimeter?" and "Can very different shapes have the same perimeter?" introduced the hints, respectively. In the former case, two similar shapes with different sizes are shown and students are encouraged to compare their perimeters by measuring their sides. The latter case, based on the same logic, shows two different shapes with the same perimeter. The third problem proposes a narrative context in which four characters determine the area of a rectangle (drawn on graph paper) using different strategies. The numerical result is the same, but three strategies are correct, and one is wrong. The first character groups the inner squares of the rectangle horizontally and then adds the obtained number as many times as the rows are. Similarly the fourth character, but grouping the squares vertically. The second character uses the classic formula $b \times h$. The third character adds the measure of the sides, using a wrong strategy. Students had to determine which options were correct and explain the solving strategy used (open-ended task). Four different hints were provided. The hint linked to the wrong resolution is based on some guiding questions that should help students identify procedural mistakes and reject the flawed approach. The hints for the correct solving processes invite students to think about how the area of the rectangle is obtainable using various groupings. The open-ended question takes the analysis to a deeper level because students had to effectively explain the method used by someone else to solve the problem. We designed this task to understand if the hints have been not just consulted but also understood and used by the students. The last task asks students to verify if the shapes presented, a rectangle and a square, are isoperimetric or equivalent. The queries are similar to the previous tasks and should guide the students in choosing the most suitable hint. According to the idea of fading scaffolding, the hints are less orienting, also to verify if the information provided with the previous scaffolding elements was kept in mind by students after completing the task.

In the survey the first questions are: 1) "What do you think of the opportunity of using suggestions to solve problems, and 2) "You have used them because…". They should allow us to understand if students consider the hints useful, to what aim they decided to use them, and if the feedback provided made them change their strategies. The other questions are oriented to identify the barriers students encountered in understanding and using feedback, as well as their perception of the effectiveness of the provided hints. The third question is open-ended: 3) "Which problem do you think was the most difficult?". The fourth 4) "For that problem, you would have had…" is a closed question that gives students three possible options: a) a simpler explanation, as I didn't understand the hint; b) more information: the hint was useful, but after reading it I still didn't know what to do; c) no changes: the hint was useful.

Results and discussion

In this section we report the frequencies of students' correct answers to the tasks and their uses of the hints, relying on the field notes of the researcher present in the classroom and the students' productions. For the first task, about 67% of the students found the solution and 50% of them used hints; 22% chose only one of the two correct answers, half of whom used all the available hints; 11% did not solve the problem, despite having consulted all the available hints. Solving the second

task, about 22% of the students identified the correct solutions, 75% of them used the hints; about 66% identified only one couple of isoperimetric shapes, 54% of them recurred to hints; finally, 11% did not find the right answers, 67% of them consulted the hints. Both groups of students, those who could not solve the problem and those who found the correct answer, used theoretical hints. In the third task, all the students identified at least one correct strategy, but only 22% of them were able to motivate their answers; 75% of these students used the hints and answered the guiding questions aimed at reconstructing the resolution strategy. About 28% of the sample gave a partially correct explanation, the totality of them recurred to hints. For the fourth task, all the students identified the correct answer, and only 22% of them used hints. The theoretical hints were the most used, by 75% of students, whilst 25% of students used the procedural ones. This last problem was the most complex because students had to apply the concepts of area and perimeter and also compare the data. Instead, only a few students required hints. This can be due to the fact that the theoretical references needed for the solution were also provided in the previous problems, and students were able to transfer them. The analysis of the collected data allowed us to identify four categories of students' behaviours for their use and perception of the scaffolding elements and the impact of the related feedback on the subsequent work. This allowed us to answer our research questions.

Effective use of scaffolding elements

About 17% of student**s** suitably required the hints, took advantage of the related feedback, and applied the suggestions provided to an effective solving strategy. These students did not make a generic use of hints but sought them according to the specific difficulty encountered. Moreover, they were able to accommodate new information in their strategies. An example is L.: he provided correct answers to the first, second, and fourth problems without using hints; solving the third problem, he fruitfully used all the hints and correctly explained all the strategies to find the area of the rectangle. In the survey, L. declared that the third problem was the most difficult and that he used the hints "*to solve doubts about the resolution method used by the characters and to understand their reasoning*". Students whose behaviour is in this category are high-achievers. They maximized the efficacy of hints and feedback since they exploited the new information to (re)organize their solving process.

Immediate use of scaffolding elements without generalization

44% of students made effective use of feedback, but only at an immediate level, without taking advantage of the received information for the subsequent tasks. These students are those who typically perform correctly standard tasks, but struggle with non-routine ones. As an example, we present the case of M. Solving the third task, M. properly motivated the first strategy, after using the hint, arguing that "*[the character] formed groups vertically and carried out the operation*", but was not able to extend the same strategy to other answers. Indeed, M. did not recur to other hints, but he was not able to correctly explain the other correct strategies. As in Winstone et al. (2017), M. seemed to exploit the feedback to overcome the procedural difficulty, rather than grasping its long-term potential. This suggests that the activation of M. remained blocked at the level of recognizing his learning needs. Although the feedback was useful and exploited to give the correct answer, M.

struggled to apply it to other cases. With respect to the research question (2), the factors preventing M.'s effective use of hints can be linked to a lack of active thinking and self-regulation in monitoring the process and the results provided. Coherently, M. declared in the survey that "*the hints were useful to give the correct answer"*, highlighting the immediate effect she expected.

Using scaffolding elements ineffectively

About 28% of students identified specific difficulties encountered in solving the tasks and decided to recur to hints. However, they were unable to use the information obtained to reorganize their solving process. In these cases, the consulted hints were not understood or were not effectively applied to a resolution strategy. Specifically, investigating the factors preventing the proper use of the hints, it emerged that "*the hints were not clear*". C. is a student whose behaviour is in this category; she is not familiar with the Italian language. She used all the hints provided in all the tasks, but in the first and the third ones she was not able to transfer the information obtained into an effective solving strategy. In the survey, C. required a simpler language. In tune with Winstone et al. (2017, p. 2030), a barrier to the effective use of feedback can be linked to "*decoding the feedback and the academic jargon*". For students whose behaviour is in this category, who are low-achievers, more orienting feedback could be useful, based on binding guiding questions that enable them to reconstruct the process and transfer the hint to an actual strategy.

Recognising difficulties but refusing to use feedback

About 11% of students chose to not use feedback, even if they often required additional help from the teacher when they faced the tasks. Our analysis of the factors preventing the students' use of hints reveals that this resistance could be linked to the fact that feedback is expected as not helpful, and students do not want to invest cognitive resources. This behaviour was displayed, among the others, by some students with a high self-efficacy sense. This behaviour is in tune with Winstone et al. (2017, p. 2038), i.e. "students' agency in using feedback can be impeded by a sense of helplessness, and by unrealistic expectations about how apparent and immediate the results of their efforts should be". As an example, E. did not use the hints, even if he asked for the teacher's advice to solve the tasks. When the teacher suggested he refer to the provided hints, he refused. In the survey, he declared "*I did not use any hints, I did not need them, I was not in difficulty"*. E.'s choice could also have been influenced by the "social cost" of seeking help, in fact as in Hattie and Timperley (2017, p. 96), "many students do not seek help because of perceived threats to self-esteem or social embarrassment". In this respect, we noticed that E. was sitting next to a competent classmate who did not need to use scaffolding elements during the test. Consequently, as in Winstone et al. (2017, p. 2037), "social influence or distraction associated with collecting feedback in public can prevent them engaging" and discourage students from using feedback even if it is needed.

Conclusive discussion

Taking responsibility for using feedback effectively is a fundamental skill that supports the development of self-regulation (Nicol & Macfarlane-Dick, 2006). In this paper, most of the participants understood that the scaffolding elements and the provided feedback are intended to help

them, but effective results can be gained only by acting upon the feedback. The analysis of the student's use of provided scaffolding allowed us to identify four categories of behaviours, corresponding to different levels of awareness and ways to convert information into action. These categories, especially the last three, are related to Winstone et al.'s (2017) classification of barriers preventing effective use of feedback. Students in the first category understood when it was necessary to recur to hints, converted the information obtained into an effective solving strategy, and acted upon the feedback. They showed awareness and mastery of the importance of feedback and its proper use. Students in the second category recognized their difficulty and consequently chose to recur to hints. However, their use of feedback remained blocked at the immediate level and was oriented to overcome a contingent difficulty. They immediately transferred the feedback into action, without extending the information to other similar cases. In tune with Winstone et al. (2017), this behaviour is linked to poor knowledge of appropriate strategies. Students in the third category consulted the hints but were not able to properly use the information obtained and translate it into action. In tune with Winstone et al. (2017), this behaviour reveals a lack of understanding of the jargon used, and of awareness of the potential usefulness of feedback. Students whose behaviour is in the last category refused to use the hints even perceiving to be in difficulty. This behaviour can be linked to a sense of "learned helplessness", by an unrealistic expectation of how the results of feedback should be, or due to social pressure. Notwithstanding the small number of participants, the results suggest that the challenge is to enable the students to take advantage of the feedback. Therefore, a potential redesign of the tasks or the methodology could consist of making feedback more accessible and communicative for students, helping them to transform information into strategies and overcome the sense of learned helplessness and unrealistic expectations of immediate pay-offs (Winstone et al., 2017). Further research is needed to deepen how to design effective scaffolding elements and improve students' sensitivity to their key role in fostering learning.

Design principles for epistemological *dépaysement* in pre-service teachers focused on interdisciplinarity mathematics and physics

Lorenzo Pollani[1], Laura Branchetti[2] and Francesca Morselli[3]

[1]Sapienza University of Rome, Mathematics Department "G. Castelnuovo", Rome, Italy; lorenzo.pollani@uniroma1.it

[3]University of Genoa, DIMA Mathematics Department, Genoa, Italy

In this theoretical paper, we develop a conceptual framework for promoting epistemological dépaysement in pre-service teacher education activities focused on interdisciplinarity between mathematics and physics. This framework is then operationalized by providing design principles for tasks. Finally, we present a specific example of a task involving textbook analysis to show how this approach might work in practice.

Keywords: Interdisciplinary approach, preservice teacher education, teacher expertise, textbooks.

Focus and rationale of the paper

This theoretical paper concerns the design of tasks for mathematics teacher education in the perspective of interdisciplinarity between mathematics and physics.

This study contributes to the body of research on the use of tasks in mathematics teacher education. Such tasks may vary widely in terms of learning goals and content. For instance, Zaslavsky (2007) discusses different uses of mathematical tasks in mathematics teacher education, where teachers may: perform the mathematical activity; analyze, compare, or create tasks for students; and analyze students' solutions to mathematical tasks. Other types of tasks promote teachers' reflections on the teaching practice and their interaction with peers and tasks, to highlight connections within mathematics, between mathematics and everyday experience, or between their own experiences as learners and teachers. Cusi and Morselli (2022), for instance, provide examples of narrative tasks where pre-service teachers, after being provided with theoretical tools concerning teaching-learning processes and the roles played by the teacher during classroom discussions, design tasks for students and create fictional classroom discussions focused on the same tasks, by referring to the theoretical tools. The comparison among peers and the discussions led by the teacher educator aims at promoting a change of perspective, from university students to future teachers, and at fostering the appreciation of theoretical lenses not just as a support for creating discussions but also as relevant guidelines for their future practice as teachers.

In our case, the learning goal is to develop expertise in an interdisciplinary perspective (Akkerman & Bakker, 2011; Erduran & Dagher, 2014). Numerous studies on interdisciplinarity emphasize the importance of becoming aware of perspectives from other disciplines (e.g., see the literature reviewed in Satanassi et al., 2023), which requires the ability to critically reflect on and discuss one's own perspective without treating it as absolute. Accordingly, we look for tasks that promote such a reflection, as we consider it part of the expertise. We draw the idea of *epistemological dépaysement*

from research on the use of history of mathematics and we study whether it is possible to exploit *dépaysement* in the not yet explored field of interdisciplinarity. Originally, the concept refers to a "cultural shock" (Jahnke et al., 2002, p. 293) that prompts critical reflection on one's epistemological assumptions about mathematics, which often remain implicit. Making these assumptions explicit leads to heightened awareness, which is crucial for effective mathematics teaching, especially in pre-service teacher education. We argue that tasks that promote epistemological *dépaysement* can create valuable learning opportunities for teachers and in turn develop their expertise, especially in the perspective of interdisciplinarity. Therefore, designing such tasks becomes a pressing priority. Our research question is: What design principles can be identified for teacher education tasks that promote epistemological *dépaysement* concerning interdisciplinarity between mathematics and physics?

We address the research question by grounding in studies on interdisciplinarity, teacher education as developing expertise, and the use of the history of mathematics in teacher education. In the subsequent paragraphs, we sketch a conceptual framework that frames *dépaysement* in interdisciplinarity and propose design principles for teacher education tasks aimed at promoting such *dépaysement*. We then propose a task that exploits textbook analysis as an instantiation of these principles. Textbooks are often recognized as instruments of change for practice (Rezat et al., 2021). In our case, we explore their potential are carriers of *dépaysement*, when inserted in carefully designed tasks.

Interdisciplinarity between mathematics and physics

Interdisciplinarity between mathematics and physics is a very broad and complex concept that was addressed by research with several different approaches. In this paper, we consider a framework for interdisciplinarity developed within the European Erasmus+ project IDENTITIES (n. 2019-1IT02-KA203-063184) that encompasses the Family Resemblance Approach (FRA; Erduran & Dagher, 2014), and the constructs of boundary, boundary objects and boundary people (Akkerman & Bakker, 2011). Specifically, "a *boundary* can be seen as a sociocultural difference leading to discontinuity in action or interaction" (p. 133). The two sides of a boundary can be linked through artifacts known as *boundary objects*. Additionally, *boundary people* are individuals who identify as members of a community and are recognized as such but whose knowledge, practices, and interests possibly extend beyond that community. These individuals can cross outside the boundary and introduce new languages and challenges. Inspired by Akkerman and Bakker, Pollani et al. (2024) describe *discipline-based communities* as communities characterized by expertise in a discipline (e.g., scientists or mathematics teacher educators). Coherently, they describe the *boundary between disciplines* as an encounter where members of a discipline-based community interact with (boundary) objects (e.g., physics textbooks for mathematics pre-service teachers, as in Pollani & Branchetti, 2022). The paradoxical nature of boundary that simultaneously belongs to both sides and neither carries not only ambiguities and risks but also opportunities. Pollani and Branchetti (2022) reflect on the learning potential of boundaries for increasing awareness by introducing the construct of disciplinary or interdisciplinary learning potential.

To reflect on the single disciplines not by separating what belongs to one discipline and what does not, Satanassi et al. (2023) propose adopting the FRA (Erduran & Dagher, 2014). In the FRA, the *epistemic core of a discipline* consists of *aims and values* (such as abstraction, objectivity,

consistency, etc.), *practices* (e.g., collecting data, making experiments, proving, etc.), *methods and methodological rules* (like inductive/deductive reasoning), and *knowledge* (like the laws of dynamics, the theorem of mean value, etc.). One common assumption is that interdisciplinarity is not merely the additive juxtaposition of disciplines. When disciplinary knowledge is analyzed critically considering all these dimensions, often it is possible to find differences in the way the same problem is addressed by different members of the same community. This heterogeneity might concern any component of the epistemic core of the disciplines and is at the basis of the scientific debates. To turn this richness into a productive complexity in education, it is necessary to expose learners to different voices and ask them to position themselves critically in such debates. Levrini et al. (2015) introduce two design principles for teaching aimed at fostering appropriation of thermodynamics and promote critical thinking at the epistemological level: *multi-perspectiveness* asserts that the same physics content should be analyzed from two different perspectives (the macroscopic and microscopic approaches to thermodynamics), each one characterized by a specific approach to the content. *Multidimensionality* asserts that the two approaches should be analyzed and compared according to different dimensions involved in physics (i.e., for their conceptual, experimental, and formal implications) but also for their philosophical-epistemological peculiarities. These principles were exploited also in the teaching of other physical topics and to trigger boundary crossing mechanisms in interdisciplinary activities involving mathematics and physics pre-service teachers (Satanassi et al., 2023).

Teacher education as developing teacher expertise

Teacher education refers to the process of fostering the transition from novice to expert, as described by Mason (2002), who states that "The mark of an expert is that they are sensitised to notice things which novices overlook" (p. 1). According to Mason, "noticing is triggered by a disturbance. […] It involves making a distinction between foreground and background, stressing some features and consequently ignoring others" (p. 148). Disturbances can manifest in various forms, such as "a surprise remark in a lesson, a particularly poor showing on a test, something said by a colleague, something asserted in a journal or book, or a moment of insight. Whatever it is, something startles me out of my current habits" (p. 10). Mason emphasizes the importance of disturbance in fostering teacher noticing, which, in turn, develops teacher expertise. He also suggests various ways to provoke disturbances, one example involves books. According to Viennot and Décamp (2018), a key characteristic of expert teachers is their engagement in intellectual dynamics in first person and their ability to critically discuss the knowledge at hand. They also highlight the value of examining this characteristic when working with textual resources designed to explain concepts, such as textbooks. Furthermore, Viennot (2001) introduces the notion of *critical detail* to describe aspects that have the potential to trigger, and deserve, critical discussion. From Viennot and Décamp's (2018) perspective, recognizing and thoroughly analyzing such critical details in textual resources can support the development of teacher expertise. In our opinion, teachers can be disturbed by various aspects they consider critical. However, we argue that an interesting kind of disturbance for developing an expertise in an interdisciplinary perspective would involve epistemological issues. Indeed, interdisciplinary teaching requires teachers, that in principle have a strong preparation on one discipline, to be prepared also to address epistemological issues emerging within the disciplines and at the boundary between different disciplinary epistemologies.

Epistemological *dépaysement* through historical sources

The concept of epistemological "*dépaysement*" emerges in research on the integration of the history of mathematics in mathematics education and in mathematics teacher education (Jahnke et al., 2002). It is a widely accepted hypothesis that reading historical texts allows for a critical examination of epistemological certainties and challenges the image of mathematics as a fixed, universal, and eternal discipline (Barbin, 1997). History is "dépaysante" because it provokes "étonnement" (Barbin, 1997, p. 21). This happens "through making the familiar unfamiliar" (Jahnke et al., 2002, p. 292). The need to engage with history is fulfilled by reading historical texts in a suitable, non-teleological way. These texts, through the intervention of a distance or difference, either cultural or geographical, between the readers and authors – both temporal and spatial – create a "cultural shock" (Jahnke et al., 2002, p. 293). This shock has the effect of altering the image of mathematics and reshaping the relationship that students and teachers may have with mathematical knowledge (Barbin, 1997). The epistemological *dépaysement* can then be interpreted as a kind of disturbance in the sense of Mason since it results in startling out of one own's current habits. In addition, it is intrinsically epistemological. Although this concept has been extensively discussed, it has not yet been clearly operationalized. Moreover, its application in interdisciplinary research and its actual role in the teacher education remain unexplored.

Conceptual framework for epistemological *dépaysement*

We propose conceptualizing the term *dépaysement* in teacher education as a complex process that involves multiple phases and agents. The primary agent in this process is the teacher experiencing it, in our case, the pre-service teacher. Based on the literature on teacher education and on epistemological *dépaysement* in history of mathematics, this process can be understood as experiencing a disturbance (Mason, 2002) or as being metaphorically placed in a foreign and unfamiliar country (Jahnke et al., 2002). From an etymological point of view, the French term "dépaysement" is formed by three components: a prefix, a root and a suffix. The prefix "de-" gives the meaning of removal, departure or separation. The root "pays" means "country", and the suffix "-ment" to form the substantive. To further clarify and unpack this concept, we provide a metaphor that helps illustrate the dynamics more clearly. In the context of electricity, imagine two plates with a potential difference generating an electric field. Not all objects within this field experience an electric force – electrically neutral objects, for instance, will not. In this situation, we can identify a *prompt for dépaysement* which is the electric field. Its potentiality for making experience *dépaysement* from one own's country can be discussed a priori. Using Mason's words, the country represents the "background" to which the disturbance is created. In this metaphorical sense, "country" can also represent one's beliefs, assumptions, habits, or previous experiences, even those of which one may be unaware. However, this is just a potential, and the actual experience depends on the background hold by the pre-service teachers. On the other hand, there could be observable behaviours due to the prompts, such as feelings of discomfort, wonder, confusion, withdrawal, questioning, vertigo, or a sense of the abyss. This distinction serves the purpose of refining our research aim in this paper, which concerns the *prompts for dépaysement*, since we are interested in the features of tasks to promote *dépaysement*, that is to make one leave his country.

The FRA helps clarifying the concept of *epistemological* prompt for *dépaysement* in this context. Specifically, a prompt for *dépaysement* is *epistemological* in nature within interdisciplinarity between mathematics and physics when the force driving one away from their own country is related to epistemological aspects. These aspects can pertain to the aims and values, methods, practices, or knowledge of a discipline. For instance, the way a proof is presented (or not presented), which may reflect the methods and practices of mathematics, can serve as a prompt for *dépaysement*.

Design principles for tasks that promote epistemological *dépaysement*

We draw the following design principles for tasks that promote epistemological *dépaysement*, which acts as instruction to generate the electric field but without guaranteeing any change, even unstable: P1. Set up a task where multiple epistemologically different voices are presented. These voices can come from various resources, as well as from discussions with individuals who have different educational backgrounds (Levrini et al., 2015). This aligns with Mason (2002)'s notion of creating a background and a foreground. In this case, they are between one own's familiar country and the incoming voices. The space between these two creates a distance or boundary, which may prompt *dépaysement* and carry a learning potential. The differences between these voices should reflect epistemological differences that prompt epistemological *dépaysement*, the feeling of unfamiliarity (Jahnke et al., 2002). This idea draws from Akkerman and Bakker's work, as well as the FRA framework. P2. Formulate the task requirement to foster reflection, encouraging pre-service teachers to write or discuss about how they interpret the content they are working on, and eventually articulate and explain their ways of thinking. This principle is grounded on the work of Viennot and Décamp (2018), which emphasizes the importance of critically discussing the knowledge at stake. This principle is linked with the previous one, as it is expected that the tension between the background and foreground each pre-service teacher experiences may foster reflection. P3. Encourage discussion, interactions and reactions to what other pre-service teachers but also teacher educators say. This principle derives from conceptualizing interactions as crucial for creating the boundary between disciplines, but also for reinforcing the disturbance. This is in line with Mason's recommendation that the disturbance is triggered by "something said by a colleague" (Mason, 2002, p. 10). Discussion, interactions and reactions are also in line with the idea of critically discussing the knowledge (Viennot & Décamp, 2018) rather accepting quick and easy answers as absolute.

Applying design principles: description of an example of task

In this section, we present a task for pre-service mathematics teacher education, which represents an instantiation of the previously established design principles (P1-P3) for including prompts for pre-service teachers epistemological *dépaysement* within interdisciplinarity. As previously outlined, the task exploits textbooks as resources. The resources are two excerpts from secondary school physics textbooks, both addressing the motion of projectiles (Ruffo, 2014, pp. 96–97; Walker, 2010, pp. 79–80; translated excerpts here https://shorturl.at/NnBE0). Pre-service teachers are asked to reflect first individually, then in small groups, and finally in a whole-class discussion, which includes teacher educators. The written assignment is as follows: "Read the two excerpts provided and then try to answer the following questions: 1. Is there any aspect that stands out for you? Why? 2. Which one of

the texts would you use in your class? Why? 3. Which one of the texts do you feel most comfortable with? Why?".

In alignment with the design principle of including reflective tasks (P2), three questions are encompassed. The first one prompts pre-service teachers to critically reflect on aspects that "stand out" to them. The use of this phrasal verb recalls the idea of a dynamics between background and foreground, as described by Mason (2002). This is an application of P1. Questions 2 and 3 encourage reflections related to a sense of familiarity, to the background. It is important to note that our goal is not to infer pre-service teachers' beliefs, although we acknowledge that these are part of the background from which we promote *dépaysement* and increased awareness. The additional request to explain their answers is intended to make pre-service teachers more aware of their own perspectives. We expect that this heightening in awareness will also be fostered through the collective discussions, both in small group and then as a whole class, aligning with P3.

Also, the choice of the topic is in line with P1. The motion of projectiles, indeed, was chosen due to its relevance in the co-evolution of mathematics and physics (see for example, Bagaglini et al., 2021; Branchetti et al., 2023). According to Bagaglini et al. (2021), physics textbooks bring an epistemological perspective on mathematics and physics, which often remains implicit. In our case, the two textbooks bring two epistemological perspectives (for more details, see Bagaglini et al., 2021), as already explored in previous works (see Bagaglini et al., 2021; Branchetti et al., 2023; Pollani et al., 2024). Bagaglini et al. (2021) compare Walker (2010) to other textbooks and underline that it is epistemologically richer because it more closely aligns with the historically development of the two disciplines. Once selected the excerpt from Walker, we sought another resource that offers a voice epistemologically distinct from Walker's. In line with P1, Ruffo (2014) was selected because it contrasts with Walker from an epistemological point of view. This contrast exposes pre-service teachers to multiple ways of presenting the same scientific concept. Both Branchetti et al. (2023) and Pollani et al. (2024) explore epistemological differences that may emerge as critical details and as prompts for *dépaysement*. The explored details are related to the use of examples and of representations. The contrasting use of these elements in the two excerpts is a prompt to creating an environment where pre-service teachers can experience epistemological *dépaysement*. Hence, the two excerpts represent two voices, as advocated by P1.

The choice of proposing two excerpts from two textbooks is also functional to promote *dépaysement* in *any* pre-service teacher. Indeed, we must consider that each pre-service teacher has an own voice; it is possible that their voices align with Walker's, and this fact may not create the desired epistemological tension needed for *dépaysement*. If a pre-service teacher's voice perfectly aligns with the text's voice it becomes harder to experience *dépaysement*, as pre-service teachers' current habits (Mason, 2002) or what they consider familiar (Jahnke et al., 2002) are not challenged. The choice of proposing two excerpts, then, is also functional to maximize the possibility of creating such tension and thus promoting *dépaysement*.

Discussion and conclusions

This contribution concerns developing expertise in an interdisciplinary perspective between mathematics and physics as a learning goal for mathematics teacher education. We argued that this

expertise can be developed by promoting *dépaysement* in the perspective of interdisciplinarity. We proposed task design principles for the aim of promoting such *dépaysement* and identified the construct of the epistemological prompt for *dépaysement* to fulfill this aim. Such elements of the task may provide experiences of disturbance, that may enhance teacher noticing, which in turn develops teacher expertise by shifting from novice towards expert, as advocated by Mason (2002). However, we do not expect a single experience of *dépaysement*, such as the task described above, to transform pre-service teachers into experts by itself. Instead, we believe that teacher education aimed at promoting interdisciplinarity should provide multiple opportunities for pre-service teachers to experience *dépaysement*, enabling them to become aware of and critically examine their perspectives. Unfortunately, this process is far from linear or stable. We are interested in how to identify and describe events in which a *dépaysement* happens. Further research is needed to analyze the factors that either stabilize a new perspective or lead to a regression to previous ones. We are currently reflecting on what evidence can inform the design and the effective implementation.

In the TransEET project, experts from various fields collaborate to design STEAM curricular resources. This collaboration is built on the exchange of prototypes within communities whose members possess diverse expertise. This paper reflects on the collaborative design process by analyzing two game-based prototypes, Carrots and Radishes and Geometry Deconstruction, showcasing their evolution through feedback and revisions. The aim is to develop a methodological tool that tracks the impact of the collaborative prototyping process on the prototypes' evolution. Since the prototypes are digital games, their evolution will be demonstrated by analyzing different game layers through a game-based framework.

Keywords: Games, prototypes, community of interest, collaborative design processes.

Introduction

Collaborative work between various stakeholders and communities in the context of mathematics task design has garnered increasing attention (Margolinas, 2013; Olsher et al., 2023). However, less focus has been placed on studying collaboration within heterogeneous teams working to develop innovative educational curricular resources, particularly involving the use of existing and emerging technologies, to drive dynamic educational transformation that meets the needs of the 21st century. The increasing attention on interdisciplinarity and transdisciplinarity and the always more sophisticated digital competencies requested bring to the fore the need for professionals with different expertise and backgrounds, and so belonging to different communities of practice (Wenger et al., 2002), to work together. Such a process should also foster the creativity of the actors involved (Essonnier et al., 2024). Even though the common interest may be clear and well defined, e.g. the design and development of a digital prototype, challenges emerge, both concerning the interlacing of different practices and the necessity to communicate and understand each other when the specific terminology used may not be understandable to the co-workers.

One of the main objectives of the project of the European Research Executive Agency 'TransEET' (Transforming Education with Emerging Technologies), is to investigate this collaborative work and suggest a methodology to approach it. Indeed, in TransEET (https://transeet.eu/), individuals with diverse expertise and academic backgrounds—including mathematics education, computer science, and arts education—from universities in Greece, Italy, the Netherlands, Austria, and the UK have formed *Communities of Interest* (CoI) (Fischer, 2001; Kynigos & Daskolia, 2021). These CoIs collaboratively co-design digital prototypes that support the integration of STEAM disciplines

(Science, Technology, Engineering, Art and Mathematics). This paper reports on the collaborative development process of game-based prototypes with mathematical content, which were co-designed in a CoI around digital games in STEAM, as a case study. Several studies, such as Byun and Joung (2018), highlight the effectiveness of digital games in mathematics education by demonstrating their potential to foster students' interest, motivate goal-setting, and encourage persistence through goal-oriented activities. In addition, games also provide opportunities for students to make critical decisions in order to solve problems, which can lead to the emergence of problem-solving strategies and process skills such as imagination and creativity

The collaborative development process takes place within the aforementioned CoI, which is composed of mathematics educators, game designers, and technology experts. The process is shaped by key elements of the TransEET project, which are briefly described in the following sections. The first two sections present the working methodology within TransEET, focusing on prototype production. The subsequent section outlines the methodology used to analyze the prototypes' evolution. Then an exemplification of its application is applied to two game prototypes, whose different versions are documented by TransEET members. Drawing on the TransEET experience, the conclusions share methodological reflections on the design process of educational games.

The TransEET project and its Co.F.E. method

The TransEET researchers and practitioners belonging to different communities of practice are engaged in CoIs (Fischer, 2001), each one of them focused on a specific and shared thematic interest. Members of CoIs are engaged in a *Flow of Rapid Prototypes* (FRP), a continuous process of creation and exchange of prototypes inside a CoI. According to existing literature, typically developed outside Mathematics Education (e.g., Syafril et al., 2021), the term *prototype* refers to the digital artefact itself, while the term *prototyping* is used to refer to the process of its development. Within the CoIs such a process develops according to the well-established phases of prototyping which are: design and development of a prototype, feedback and evaluation of the prototype, and redesign. Getting feedback during the development process, before waiting to have the final product, typically allows the designers to save time and energy. In this case, the goal of the FRP is not to have perfect digital tools, but to stimulate the process of creation and the creativity of the members involved (Essonier et al., 2023). Therefore, the term *rapid* in the acronym FRP remarks that such prototypes should not be considered as finished tools, but as artifacts with enough technical readiness to be shared, discussed, and exchanged within a CoI. While engaging in such a productive and creative process, the members of a CoI interact with other members of the CoI and develop and acquire new skills external to their initial background. We may say that they evolve into *actors with hybrid Expertise*.
The three aspects described so far, namely CoIs, FRP, and actors with hybrid Expertise, constitute the pillars of the working methodology within the TransEET project: the so-called Co.F.E method. In the present study we focus on the FRP, in particular on the flow of evolution of two prototypes.

FRP within TransEET

The FRP within a CoI is expressed through the exchange of digital prototypes accompanied by a document called *Prototyping Design (PD) document*, which contains a description of the prototype

elaborated by the designers/developers, as well as its reviews produced by other members of the CoIs. If the format allows it, the digital prototypes are collected in a shared Google Drive folder, otherwise exemplary videos or codes are shared within the community. In both cases, the prototypes are presented and discussed by their designers during the CoI meetings and project meetings. Then they are tried out and reviewed by 1-10 TransEET members who volunteer to engage in such a reviewing process. This leads to the production of 2 to 4 reviews of the prototype. Reviewers can have access to the prototype's code in certain cases (in this case the prototype is called *authorable,* meaning that anyone can modify it and generate a new version) while other prototypes require more technical knowledge to work on the code (hence the prototype are only *partially authorable*). Most prototypes within the CoI are open source to foster accessibility and collaboration. The reviews are strongly influenced by the reviewers' expertise hence different reviewers can focus on different aspects of the prototype. Examples of expertise within the CoI are mathematics, education, game design, game based learning and software engineering. The reviews are strongly influenced by the reviewers' expertise hence different reviewers can focus on different aspects of the prototype. Reviews are written into the PD document, based on which the designers can prepare a new version of the prototype, which triggers a new review within a new PD document and eventually a new version of the prototype. Each PD document refers to a single version of the prototype. The collection of different PD documents referring to different versions of the same initial prototype allows us to follow its evolution from different points of view. More in detail, the PD document is structured in two main parts as follows: 1) the *presentation* of the prototype and 2) all its subsequent *reviews*.

The *presentation* of the prototype is divided into four subsections containing the identikit of the prototype, its detailed description, an example of an educational activity and some screenshots of the prototype. The *reviews* of the prototype contain strengths and weaknesses of the prototype, possible extensions or changes, an example of activity flow with the modified version of the prototype and possible integration of emerging technologies if not yet present. The names of the designers and reviewers are also recorded in the PD documents.

Method

The PD documents produced during the FRP process track the design changes and evolution of the prototypes. To investigate this evolution, we qualitatively analyzed the data contained in these PD documents using a deductive approach. This involved identifying aspects related to three main categories considered in the PD documents: educational, technological, and mathematical aspects. We then observed how the FRP process influenced the evolution of the prototypes. Since the prototypes discussed in this paper are digital games, we employed a framework from game design literature to analyze the evolution of game-related elements within the three categories mentioned above. The framework, known as MDA (Hunicke et al., 2004), consists of three elements. The mechanics (M) of a game refer to its fundamental components, such as rules, goals, and players' available actions. The dynamics (D) refer to the behaviors that emerge from applying these mechanics and player interactions during gameplay. The aesthetics (A) involve the player's subjective experience, including elements like emotion, enjoyment, sensation, fantasy, narrative, challenge, fellowship, discovery, expression, and submission. In our case, aesthetics will include also and in a primary way the player's mathematical experience, considered as a subjective experience. When a

game is played, the mechanics generate its dynamics, which in turn evoke a particular aesthetic. These three aspects should be considered together and do not follow a specific order.

In this paper, we apply the MDA framework to analyze the features of two prototypes and their evolution throughout the FRP process, as documented in the PD records. Our research interest lies at a methodological level, specifically in the use of PD documents as tools to support the collaborative design of mathematics digital game prototypes. The prototypes, described below, were selected for their contrasting characteristics, representing the variety of prototypes that emerged within the CoI. Their FRP processes are marked by an initial version, at least one review, and a second version. For both prototypes, we collected the digital files and corresponding PD documents for each version.

Two examples of evolution of game-based prototypes

Prototype 1: Carrots and Radishes

Carrots and Radishes (CR) is a game meant to stimulate the learning of multiplicative relations between quantities (specifically, those of carrots and radishes).

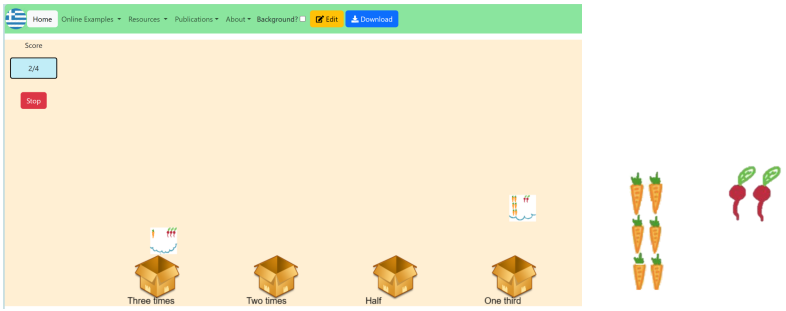

Figure 1: On the left: first version of CR prototype. On the right: an example of falling object

CR has been developed by means of *SorBET* (Sorting Based on Educational Technology)[1], a digital tool that enables the development of decision-making games in which players have to classify objects under time-critical conditions. These games help develop essential cognitive skills such as set operations, class encapsulation, and property discrimination, making them versatile tools across any learning context. The content of these games can be tailored to various domains, and they are supported by fully authorable tools that allow educators to modify existing game structures or create new ones from scratch. In CR, a game co-developed by the first and third author, figures representing a certain number of carrots and a certain number of radishes fall on the screen (an example is provided in Figure 1, right side) and must be moved to boxes labelled as: one third, half, twice, or three times, depending on how they are depicted in the various images (Figure 1, left side). The game is connected with mathematics representations, in particular, it requires conversions between different registers of representations, in the sense of Duval (2017), and specifically from graphical representations of quantities to verbal expressions of the relations between the same quantities. Boxes and pictures have been chosen in a way that the same relation between carrots and radishes can be described through a multiplicative relation or a ratio.

[1] http://etl.ppp.uoa.gr/sorbet/

The player's *aesthetic* experience is influenced by the challenge of moving the falling objects aligned with the boxes representing the object's category, so that it can fall inside. The *dynamics* of the game are fast-paced: players feel the time pressure in decision making because they lose a point if the object does not fall in the correct box. SorBET allows the user to modify the time of falling objects by acting on the setting hence the teacher (or player) can diminish the time pressure and therefore also the challenge. Moreover it is possible to modify the falling objects increasing or decreasing the mathematical challenge. The core game *mechanics* in CR is ordering the objects; other mechanics are: objects are falling from the sky, the player needs to drag the objects in the direction of one box; there is a limited amount of time to drag an object. The falling objects the student sees are randomly picked from a set of pictures uploaded by the designer. The labels of the boxes are chosen by the designer. Advanced players who recognize that the same object can belong to more than one category can randomly choose between the boxes. At the end of the entire game, the choices made during that play can be shown to players.

The following table reports some comments made by the CoI members within the prototyping PD document and the analysis using the MDA framework (text in italic). The comments are organised according to the three rows: mathematical, technological and educational aspects.

Table 1: Analysis of the FRP of Carrots and Radishes prototype

CR	Version 1	Review 1	Version 2
Mathematical aspects	The relations among quantities in the falling objects is expressed through deployed radishes and carrots. The labels of boxes express the multiple/ratio relation in words.	"The use of mathematical symbolism is missing (fractions, decimals and percentages)."	*Aesthetics: use of mathematical language and symbols to express the multiple and ratio/relation.* *Dynamic: some representations express the same relation adopting different registers*
Technological aspects	Move the figures to place them in the correct box.	"We could create different levels to strengthen the game approach. With AR or VR students could move images with their hands."	*The reviewer's comments did not provoke any change in the dynamic (levels of difficulty) and in the aesthetic (moving images using hands)*
Educational aspects	Ratio and multiple of quantities expressed as quantities of vegetables (carrots and radishes).	"We could change/add the boxes to display more relations."	*The reviewer's comments did not provoke any change in aesthetics of the prototype.*

Regarding the *mathematical aspect*, Review 1 suggested a change in the prototype that influences the game's *aesthetics*, as it affects the mathematical experience students can have while playing.

Specifically, the suggestion involves introducing mathematical language and symbols into the prototype. The revision of *technical aspects* impacts the *dynamic* of the game, recommending the addition of different levels of difficulty and the *aesthetic* aspect, as the mathematical experience changes when students move objects with their hands instead of dragging them with a mouse. Finally, the revision of the *educational aspects* is meant to the game's *dynamics* by encouraging players to think about multiple relationships at the same time.

Prototype 2: Geometry Deconstruction

Geometry Deconstruction (GD) is an educational Augmented Reality (AR) game prototype designed to facilitate the learning of surface area and volume formulas at primary education and lower secondary education. In GD, players interact with a variety of three-dimensional objects such as cubes, cuboids, cylinders, spheres, cones and various types of prisms and pyramids. Utilising AR technology, players must select the faces of these objects and assign the appropriate mathematical formulas to calculate their surface areas. This interactive approach aids in reinforcing geometric concepts by connecting visual and spatial recognition with mathematical reasoning, providing immediate feedback to enhance learning outcomes. The game is co-developed by Patrick Tibboel and researchers from the Smart Education Lab at the AUAS (Tibboel, 2024).

In the GD the *aesthetic* experience is centered around exploring and trying out. The player has to move around the object to be able to select surfaces, which gives more physical interaction. This is possible because the AR object stays stationary in place, which allows the player to walk around it. The *dynamics* of the game are slow-paced; there is no time pressure in the game. The players can take as much time as they need to explore the geometrical figures and think about the connection between their shape and the analytical formula. The various geometrical figures have been grouped into four difficulty levels. The player can select which difficulty they want to start with and play from there. The core game *mechanics* in GD are exploring geometrical figures by moving around an object and deconstructing it, by associating the right formula for calculating the area of a particular surface area of the object. The object the student sees is randomly picked from a set. The student selects a surface of the geometrical object, and chooses a formula for the selected surface area. Advanced players who recognize that multiple sides are identical are able to select multiple surfaces at once instead of just one. After a confirmation step, the system checks whether the answer was correct. If it was correct, the selected surface is highlighted briefly and removed from the figure. If not, feedback is given to indicate the answer was wrong, and the student has to try again.

Figure 2: Left is a wrong answer and right the correct answer

Table 2: Analysis of the FRP of Geometry Deconstruction

GD	Version 1	Review 1	Version 2
Mathematical aspects	Formulas for the area of surfaces are connected to 3D images of geometrical objects	"Maybe you can do something with volume, e.g., select the right formula for the volume to make the whole object disappear?" "You could add labels like L & H for variables such as length and height."	*Mechanics: Formula for volume added, as step after calculating areas.* *Aesthetic: Variable labels added to figure and explanations of labels added.* Selected formula remains visible on the surface.
Technological aspects	Randomize what object the students get. Geometrical surface disappears when the correct formula has been used.	Order of objects sometimes included repetition or too difficult objects to start with. Feedback after correct/incorrect answer was not always clear to players	*Dynamics: Geometrical objects grouped into four difficulty levels* *Aesthetics: Enhanced visual feedback; color adjusted for accessibility and preferences*
Educational aspects	Markerless-based AR used to prevent need for preparing markers, allowing more freedom; User placement of object	"Walking around to change perspective helps to distinguish the object." "I liked walking around the figure - different perspectives and 3D experience"	*Aesthetics: Audio feedback (e.g., applause) added after answer to complement visual feedback*

The revision concerned all three aspects of the MDA framework and specific suggestions were made to improve the mechanics, dynamics and aesthetics of the game. The second version of the prototype included a better didactical approach to learning geometry: the formula for volume is added, as step after calculating areas and grouping the objects by levels. Moreover aspects such as visual and audio feedback are expected to improve the overall learning experience.

Concluding remarks

This paper shares some methodological reflections on the collaborative design process of digital educational games drawing on the experience of the TransEEt project. In particular, we investigated the collaborative prototyping processes of two digital games with mathematical content undergoing the FRP. For this analytical purpose we used a table with rows that reflect the nature of the prototypes—technological, educational, and specifically focused on mathematics education. Through the PD documents, we tracked the modifications made to the prototypes. In the CR game, the changes primarily affected the dynamics and aesthetics of the game. In GD the changes impacted all three aspects. These cases demonstrate that the collaborative rapid prototyping process significantly influences the quality of the prototypes, particularly in terms of their potential for facilitating

mathematics learning. Rather than focusing on defining patterns of affected aspects, we believe it is more urgent to develop a methodological tool for collaborative prototyping. In this sense, the PD seems a promising and accessible methodological tool to support work within a CoI. So far, the PD and prototype reviews have only been shared within the TransEEt project. Making them public could help gather broader feedback on their potential.

Learning goals in view: Design of an intelligent environment for arranging and monitoring secondary mathematics education

Sylvia van Borkulo, Peter Boon and Johan Jeuring

Utrecht University, Faculty of Science, Freudenthal Institute, Utrecht, The Netherlands;
s.vanborkulo@uu.nl

Keywords: Secondary mathematics education, learning goals, intelligent environment, curriculum mapping, teacher autonomy, visual representation.

Introduction

In secondary mathematics education, the integration of self-developed materials and innovative resources, such as online instructional videos and digital practice environments, is becoming increasingly common (Engelbrecht & Borba, 2024; Inganah et al., 2023; Kennisrotonde, 2019; Purnomo et al., 2019). However, ensuring these materials align with curriculum goals introduces several challenges. Our project addresses these challenges by developing an AI-based environment that maps resources to learning goals, visualizes the interrelations between learning goals, and tracks student progress. The system enables flexible curriculum adaptation, offering tools for teachers to integrate diverse resources. Key innovations include graphical learning goal representations and AI-supported material mapping. Initial efforts focus on the topic of differentiation in upper-secondary mathematics, with principles applicable across subjects.

System Design Principles

The intelligent system will be developed by Numworx (https://www.numworx.nl/en), a company affiliated with Utrecht University. Numworx provides a digital math environment with online exercises and lessons for secondary and higher education. Their software supports mathematics education through comprehensive lesson materials and interactive assignments, visual development tools, and flexible classroom management.

Our system will be based on the following design principles:

1. Flexibility and customization: Teachers can integrate materials into existing curricula.
2. Alignment with learning goals: AI aids in linking materials to curriculum objectives.
3. Graphical representation of learning objectives: Graphical representations in the form of a graph show learning goal dependencies, facilitating informed decisions on curriculum adaptation.
4. Performance monitoring: Detailed student models guide targeted support.

Following these design principles, we aim to create an intelligent environment for arranging and monitoring secondary mathematics education. Teachers are empowered with actionable insights, and students benefit from a tailored learning experience.

Research Questions

1. How does the environment support linking teaching materials to learning objectives?
2. How do teachers and students utilize this environment?

3. How can student data enhance teaching materials quality?

Methods

A three-phase approach will guide the research: (1) Conceptual design of learning goals, (2) Development through intervention studies, and (3) Validation in classroom settings. Methods like Bayesian Knowledge Tracing (Yudelson et al., 2013) will create and update student models.

Outlook

The project seeks to empower teachers and foster personalized learning, offering a flexible framework for educational innovation.

Acknowledgment

The project is a collaboration between Numworx, Coornhert Gymnasium, and Utrecht University, and is (partly) financed by NOLAI (National Education Lab Artificial Intelligence), project number 2408.

Conceptualisation of number in curricular resources: Does it matter?

Jana Višňovská[1,2] and José Luis Cortina[3]

[1]The University of Queensland, Australia; j.visnovska@uq.edu.au

[2]P. J. Šafárik University, Slovakia

[3]Universidad Pedagógica Nacional, Mexico

We analyse one national curriculum framework by searching for presence and role of continuous quantities in how the notion of number is developed. We justify this focus drawing on number conceptualisations that allow students to encounter fractions and whole numbers as the same kind of number. We demonstrate that, in the analysed curriculum, attention to continuous quantities is highly restricted. We explain that this curricular stance has a historical connotation and argue that its perpetuation prevents the curriculum from providing a more adequate support for teaching and learning number. This curricular stance more broadly counteracts research and improvement efforts, which typically share a different view of what mathematics is and what it needs to be in school.

Keywords: Curriculum, number, length measurement, continuous quantity, design research.

Analysis context and motivation

In this paper, we invite readers to consider an analysis of a national curriculum framework, one currently used in Australia, as a case on which we highlight some of the 'forces' that shape the space of design, research, and use of teaching resources, including but not limited to textbooks and tasks.

Our motivation to analyse a national curriculum framework emerged as part of our ongoing endeavours to understand the demand that researcher-produced teaching resources present for teachers who would want to use these resources in their classrooms (cf. Cobb & Jackson, 2015). To contextualise our approach to the presented analysis, we briefly overview our work with the *Fraction as Measure* instructional sequence (Cortina et al., 2014), which we initially developed in classroom design studies (Cobb et al., 2003) conducted in under-resourced classrooms in Mexico. The sequence was subsequently trialled in classrooms in multiple countries, with consistent, cautiously optimistic results (e.g., Vale & Graven, 2018, discuss a trial in South Africa).

The sequencing of mathematical ideas in the designed resource proved key to its viability in classroom teaching. However, its misalignment with the content sequencing in local curricular framework made it unethical for us to trial the resource in Australian primary classrooms, where teachers are typically accountable for closely adhering to the sequencing outlined in the curriculum.

Later we became aware of additional differences, both less obvious and more impactful than the sequencing of the content alone: Our work in fractions and proportionality heavily built on students' reasoning with continuous quantities in the context of length measurement. However, students often did not have experiences in reasoning with continuous quantities in whole number contexts, which we were hoping to leverage. The notion of whole numbers as something that is produced multiplicatively via an iteration of a unit was foreign to many. We started noticing that tasks where whole number arithmetic scenarios would be situated in contexts that involved comparison,

measurement of, or reasoning with continuous quantities were rare in both Australian and Mexican textbooks. This oriented us to explore the institutional contexts, where we hoped our sequence could be used. The curriculum framework analysis presented here is part of those explorations.

We situate the overview of method of analysis in our design research work. The aim to teach fractions well in schools highlighted to us the importance of what is included in conceptualisations of number in curricula, which then guided our choices of analysis categories and directions.

Fraction as Measure sequence

The conceptualisation of number that guides our fraction design work aligns closely with the mutually consistent conceptualisations put forth by Davydov, Bass, and Freudenthal. According to Davydov (1990, p. 196), number is "a particular case of the representation of a *general relationship* of quantities, where one of them is taken as a measure and is computing the other". Bass (2018, p. 466), building on Davydov's work, clarifies that number "arises from *measuring* one quantity by another, taken to be the 'unit': How 'much' (or many) of the unit is needed to constitute the given quantity?"

In these statements, "quantities" exist in the physical, material world, and they are something that can be compared. As a result of such comparison, a quantity can be the same as, or bigger than, or smaller than that to which it is compared. By treating one quantity as a reference unit, number emerges as a tool that makes further organisation of comparisons among multiple quantities possible. While some quantities in the physical world are discrete and some are continuous, only measurement of continuous quantities produces whole numbers and fractions as numbers that are experientially alike. Bass highlighted the need for such alikeness stating that "the measure pathway [unlike the counting, discrete pathway] … makes available from the beginning the continuous number line as a coherent geometric environment in which all numbers of school mathematics eventually reside" (p. 467).

The view of fraction as a comparison (of two magnitudes) is central to Freudenthal's (1983) didactical phenomenology of number. From the two types of situations in which fraction comparisons arise, Freudenthal highlighted *fraction as comparer* situations—where two physically separate quantities are compared, with one of them serving as a reference unit—as being neglected and mathematically more robust than the current approaches based on *fraction as fracturer* (equipartition) situations.

In the designed sequence, fractions are introduced through *fraction as comparer* situations, following students' experiences with whole number measurement in context of continuous quantities. Fractions are introduced in response to a need for increased precision and sophistication in length measurement, the evolution of which is simulated in the classroom. For instance, unit fractions are defined in reference to the previously used measurement unit (*the stick*), when new units of a smaller size (sub-units) are needed (e.g., a rod corresponding to a sub-unit known as *a third* would be of such length that the stick measured with this rod measures three, see Figure 1).

Figure 1: Three iterations of *a third* (dark rod) are the same length as the stick (i.e., reference unit)

As a result, students come to reason with fractions as representing quantities (amounts, sizes), and in terms of actions on these quantities. Fraction reasoning emerges as being mathematically consistent with whole number reasoning, and fractions emerge as numbers (e.g., Bass, 2018).

We came to appreciate the importance of viewing number as arising from the measurement of continuous quantities for teaching and learning and felt that this was not a conceptualisation broadly available to teachers. This oriented our initial analysis towards documenting how AC:M includes number, measurement, unit, counting, and continuous and discrete quantity.

Analysed curriculum framework

We analysed Version 9 of the Australian Curriculum: Mathematics (AC:M), Foundation through Year 6 (Australian Curriculum, Assessment and Reporting Agency [ACARA], n.d.). This version came to use in 2024 as the first notable modification of the national curriculum introduced in 2012. Foundation year precedes Year 1. Students start Foundation when between 4.5 and 5.5 years old.

In each year, AC:M includes six content strands (number, algebra, measurement, space, statistics, probability). For each year level, the document provides two overview sections, *Year level description* and *Achievement standard*, each about 250 words. These are followed by *Content descriptions* and *Content elaborations* for each of the six content strands, at about 3500 words per year level.

Method

We conducted the analysis of AC:M to document *where* continuous quantities were included, and *what kinds* of reasoning with these quantities were described or implied. Doing this, we aimed to highlight how AC:M developed numbers beyond whole numbers. First, the two authors red through AC:M document, outlining the gradated coding categories to capture treatment of number in terms of continuous quantity: from absence of continuous quantity (Counting Number), through continuous quantity included implicitly, with or without focus on counting (Counting Number Plus, Potentially Continuous, respectively), to continuous quantity included overtly (Continuous), and included without references to number (Measurement Literacy, see Table 1).

Table 1. Coding scheme

Code	Description	Example
Counting Number	Overt references to order, counting, and discrete quantity	Naming discrete things to be counted or used in tasks (e.g., beads, people)
Counting Number Plus	Instances of focus on counting, which could (to some extent, or inadvertently) facilitate quantitative sense of discrete collections	Size of the arrangement with dots in subitising activities (the space the arrangement takes), ten frames, frequency graphs in statistics, calendars as a means to compare duration in days, months
Potentially Continuous	Potential to position numbers as accounting for quantitative	Claims/tools where interpretation of continuous quantity can be made, even though it is not

	differences around us (i.e., grounding in measurement of quantity)	suggested (e.g., number line, even if not used to represent accumulation of quantity)
Continuous	Overt references to continuous quantity in relation to number	Quantification of comparisons of relative size
Measurement Literacy	Measurement without link to conceptualisation of number	Named attributes to be measured, standardised units of measurement, "uniform units" (sic)

Second, as the *Year level description* and *Achievement standard* sections appeared to offer a more generous codes for quantity, these were independently coded by the authors, the resulting codes were compared, and the differences (fewer than 10% of the codes) reconciled. Third, the coded documents were used to create a narrative overview of each year level and finalise Table 1 Descriptions and Examples. Verifications and rebuttals of the developed claims were sought in the *Content* sections, including checking for elements that appeared to be missing from the year level overviews.

We report a narrative of the findings based on the claims that could be robustly supported with data. Where possible, we include illustrations. While we restrict our findings to number and measurement sections, we note that the character of the document was consistent across the remaining sections.

Finding 1: Different kinds of numbers

Overall, AC:M conceptualises number in the early years as a *counting number only*. For all practical purposes, number is equated to the cardinality of discrete collection of objects. The extent to which this was the case was striking to us. For example, between Foundation and Year 3, AC:M names 77 different countable things in *Content elaborations*. These include counters, dots, dice, but also pencils, tigers, bolts, or windows in a train carriage. In contrast, there are only three *elaborations* in the same range, where an overt reference to a continuous quantity is made in relation to number:

(1) use of "a lump of playdough" and "a cup of water" to indicate half (Year 2 Number),
(2) "estimat[e] the height of a tree by comparing it to the height of their friend and quot[e] the result as 'the tree is about 3 times as tall [as my friend]'" (Year 3 Measurement), and
(3) markings on measurement tools (a ruler, measuring jugs, scales) interpreted as "the beginning and end of each unit" with no meaning for "unit" given (Year 3 Measurement).

While words such as *quantity* and *comparison* occasionally appear, their meaning is not clarified. The interpretation most consistent with the rest of the analysis is that these words refer to discrete quantities, and to comparisons of numerical order or one-to-one mappings, that is, to additive comparisons. Foundation year contains words quantity, quantifying, comparison, sameness, difference. Some of these refer to qualitative comparisons that are important at this level (e.g., same and different colour) but as comparisons of length or size remain a possibility, they were coded as Potentially Continuous. From Year 1, students seem to be expected to know and use numbers, and the discourse shifts away from quantities to numbers: *numbers* are to be partitioned, compared (i.e., ordered), give rise to patterns, and are equated with their symbolic form: having increasingly more digits every year. Phrases "quantify collections" and "quantify sets of objects" in AC:M describe

subitizing, counting, and one-to-one correspondence (Foundation), and skip counting and partitioning (Year 1). This suggests that "enumerate" (assign a number) would be a more accurate word to use. After Year 1, "quantification" is no longer present.

From Year 4, word "numbers" refers to whole numbers only. For instance, statement "Students use their proficiency … to … multiply and divide numbers efficiently" (Year 4) does not refer to fractions or decimals, because multiplication and division with those had not yet been introduced. The most reasonable conclusion is that fractions and decimals are, indeed, not considered to be numbers. When this problem is later resolved, it is not by admission of fractions and decimals among numbers. Instead, it is done by an introduction of a new umbrella notion of *rational numbers*, which subsume whole numbers, fractions, and decimals by an unspecified mechanism: "[students] expand the repertoire of numbers they work with to include rational numbers and the use of (sic) integers" (Year 6). This unification is considered as a mere renaming, but it is indeed a unification of mathematical objects that—from students' perspective—do not share their origin, meaning, or operations.

Returning to fractions, AC:M does not offer a way in which to conceptualise fractions as numbers at the time of their introduction. When it first introduces fractions (Year 2) the overwhelming—if not the only—meaning of number is created through cardinality and counting. We know that fractions cannot be meaningfully defined as numbers through counting at this level of schooling (Bass, 2018).

Finding 2: Measurement only as measurement literacy

With the two exceptions noted above, whenever shape, space, and measurement sections of AC:M attend to continuous quantities, they pursue aims of establishing what we refer to as a basic *measurement literacy*. This focus includes familiarisation of students with the attribute to be compared or measured, and the introduction of informal and formal tools with which the attribute could be compared or measured (including assigning a number to it). The focus of these themes does not include mathematising of measurement, such as through exploring the construction of measurement tools (e.g., creating a measurement strip to speed up measuring, and coming to view it as a record of accumulation of length, Stephan et al., 2003).

Attempting to guide some explorations of measurement, AC:M makes references to "uniform informal units" (Year 1), "uniform units" (Year 2), progressing to introducing uniformly segmented "conventional instruments" with metric units (Year 4). These descriptions rely on solely additive imagery, and miss the multiplicative imagery that measurement affords. The specification that the units used are to be "uniform" suggests that to determine whether a desk fits through a door frame, the width of the desk and that of the door opening are to be covered with, say, toothpicks to determine whether the door opening is large enough. This, of course, is only meaningful if one uses toothpicks of the same length. However, unit of length in this situation is not 'the uniform toothpicks'. The unit is the length of *a toothpick*, and the measurement is the iterative process in which the number of times (N) that the toothpick length can be stacked up to match the relevant dimension of the desk is being determined. This gives rise to a potential that the resulting length will be viewed in relation to the length of the toothpick as being N-times as long, a multiplicative comparison of the two lengths. While the initial measurement comparison certainly can be enacted with multiple toothpicks of the same length, the mathematically important conceptualisation of notions of measurement unit and

measurement as the iteration of this unit are not currently included in AC:M. Similarly, the notion of unit fraction as a unit through which other lengths are established multiplicatively, is also omitted.

Finding 3: Nature of mathematics

The final observation relates to how views of what mathematics is shape opinions on *what mathematics should be learned* (Borba & Skovsmose, 1997; Clements et al., 2012; Sfard, 1998). Is mathematics a collection of important facts and calculations? Is it a collection of specific disciplinary practices? Is mathematics *natural*, out there to be discovered? Is it a human practice to be invented and re-invented based on a perceived need?

From Year 2 on, AC:M overtly positions mathematics as something that is outside of, and separate from, the (students') world. Mathematics, instead, is presented as something brought to students so that they could model the world with it: "mathematics can be used to investigate things they [students] are curious about, to solve practical problems and model everyday situations" (Year 2). Instead of positioning students' experiences as something from which they could, when adequately supported, make mathematics (i.e., mathematise phenomena to give rise to new ideas and ways of organising the world, Freudenthal, 1981), AC:M encourages teachers to guide students' recognition of the opposite relationship. Mathematics is to be seen as helping students understand their everyday experiences, which would, presumably, not be understandable to them without mathematics. It is never clarified in AC:M where this kind of essential mathematics comes from.

For example, base-10 place value system is presented as a numerical pattern to be learned for the purposes of increasing one's calculational fluency (e.g., "manipulate numbers," Year 3). It is not presented as a human invention that encapsulates increasing effectiveness in both measurement and calculation, in response to a need for such effectiveness (Bass, 2018). Similarly, *mathematics* is discussed as something to be represented: students are to "become aware of the importance of context and purpose … [in] how they choose to represent mathematics" (Year 4). This evokes an image that is very different from a classroom practice where *problem situations* are to be represented and organised, with increasing sophistication, thus giving rise to new insights about the situation as well as to new mathematical ideas that made such insights possible. The discourse employed in the content overviews indicates how mathematics is what is being given to students to be learned, represented, and applied. It is not something to be created or produced in the classroom, and the purposes for and the ways of its creation are not to be explored in classroom activities.

Discussion and elaboration of findings

To summarise, AC:M develops counting number which emerges from enumeration of discrete objects, meaning of number is not anchored in measurement of continuous quantities, and mathematics is learned so it can be applied to make sense of the world. To argue that this summary is of broader significance, two additional clarifications are needed: (1) Australia's curriculum is not unusual, and (2) the notions for which AC:M was analysed are not solely of importance in relation to authors' pet research-based resource on fractions. Our final aim in this paper is to address these points.

The choices that currently organise AC:M are at play in other national curricula (e.g., Mexico, analysis under development). These choices are consistent with the broad curricular framing changes

characteristic of New Math reform (Kilpatrick, 2012), a period when many mathematics curricula transitioned from being organised by classical mathematical theory to modern mathematical theory. Within classical approaches, mathematics was a description of reality. The objects that mathematics studied (e.g., numbers) found their source and their reference in reality (e.g., in the measurement of continuous magnitudes). The shift to modern mathematics (where set theory became a foundation of formal axiomatics) came about as "[m]athematicians began to reflect more profoundly *about their own constructions and activities*, rather than about the givens of the external world" (Otte, 2007, p. 247, italics ours). In modern mathematics, axioms only refer to reality through object attributes: They define *properties* of number sets (e.g., existence of an additive inverse, commutativity of multiplication) but the meaning of numbers is no longer a concern of mathematics as a discipline.

The change towards set theoretical abstraction benefited the discipline. But thanks to the intentional separation from reality, modern mathematics could only ground school mathematics in abstraction (Freudenthal, 1979). Given that numbers were now defined in relation to *sets* (i.e., collections of objects and operations that satisfy specific conditions), their source or reference was discrete. Whole number, now a cardinality of a set, became tightly linked to counting. Inheriting a set theory definition of rational numbers, fraction became a pair of whole numbers. The tools for reasoning with numbers that were previously essential—quantity, units, and measurement—were no longer central to the notion of number in mathematical theory and thus were no longer central in school. Measurement was separated from number; algebraic manipulations were brought in to organise operations and reasoning with numbers, replacing reasoning with quantity; abstract mathematics had to be taught to students first, then illustrated by examples, and then applied to reality (Chambris & Visnovska, 2022).

A common belief about the New Math reform is that it proved unsuccessful, and the changes were later reverted. Considering our findings, Kilpatrick's (2012, p. 569) note that "(i)n no country did school mathematics return to where it had been before the New Math movement began" reads as a call for a more thorough exploration of what exactly was changed. May some of the widespread 'learning difficulties' we face today be a consequence of those past changes? The omission of a conceptualisation capable of supporting students to understand fractions—an area where many face difficulties—seems, indeed, problematic. Where this omission was accepted, it had time to propagate through teaching resources, through what teachers teach, and through what researchers notice.

Flexible instructional trajectories for learners' self-regulation in 9th Grade Algebra

Annika Volt, Kairit Tammets and Mart Laanpere

Tallinn University, Tallinn, Estonia; annika.volt@tlu.ee

Personalised learning has become increasingly prominent in educational policies as it has shown some promises in research as one of the potential means to increase students' motivation to learn difficult subjects such as mathematics. Systemic and scalable approach to personalisation requires introducing more flexibility and non-linearity in designing our curricula, learning resources and instructions. This paper reflects on an empirical study carried out in Eduflex project that aimed to develop a concept of learner-centred learning through flexible instructional trajectory. The study was conducted in an authentic classroom situation with 156 9th grade students using a flexible instructional trajectory with a set of interactive learning resources targeting the 9th grade algebra learning outcomes in Estonian national mathematics curriculum.

Keywords: Flexible learning, flexible learning path, personalised learning, instructional trajectory, self-regulation.

Introduction

Both educational policies in Estonia (Education Strategy 2021-2035, 2020) and international research results (e.g. Shemshack & Spector, 2020) support effectiveness of learner-centred approaches to teaching and learning, where the digital technologies have a potential to play an important role. While research demonstrates that the use of technology in learning can increase student motivation (Rovai et al., 2007), there are also examples to the contrary (Tang & Hsu, 2014) or studies showing that the use of technology does not directly benefit or harm learning process (Müller & Mildenberger, 2021). Therefore, the quality of the learning resources, interaction between students and teacher and the mode of feedback should be more important than the format of learning (Müller & Mildenberger, 2021). In order to provide large groups of students with effective, personalised and flexible learning instructions where student does not become "programmed" by predefined computer algorithms, the new approach is needed to designing the digital learning resources, scaffolding, and learning activities where control over learning remains on the side of humans - learners and teachers. To effectively design flexible instructional trajectories, it is essential to understand how different factors (including learners' characteristics, perceptions and the instructional design of learning activities) impact learning outcomes. Therefore, the following research question was formulated:

1) How do learners' perceptions of flexible learning activities vary in the context of flexible learning trajectories that incorporate digital learning resources in middle school algebra?

This paper presents findings from an intervention study where 9th-grade students engaged with a flexible instructional trajectory designed within an interactive digital learning environment. The study aimed to explore how the use of these resources supports achieving learning outcomes in algebra, focusing on learner diversity in perceptions and experiences.

Literature review and theoretical background

When referring to flexible ways of learning, three important attributes are mentioned: time, place and the mode of learning (Hammersley et al., 2013). These features require students to be able to orient themselves in their choices and to recognise the situations and factors that trigger their learning. In a technology-enriched learning environment (TEL), students need to organise and regulate their learning more autonomously, as there might be limited external guidance (Pelikan et al., 2021). The use of self-regulated learning strategies, such as planning, goal setting and self-monitoring, is therefore seen as critical for successful learning outcomes (Bol & Garner, 2011). Also, it requires from student the ability to cope with a moderate cognitive load, as self-regulation and cognitive load have interplay to each other (Seufert, 2018). To reduce the cognitive load for student, it is important to provide consistent structures, support, and affirmations that allow the student to know what to expect and how to free up space for more challenging tasks (Darling-Hammond et al., 2019).

Since the level of instruction in a TEL environment can be limited and unguided, learning often leads to suboptimal outcomes (Kirschner et al., 2006), it is important to design the learning process with a strong didactic rationale. For reducing the cognitive load, the opportunity is seen to provide the student with a sequence of tasks from easier to more complex (van Merriënboer et al., 2003). Task complexity can be controlled by task design: e.g. number of element interactivity, number of distinct acts and concepts used to perform a task, the number of distinct hints to be processed for performing acts, the relations among acts (Chen et al., 2023).

Research methodology

The following provides an overview of the context of the survey, key concepts, survey design, data collection and analysis.

The context and key concepts of the study

The research on flexible learning was part of the EduFlex project funded by the Estonian Ministry of Education and Research guided by the aim to develop the concept of flexible and personalised learning to provide a methodology and tools for analysing and supporting flexible teaching practices.

In our research, we have decided to split the generic term of flexible learning paths in two distinct parts: (1) instructional trajectory that belongs to the realm of instructional design and (2) learning path that belongs to the field of learning analytics. An instructional trajectory is a forward-looking plan for teaching and learning designed by a teacher or instructional designer on the basis of a domain model and curriculum of the given subject. It contains expected learning outcomes and related instructional episodes that follow a predefined order of activities based on a domain model, providing a coherent progression, as well as tools and techniques for teaching, learning and assessment (Volt et al., 2025). Flexibility is designed into trajectories by adding non-mandatory tasks, possibilities for selection of type or complexity level and pace of learning tasks, guided metacognitive prompts for reflection, analysis, repetition and recalling, visualisation of basic learning analytics to support data-informed decision making. The learning path represents a digital footprint of the learner's interaction with digital learning resources: it documents in a machine-readable way the learner's actions, choices

and outcomes that can be used for learning analytics and visualised for teacher and learner to support their personalised control over the learning process (Volt et al., 2025).

Research design

This study follows the design-based research (DBR) approach, which is applicable to educational research and for designing TEL environments (Wang & Hannafin, 2005). Study was informed by a previously conducted pilot-study in 2023 to validate the initial model of instructional trajectory. Therefore, this study is a second cycle of DBR where, building on the research that preceded this intervention, we developed characteristics of a flexible learning environment that could better support students. In this phase of the study, we examined the flexible delivery mode of the created instructional trajectory in order to investigate the features of flexible learning and the perceived effect of these characteristics on students. To this purpose, instructional trajectories for the 9th grade algebra learning outcomes and an instructional delivery mode were developed. Learning resources and instructional trajectories were designed to cover two learning outcomes from national curriculum:

1) learner cancels and expands an algebraic fraction; adds, subtracts, multiplies and divides algebraic fractions, including adding and subtracting both like and unlike fractions;
2) learner simplifies rational expressions which includes maximum two operations.

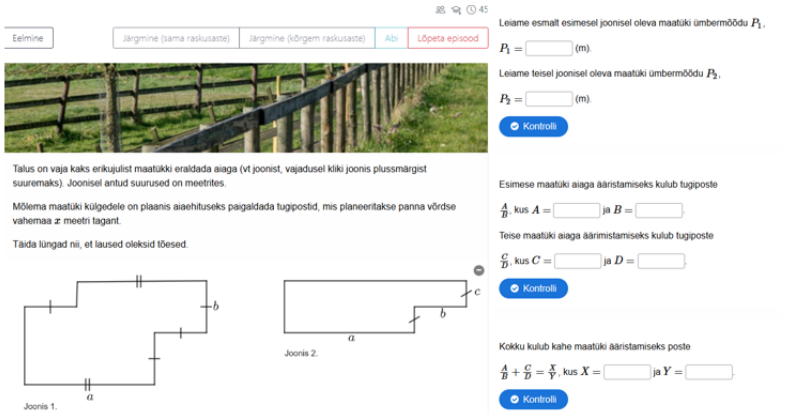

Figure 1: An example of a student's view on an instructional trajectory: task display with options to view supporting material, hints, and navigate to a more complex or less complex task

The creation of instructional trajectory is based on a domain model in a form of a Bayesian network derived from didactic principles and developmental psychology, which describes in a machine-readable way the anticipated cognitive development trajectory of the learner, presenting the units of knowledge (the units of conceptual and procedural knowledge), along with their interconnections (prerequisite, kind-of and part-of relationships). To design our pedagogical approach, we relied on the principals of the 4C/ID (Four-Component Instructional Design Model) framework (van Merriënboer & Kirschner, 2007) and Merrill's (2002) key learning principles. The learning resources were presented to the student at increasing levels of complexity and in an intuitive easy-to-use interface, where the student had the freedom to decide whether to increase or decrease the complexity of the tasks or to remain at the same level of complexity (in Figure 1). Some of the tasks in the trajectory were compulsory for the student, while some were optional and their completion depended

solely on the student's free initiative. The learning resources include multiple-choice, fill-in-the-blanks, branching scenario and interactive video content types in the design of tasks and supporting materials.

Intervention, data collection and analysis

Convenience sample of teachers, who were already active users of digital learning resources, was used to conduct the study. Five teachers from four schools participated in the study, involving a total of 156 9th-grade students. Data from 129 students were included in the analysis, comprising 56 boys, 64 girls, and 6 students who chose not to specify their gender.

The students participated in the study under pseudonyms: teachers assigned the students' usernames at their discretion, and the researchers were able to associate the username with the student's gender and the data collected on the student's track record from the learning path. Intervention was designed as part of students' normal classroom situation in math. For all the students, the topic learnt was novel, and the teachers taught the topic according to their own schedules, i.e. some teachers started at the beginning of December 2023 and some teachers started at the end of January 2024. The duration of the study ranged from one month to one and a half months, depending on the teacher. In addition (to completing the digital learning trajectory with students), the teachers conducted in between also practice lessons of their own choice and frequency to consolidate what they had learnt when using the instructional trajectory. Depending on the teacher, the practice lessons were either collaborative or individual task-solving lessons.

The environment students used was a closed H5P-Drupal based learning environment, where students logged in with their username to interact with digital learning resources, as well as to compare interactions with the data obtained from the questionnaire responses. To understand students' learning experiences, a survey was distributed in the end of the intervention. In designing the survey, we used existing and validated instruments, and also designed new items to answer our research question. Survey integrated following blocks: perceived efficiency (Tammets et al, 2021); shared classroom control (Eshel & Kohavi, 2003); cognitive load and technology acceptance (Hwang et al., 2013). Additionally, questions were created to understand how students perceived their own role in flexible learning scenarios (for instance the student was asked to evaluate a claim: *Even when the topic was boring or difficult, I made an effort to complete the tasks*).

Students answered the questionnaire after the intervention ended and evaluated items using a 1-5 Likert scale. A follow-up questionnaire was completed by 146 students, including 129 students whose responses to the follow-up questionnaire could be matched with the data from the learning path and who had given their consent for their data to be used in the study. The data were analysed using confirmatory factor analysis and cluster analysis to examine which groups of students emerged based on the identified factors.

Results

In the following, we examine the results of which factors influenced students' perceived experience of flexible learning and which groups of students emerged from the given experience. To perform the analysis, we used Jamovi v. 2.6 to conduct a confirmatory factor analysis (CFA) with the aim of

exploring the factors that are important determinants when using a flexible instructional trajectory and conducted a K-means cluster analysis to explore emerging student profiles.

Factors affecting students' learning experiences in flexible learning scenario

According to CFA findings, we focused on four main factors: perceived efficiency, shared control, cognitive load and the importance of one's role. The empirical data showed a good fit with this 4-factor model: CMIN=221, CMIN/df=1.534, CFI=.945, TLI=.935, SRMR=.0687, RMSEA=.0645.

Table 1: Confirmatory factor analysis

Factor	Indicator and standard deviation of factor loading			
Perceived efficiency	TAJT_1	0.884	TAJT_2	0.865
	TAJT_3	0.767	TAJT_4	0.764
	TAJT_6	0.713		
Shared control	JAG_KT_4	0.559	JAG_KT_5	0.556
	JAG_KT_6	0.597	JAG_KT_7	0.601
	JAG_KT_8	0.647		
Cognitive load	KOG_KOORM_1	0.791	KOG_KOORM_2	0.837
	KOG_KOORM_3	0.896	KOG_KOORM_4	0.767
	KOG_KOORM_6	0.685	KOG_KOORM_7	0.867
	KOG_KOORM_8	0.784		
Importance of learner's own role	ISE_3	0.698	ISE_4	0.761

While this represents a preliminary analysis, demanding further investigation, the identified factors highlight key influences on learning in flexible, TEL environments. These factors include cognitive load, which reflects the mental effort required to navigate and engage with the learning environment; the perceived importance of students taking ownership of their learning, emphasizing their active role in the process; the shared control between teachers and students in the classroom, illustrating the collaborative dynamics essential for flexible learning; and students' perceptions of how the flexible learning environment supports their individual learning and skill development. Together, these elements underscore the complexity of designing effective flexible learning environments and the need for a balanced approach that considers both student autonomy and teacher guidance.

Students' profiles in flexible learning scenarios

Next, we sought to understand whether there are differences between students' experiences, as it can be assumed that not all students are exposed to flexible learning in the same way. Therefore, a K-means cluster analysis was carried out to investigate which clusters of students emerge when four

factors influencing the learning are considered: perceived efficiency, shared control, cognitive load and the importance of one's role in the flexible learning process.

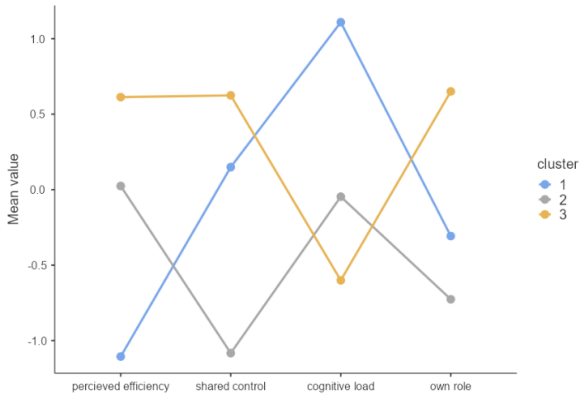

Figure 2: Plot of means across the clusters derived from aggregation of items in factors

Figure 2 shows that three clusters emerged: Independent learners (N=58, cluster 3), Habitual learners (N=38, cluster 2) and Struggling learners (N=33, cluster 1).

Independent learners had the most to gain from flexible learning. They were autonomous and perceived their learning as effective: students felt the freedom to decide their own pace, perceived the teacher as a support rather than a controlling factor and perceived setting for learning to be effective. Compared to other groups of students, independent learners had the lowest cognitive load, and students in this group perceived the importance of their own role as the most important among peers.

Habitual learners perceived the learning experience to be somewhat less effective, but still effective, compared to independent learners. At the same time, however, students in this group did not perceive the importance of their own role in the learning process and saw the teacher as more responsible for guiding learning than themselves, their peers or the technology. Habitual students perceived their role in directing their own learning to be low, felt a lack of control over the pace of their own learning and teacher was not perceived as a valuable resource of help. Although the cognitive load of this group is moderate and closer to the perceived cognitive load of the first group than that of the third group, these students do not see opportunities to implement self-regulatory strategies. Rather, these students seem to be used to the traditional rhythm of the classroom, where they have fewer opportunities to decide for themselves.

Learners in difficulty perceived compared to other groups of students' cognitive load as the highest and also perceived learning opportunities as inefficient. Although these students' perception of shared control is closer to that of the first group, learners in difficulty do not perceive the importance of their role as high and perceive the importance of their role rather close to the students in the habitual learners group.

Conclusion

The aim of this study was to investigate how students perceive and engage with a flexible learning environment designed for 9th grade algebra, particularly in terms of the perceived efficiency, shared control, perceived cognitive load and importance of their own role in the learning process. The

findings reveal that students' perceptions of the flexible learning environment varied significantly across the identified groups, with distinct differences in perceived efficiency, shared control, cognitive load, and recognition of their own role in learning. As self-regulated learning strategies are essential for effective learning (Bol & Garner, 2011) and student autonomy plays a crucial role in technology-enriched learning environments (Pelikan et al., 2021), the results suggest that students who value their role in learning and demonstrate autonomy are better equipped to thrive in flexible learning settings.

To enhance learning outcomes, it is crucial to reduce cognitive load by providing consistent structures, targeted support, and affirmations, thereby freeing cognitive resources for more complex tasks (Darling-Hammond et al., 2019). Since the flexible instructional trajectory was designed based on the mentioned design principles, some students still perceived the learning process as inefficient and struggled to recognize their role in learning. This raises important questions about how such students interact with and make choices in the learning environment. Similarly, the findings prompt investigation into why habitual learners did not perceive flexibility as an opportunity to make meaningful choices. Future research will focus on examining learning analytics data collected from students' interactions comparing the behaviours and choices of students in different clusters (e.g. independent vs struggling student) to improve design requirements for flexible learning features.

ChatGPT as a resource for pre-service mathematics teachers to design their lesson plans and lesson scenarios

Burcu Nur Baştürk[1] and Menekşe Seden Tapan Broutin[2]

[1]Izmir Democracy University, Faculty of Education, İzmir, Türkiye; burcunur.basturk@idu.edu.tr

[2]Bursa Uludağ University, Türkiye

Keywords: ChatGPT, documentational approach to didactics, lesson plan, lesson scenario.

Introduction

Generative AI tools like ChatGPT have found various purposes in education, especially among students, as in other fields (Albadarin et al., 2024). While students use generative AI tools for education purposes, it is crucial to examine how teachers will shape their lessons with the knowledge that this tool is around their students. For teachers, knowing and using these tools are important, because they can only understand the nature of these tools when they use them. Using these tools can shape the professional activities of pre-service teachers and in-service teachers. The investigation of how the use of generative AI tools by teachers and pre-service teachers influences their professional activities is a crucial research topic that can provide valuable insights of its impact on the teaching. In this context, the aim of this study is to explore how and for what purposes pre-service mathematics teachers (PSTs) collaborate with ChatGPT to develop lesson plans and lesson scenarios, with particular attention to the usage purposes and usage schemes.

Theoretical Framework

In the full version of this research, since PSTs mentioned ChatGPT with their other resources such as digital resources and textbooks, we decided to analyse the usage schemes of all the resources with the Documentational Approach of Didactics (Herein after DAD) (Gueudet & Trouche, 2009). However, the usage of ChatGPT as a resource was interesting. Mentioning the resource as a concept, DAD explains the resource as a special concept more than a tool. For instance, teachers' drawings on the blackboard can be a resource (a tool), however students' responses and teacher's explanations can be a resource, too. In this case, the conversations between PSTs and ChatGPT can be accepted as resources.

Method

This paper is a part of a bigger study which was designed as a case study and was conducted during the spring semester of the 2022-2023 academic year. The participants are chosen purposefully from a classroom with 25 PSTs enrolled in the second year of a Middle School Mathematics Teaching program in a state university in Turkey. Ten PSTs who did not use ChatGPT before for educational purposes are chosen for this study. In addition, the participants have attended theoretical lessons about teaching mathematics but they did not have any practical teaching experience. Thus, it is aimed that they feel the need to use ChatGPT as a requirement of social interaction in their plans and scenarios. The study lasted for eight weeks, with sessions of 2 hours per week.

Table 1: Data collection process

Weeks	Actions	Data Collection Tools
Week 1	Access to ChatGPT and Initiation	No data collected
	Choice of teaching subject for lesson planning	
Week 2 – Week 7	Interactions with ChatGPT to prepare lesson plans and lesson scenarios	Screenshots of participants' conversations with ChatGPT
		Participants' diaries
Week 8	Finalization	Participants' lesson plans and lesson scenarios

The data collection tools used included participants' diaries filled out when interacting with ChatGPT, screenshots of participants' conversations with ChatGPT, video recordings of the sessions that served for the monitoring of PSTs' progress where they mainly discussed teaching concepts or situations they found difficult or were hesitant about, and lesson plans and scenarios prepared in collaboration with ChatGPT.

Data Analysis

First, the data is coded for "usage purposes" after several readings of the transcripts of PSTs' diaries, screenshots and video recordings in addition to lesson plans and scenarios. Each data first analysed separately, then used to check each other's reliability. Secondly, the data is coded for revealing "usage schemes", so all data is analysed with the aim to find the stable organizations for similar situations.

Results

In this study, we have resulted that PSTs used ChatGPT for the purposes of (i)obtaining theoretical and pedagogical knowledge, (ii)consulting for ideas and validation, (iii)simulating the students' behaviours or responses. In addition, PSTs used ChatGPT for these (possible) usage schemes (i) asking for simulations, (ii) asking for preparing the lesson, (iii) asking for using suitable materials.

Prime Times: a game to develop multiplicative reasoning

James Gray

OsloMet – Oslo Metropolitan University, Oslo, Norway; james.gray@oslomet.no

Keywords: Number theory, expressions, educational games, task design.

Introduction

Even though number theory has its roots in arithmetic and is closely related to algebra, its didactics are less well researched. It is common to refer to the whole of the relations involving multiplication in the natural numbers as its multiplicative structure (Brown et al., 2002). The proposed poster will introduce and illustrate *Prime Times*, a game I am developing which provides a learning environment rich in representations of the multiplicative structure of the natural numbers, and is part of a project addressing the research question: How can the design of a game develop students' multiplicative reasoning? This proposal will report on the theoretical development of the game's design principles.

Theoretical framework and previous studies

From a synthesis of the well-developed research field of algebra education, Tondorf and Prediger (2022) extracted three typical perspectives adopted by students when considering algebraic expressions: operational, transformational, and relational. In an *operational* perspective, expressions encode a calculation and thus the student will focus on the surface syntax of the operations to perform the calculation. In a *transformational* perspective, expressions are seen as sets of symbols that can be transformed by use of rules. In a *relational* perspective, expressions are connected in a web of relations and representations that give them meaning.

Through the lens of this theoretical framework, research shows that there is a dominance of operational approaches in students' reasoning. From an analysis of preservice elementary teachers interview responses, Brown et al. (2002) conclude that they "believe that it is common for students to see prime factorizations as processes. Rather than treating a number in prime-factored form as a single number, students often perceive it only as a string of numbers, providing a set of instructions for obtaining the intended number" (p. 79).

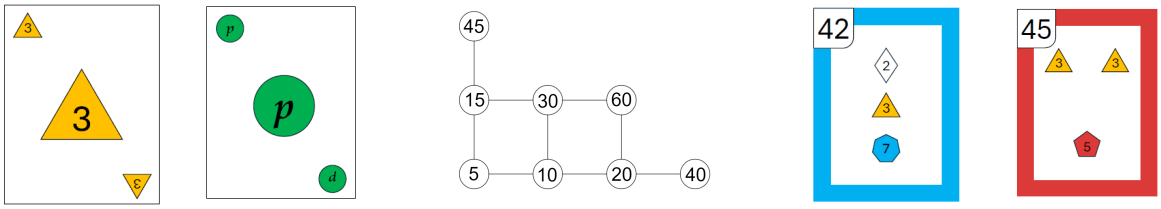

Figure 1: Examples of playing cards (left), part of playing board (centre), and objective cards (right)

Later theoretical studies have suggested ways to promote relational perspectives using representations of the multiplicative structure. Dias (2005) reports on using a lattice representation of factors (e.g. see figure 1, centre) to give intuitive explanations of the greatest common divisor (GCD) and least common multiple (LCM) with preservice teachers. Kiss (2020) proposes using cards with primes on them as a manipulative, and to have learners construct numbers multiplicatively (to introduce the idea

of the fundamental theorem of arithmetic) and to discover relationships with the GCD. There are no empirical studies of these representations in classroom settings, and the present study addresses that need with a possible aim to further develop a sequence of lessons based on these representations.

Method and design principles

This project will employ design research with cycles of conducting and analysing design experiments. A preliminary cycle with 18 in-service middle school teachers attending a professional development course was conducted to gain initial feedback, and to recruit classrooms for further cycles. Subsequence cycles will be performed with eighth-grade students because of curriculum suitability.

The game is played on a board with a lattice representation of divisibility of the natural numbers up to 64 (excluding primes greater than 32) and makes use of two sets of cards: playing cards for the primes two, three, five and seven, and wild prime cards marked with a p (multiple copies of each); and objective cards for each number on the board. During play, the players use the playing cards to form prime factorisations and place counters on the board. The aim is cover as many of the numbers corresponding to their objective cards as possible. Games last about 30 minutes and in the design experiments students played pair against pair. This led to discussion of strategies which is seen as an integral part of the game's learning environment. The game play was developed according to the following principles:

- From the findings of Tondorf and Prediger (2022), there is learning potential through promoting relational and transformational perspectives and their interaction. Through multiple representations, play invites relational perspectives. The playing cards can also be used to multiply or divide a number covered by a player's counter thereby encouraging a transformational perspective for prime factorisations.
- In addition, to counter the dominance of operational perspectives, the lattice and goal card representations offer transformational and relational perspectives that are less cognitively demanding than the operational alternatives.
- Because there are multiple goal cards visible at any time, play advantages covering the GCD or LCM of the objective cards, or an already covered number and an objective card.
- Rules should be simple as possible so that valuable class time is not used to learn them.

A proposal of tasks to integrate sustainability in the early ages from mathematics education

Nataly Pincheira, Paula López, Marta Gual and Ángel Alsina

University of Girona, Faculty of Education and Psychology, Girona, Spain;
nataly.pincheira@udg.edu

Keywords: Sustainability, education for sustainable development, mathematics tasks, primary education.

Education for sustainable development

Since the first international calls on sustainability to address social, environmental and economic crises began to emerge several decades ago Education for Sustainable Development (ESD) has been gradually incorporated into all educational stages, to promote the development of sustainability skills (e.g., Tilbury, 2011; UNESCO, 2017). To establish a strategy as united as possible, UNESCO (2017) initially suggested 17 Sustainable Development Goals (SDGs) linked to economic growth, social inclusion and environmental protection.

This initiative has already begun to generate various research results in recent years on the knowledge and beliefs of pre-service and/or in-service teachers in various stages of integrating sustainability into mathematics education (e.g., Coles and Helliwell, 2023; Roe et al., 2018). Alsina (2023) notes that, currently, it does not seem to make much sense to train teachers to teach mathematics if doing so does not have any effect on the great challenges and transformations of our day. Therefore, according to this author, both in the initial and ongoing training of mathematics teachers, the necessary knowledge and tools should be provided so that teachers can play an effective role as agents of social change. From this perspective, our aim is to propose a series of task to enable teachers to play an effective role as agents of social change by integrating sustainability in early childhood mathematics education.

Tasks for integrating sustainability from mathematics education

Below are three tasks that integrate sustainability from mathematics education and discuss the National Council of Teachers of Mathematics [NCTM] (2000) standards involved and their link to the SDGs (UNESCO, 2017).

Task 1: Can we run out of bread? *Description:* Every day in classrooms a lot of leftover bread is thrown away and on a global scale it is a problem called food waste. By becoming aware of the processes involved in the production of this food, it is possible to change consumption habits and assess whether bread can run out and what can be done to prevent this from happening. *Data Analysis and Probability:* Propose questions and collect data about themselves and their environment; Data representation using concrete objects, drawings and graphs; *Measurement:* Understand how to measure using non-standard and standard units. *SDGs:* SDG 2 Zero Hunger; SDG 3 Good Health and Well-being; SDG 12 Responsible Consumption and Production.

Task 2: What do we find on the beach? *Description:* Increasingly, different elements are found on beaches, some of which can pollute the environment. Based on the question posed, different elements

are identified and classified, and their origin and the consequences of human action are reflected upon. *Algebra:* Select, classify, and order objects by size, quantity, and other properties. *SDGs:* SDG 14 Life Below Water; SDG 13 Climate Action.

Task 3: Houses around the world *Description:* Through the discovery of houses around the world, students will learn how to describe a house. In addition, they will understand that each country has different houses depending on resources and climate. *Algebra:* Select, classify, and order objects by size, quantity, and other properties; Describe qualitative changes; *Geometry:* Recognize, construct, draw, compare and classify two- and three-dimensional shapes. *SDGs:* SDG 10 Reduced inequalities; SDG 11 Sustainable cities and communities.

Final considerations

The analysis of the mathematical tasks has shown that it is possible to establish bridges between education for sustainability and mathematics education from an early age. Furthermore, the treatment of the tasks makes it possible to address the various standards of the mathematics curriculum (NCTM, 2000). The mathematical task proposal that has been presented follows this approach, with the purpose of guiding teachers working in the first years of primary school in the design of authentic proposals and contextualized in sustainability. Therefore, it is necessary to offer teachers tools that allow them to develop students' motivation and ability to understand, interpret and critically evaluate, that is, to lead students, in the long term, to conscious decision-making in order to create a more sustainable world (UNESCO, 2017).

With great freedom comes great responsibility: Exploring potentials and pitfalls of using open environments through a discourse analysis

Cristina Poli

University of Pisa, Italy; cristina.poli@phd.unipi.it

Keywords: Task design, open environments, digital technologies, teaching, discourse analysis.

Motivation and theoretical framework

Many studies grounded in socio-constructivist approaches highlight that open-ended assignments in open learning environments promote student learning and participation in mathematical discourse. (Baccaglini-Frank et al., 2020). Aligning with this perspective, the DynaMat project has designed and implemented sequences of mathematical activities[1] with interactive digital environments with Italian 10th-grade students (https://www.carme.center/progetto-dynamat/). These activities were designed to promote exploration and encourage students to develop various solution strategies. However, despite these intentions, the author, who participated in the project as a tutor for one of the students, frequently encountered challenges in helping the student to make sense of the activities, and she felt the student's answers did not align with her expectations. Therefore, in this poster proposal, we aim to explore the potential of such activities in open digital environments in terms of the discourse they allow to create, focusing on the tutor's role in these situations.

To capture the aspects of the mathematical discourse emerging during the activities, we use a commognitive lens (Lavie et al., 2019). Within this framework, a *task situation* is defined as any setting in which a person feels obliged to act, often created by a teacher's assignment or question. The student's interpretation of the task situation, i.e. what they consider that needs to be done, is defined as the *task*, while the *procedure* is what the student does in response to the task they interpret.

The research aim is to study the role of the tutors in the context of DynaMat activities by analysing students' and tutors' discourses to identify the tasks emerging through the interaction. More precisely, we ask the following questions: How do the students' tasks change in the context of open-ended assignments with digital environments? How does the tutor manage these changes?

Methods

In this poster we will present an example of an activity involving a GeoGebra artifact designed for the dynamic exploration of functions, called *dynagraph* (Antonini & Lisarelli, 2021). In this activity, students manipulate a slider representing the independent variable along a numbered line, while parallel lines show sliders for the dependent variables, defined by mathematical expressions input by the students. The assignment that sets the task situation in this case is: "By entering any expression you like, make sure that one of the sliders is always to the right of the other." The goal is to engage students in exploring relationships between functions by observing the movements and relative

[1] We use the word "activity" to refer to the interaction with a digital artifact to accomplish a given assignment. We avoid using the word "task" to prevent confusion with the commognitive construct that we introduce later.

positions of the sliders while developing a mathematical discourse on how expressions should be formulated to achieve the desired relationship. Two tutoring sessions in which this activity was done were video-recorded and the discourse of students and tutors was analysed, identifying the tasks by looking at the procedures implemented. The discourse analysis will be illustrated on the poster.

Findings

The first episode involves a tutor, Giulia, with two students, Irma and Sonia. From the discourse analysis of this episode, it emerged that, after accomplishing the initial task situation, the students shifted to new tasks, such as finding alternative solutions or generalizing their findings. This led them to implement various procedures that achieved the goal of the activity and encouraged the tutor to propose new task situations.

Another episode involves the author interacting with a student named Carlo. From the analysis of this episode, a *communicational gap* (Sfard, 2023) was identified: the student's task differed from the tutor's task. This is evident from Carlo's continued use of the expression "ahead" instead of "to the right" to describe the relative position of the sliders. Hence, the tutor shifted her task, engaging in a discussion on the relationships between the expressions "greater than", "to the right", and "ahead" on the number line. However, this still did not help the student reach the goal of the activity.

Discussion and conclusions

These examples highlight how open-ended assignments can generate a wealth of diverse tasks, while also leaving significant responsibility to the tutor to manage these situations. Our broader goal is to develop teacher guides that can support educators in exploiting the richness of open digital environments to align with mathematical and educational goals while offering suggestions on how to adapt the activities to meet the specific needs of their students.

TWG 23: Implementation of Research Findings in Mathematics Education

An introduction to TWG23: Implementation of research findings in mathematics education

Linda Marie Ahl[1], Ola Helenius[1], Boris Koichu[2], Julie Vangsøe Færch[3]and Mario Sánchez Aguilar[4]

[1]University of Gothenburg, Sweden; linda.ahl@ncm.gu.se

[2]Weizmann Institute of Science, Department of Science Teaching, Israel

[3]University College Copenhagen, Denmark

[4]Instituto Politécnico Nacional, CICATA Legaria, Mexico

Introduction

This introduction outlines the thirteen contributions presented at TWG23 during CERME14. The content of the contributions revolves around seven pivotal themes, to be elaborated on below. Furthermore, three thematic discussions took place, emphasizing the following key points: Core Elements of Innovation and Fidelity of Implementation; The Life Cycle of Implementation and Criteria for Success; and Conflicting Goals, Perspectives, and Theories in Implementation. The thematic discussions in TWG23 at CERME14 were not explicitly related to any particular presentation but instead concerned a holistic view of the implementation research field.

Contributions to the TWG23 at CERME14

The TWG23 at CERME14 was led by Ola Helenius, Boris Koichu, Linda Marie Ahl, and Julie Vangsøe Færch. The TWG23 accepted 11 papers and 2 posters, addressing different aspects of implementation research in mathematics education. The authors of the contributions came from Denmark, Israel, Sweden, the Faroe Islands, and the United Kingdom. The contributions were organized into thematic categories:

1. Reporting guidelines for implementation research
2. Design principles
3. Fidelity and adaptations
4. Scaling issues
5. Replication
6. The role of Habits
7. Pre-, present-, and post-implementation issues

Reporting guidelines for implementation research

The session began with a poster by David Nordqvist, Tina Åkegård, Ola Helenius, and Linda Marie Ahl, exploring what should be reported in implementation research. Hill, Lynch, and Polanin (2024) recently highlighted that inconsistent reporting of classroom interventions impedes knowledge accumulation. They recommend structured guidelines that detail aspects such as intervention content, teacher preparation, and implementation support. Nordqvist and colleagues tested this framework by applying it to "Algebra Monday," a program aiming to strengthen foundational algebra across grades. Using a cascading scaling model, the program trains lead teachers, who in turn train others within their municipality. The researchers found Hill et al.'s guidelines to be broadly applicable, although they lacked elements specific to implementation and scaling. They concluded that the framework is promising but needs to be extended to

capture scaling design processes.

Design principles

Julia Tsygan presented a study on implementing the MUSK model to enhance students' mathematical communication. Instead of the typical fidelity-versus-adaptation lens, the study used an integrity framework, examining how core elements were preserved while adapting to local needs. Using the Professional Obligations model (Herbst & Chazan, 2012), it explored how institutional and practical demands shaped decisions. Adaptations, such as feedback cycles and explicit reasoning instruction, made the model more sensible, although they also revealed tensions between innovation design and school conditions. The study emphasized the need for alignment with professional norms and assessment structures.

In the Faroe Islands, a project used design research to address declining PISA performance. With support from the Ministry of Education, the initiative applies iterative, classroom-based principles to bridge theory and practice. Building on the work of Century and Cassata (2016) and Koichu et al. (2021), this framework views innovation as an ecological disruption and promotes teacher collaboration through Communities of Practice. Project MAC targets mathematical modeling and digital tool use through three guiding principles: problem formulation, digital tool integration, and teacher collaboration. It operates across three schools, emphasizing iterative cycles and combined evaluations to inform broader application.

Fidelity and adaptations

Hanna Palmér, Jessica Elofsson, and Camilla Björklund explored fidelity and adaptation in scaling a preschool math intervention. Using frameworks from Century and Cassata (2016) and Coburn (2003), they evaluated how key elements were preserved or adapted. Coburn's dimensions—depth, sustainability, spread, and ownership—guided the analysis. Though early results were promising, scaling raised challenges in maintaining integrity. Productive adaptations occurred when teachers understood and applied core concepts in a flexible manner. Rigid use or superficial changes often limited effectiveness. The authors noted that local contexts, like Sweden's emphasis on preschool teacher autonomy, significantly influence outcomes.

Mark Boylan's contribution examined fidelity through two lenses: design and theory. In mathematics education, where teacher agency is vital, striking a balance between these is essential for effective scaling. Using the Maths Excellence programs as a case, Boylan showed how different components may require different fidelity approaches, aligning core principles with contextual flexibility.

Scaling issues

Uffe Thomas Jankvist, Linda Marie Ahl, Johan Prytz, and Iresha Ratnayake presented a review showing that implementation success varies by scale. Small-scale projects benefit from direct links between developers and practitioners. Medium-scale efforts rely on structured support and voluntary participation. Large-scale initiatives often succeed when focusing on curriculum rather than pedagogy, as altering teaching practices proves to be more challenging. Scaling pedagogical change requires deep, context-specific support rather than top-down mandates.

Tomas Højgaard discussed the Danish Ishøj Project, which aimed to embed competency-based teaching through school-based seminars and teacher collaboration. While the initiative reached all K-9 math

teachers in the municipality and showed progress, it faced challenges such as limited supervisor expertise, leadership gaps, and constrained resources. Effective scaling, the study concludes, needs strong support systems and leadership commitment.

The MIST (Middle-School Mathematics and the Institutional Setting of Teaching) project, presented by Johan Prytz, Iresha Ratnayake, Linda Marie Ahl, and Uffe Thomas Jankvist, used a Design-Based Implementation Research approach. MIST's Theory of Action focused on leveraging district leadership to enhance teaching quality. The project emphasized structured communication and accountability, with district leaders translating feedback into professional development strategies. MIST's success depended on systemic alignment, suggesting that replicating it requires similar leadership capacity and infrastructure.

Julie Vangsøe Færch presented the only replication study, which examined young students' proportional reasoning. The discussion centered on the role of replication in validating findings, understanding contextual limits, and exploring how adaptations affect outcomes. The overlap between replication and implementation research was acknowledged, with both focusing on variability and context.

Habits and Routines

Andrew Grant explored how interleaved practice challenges teachers' planning habits. Although not unique to mathematics education, this practice necessitates adjustments in how teachers structure lessons. For successful implementation, habit formation strategies must be integrated into professional routines, ensuring that innovations become an integral part of daily teaching.

Pre-, Present-, and Post-implementation projects

Morten Misfeldt and colleagues investigated the integration of programming into math education, which remains a challenge. Tools like Scratch can introduce unfamiliar content that clashes with standard curricula. The team distinguished between Computational Thinking (CT), which aligns with existing structures, and Computational Literacy (CL), which requires broader pedagogical change. Based on Piagetian theory, CT is seen as assimilation, while CL reflects accommodation. The study illustrated how each reshapes geometry learning differently.

Jason Cooper and Boris Koichu discussed post-implementation sustainability. In Israel, some teachers continued to engage in problem-solving after formal incentives ended, motivated by enjoyment. Although classroom integration remained limited, their ongoing involvement suggested increased agency and readiness for future innovation.

Finally, Cecilie Carlsen Bach and colleagues introduced a poster on Technology Comprehension (TC) in math education. Using speculative tarot cards, they encouraged teachers to imagine future digital learning scenarios. This participatory approach aimed to foster ownership and align educational innovations with the perspectives of both teachers and students, countering top-down impositions.

Emerging Themes in Educational Implementation Research

One strength of the CERME conference, particularly within smaller discussion groups like TWG23, is the time available for deep dialogue. This summary captures overarching discussions not tied to individual papers but relevant to the broader field of implementation research.

Core Elements of Innovation and Fidelity of Implementation

There is increasing agreement that innovations should clearly define their core components. These "non-negotiables" support fidelity but must still allow space for context-sensitive adaptations. Determining how specific these elements should be remains a challenge, especially as implementation moves from research to practice. Definitions of *productive adaptation* differ, and while overarching concepts are applicable, local adaptations vary widely. Teachers often carry the burden of interpreting innovations, so involving them in co-design from the outset was identified as key to balancing clarity and flexibility.

The Life Cycle of Implementation and Criteria for Success

Implementation efforts typically unfold across dynamic life cycles influenced by institutional backing, funding, and stakeholder engagement. Our discussions raised questions about how to define success, whether in terms of short-term project outcomes or longer-term, systemic change. Readiness for change, both at the individual and institutional levels, was considered essential but challenging to sustain over time. Success criteria should include fidelity of implementation, stakeholder learning, and sustainability, in addition to student learning outcomes.

Conflicting Goals, Perspectives, and Theories in Implementation

The group acknowledged that differing goals and perspectives often shape implementation efforts. At the practitioner level, clarity on shared strategies or theories of change is usually lacking. Similarly, within the research community, debates continue about how much conceptual agreement is necessary to advance the field. This diversity can be productive, but may also create barriers for newcomers. A significant theme was the inherently political nature of educational settings, in contrast to more technical fields. Ignoring these dynamics risks oversimplifying implementation. Researchers were encouraged to address policy, power, and ideology explicitly, as exemplified in Mark Boylan's work.

Future Themes and Research Directions

The group identified key future directions that may be explored further at CERME15:

- Specifying core elements across phases and contexts
- Defining and evaluating success and failure
- Understanding transitions between small-, medium-, and large-scale implementations
- Revisiting foundational literature to develop updated theoretical tools

The discussions reinforced CERME's spirit of collaboration and thoughtful critique. Building implementation research within mathematics education requires shared commitment, open dialogue, and a culture that supports both rigor and inclusivity.

The implementation of mathematics education programmes: fidelity to design and fidelity to theory

Mark Boylan

Sheffield Institute of Education, Sheffield Hallam University, UK; m.s.boylan@shu.ac.uk

Considering fidelity and adaptation are important to the implementation of mathematics education programmes for designers, evaluators, and users. Researchers sometimes view fidelity and adaptation as opposites, where fidelity refers to faithfully implementing processes, and adaptation deviates from this. However, for some mathematics education programmes this is a false dichotomy. An expanded understanding of fidelity can address this in cases where fidelity to programme theory or causal assumptions is important rather than fidelity to planned implementation or design. The differences between these two forms of fidelity and the value of considering both are illustrated by considering a set of four programmes, each with multiple components, that aim to improve outcomes and progression for disadvantaged pupils in England.

Keywords: Fidelity, adaptation, implementation.

Introduction

The concept of fidelity is central to the study and evaluation of implementation in education generally and important in mathematics education (Munter et al., 2016). In the study of implementation in education, fidelity carries both technical and common language meanings and is also used in various ways in mathematics education (Jankvist et al., 2022). Adaptation is also important to innovation in mathematics education for designers, evaluators, and users, including when implementing research findings. Fidelity and adaptation are sometimes viewed as opposites. However, clarifying different meanings of fidelity dispels this false dichotomy. In this paper, I distinguish between fidelity to design and fidelity to theory.

Fidelity to design is the common meaning used in the study of implementation and means adherence to a programme's design, structure, and processes: doing what was intended and planned for (O'Donnell, 2008). Attention to fidelity to design allows for the identification of essential features of innovations and ensures these are implemented when programmes are replicated. Where the programme is not implemented as planned, attending to fidelity brings a focus to key moderating influences and contextual factors. However, where innovations are being developed, adaptation will be inevitable and desirable to develop an effective innovation. This will often be the case in early applications of research findings or in design research phases in many mathematics education innovations, but also when replicating or scaling to understand contextual influences (Cai et al., 2020). Further, there are features of mathematics education curricula, pedagogy, and professional development where flexibility, agency, and an adaptive orientation are essential to intended practice**.** In such cases, what is important is fidelity to the underpinning theory of how activity will lead to outcome, the core ideas of the innovation (Cai et al., 2020; Jankvist et al., 2022), and echoes arguments for flexibility within fidelity (Kendall & Frank, 2018).

These two meanings may not cover all cases. In some cases, where very high levels of adaptation may be desirable or acceptable, for example, in pilot or exploratory stages of innovations, a further form of fidelity may be relevant. This is fidelity to programme goals. McNeill et al. (2018) report an example in science education where they contrast fidelity to procedure with fidelity to the goal—in the case they consider the goal of developing scientific argumentation. It is not clear in such cases whether it is then meaningful to consider activity as implementation, and so I note this third possible meaning of fidelity but do not consider it further in this paper.

In the next two sections, I develop the argument for distinguishing the two forms of fidelity. I consider fidelity in implementation science in general and then briefly summarise discussion of fidelity in mathematics education, drawing on examples from mathematics education innovations. Following this, I illustrate the application of the two forms of fidelity through an example of four programmes that aim to improve outcomes and progression for disadvantaged pupils in England.

Fidelity and implementation

As stated, fidelity is a key concept in implementation science, and proponents of its importance have developed various models of different aspects of fidelity and how frameworks to guide its measurement are based to varying extents on conceptual theorising or reviews of how fidelity is used and applied by researchers and others (see Gage et al., 2020 for examples). These frameworks are concerned with the common meaning of fidelity as implementation of the designed programme. For the purposes of distinguishing between the implementation of design and the implementation of theory, and given the limits of this paper, I illustrate with components of an early influential model of fidelity (Dane & Schneider, 1998). In summary in this model, fidelity consists of a combination of:

- adherence of delivery to the prescribed programme
- exposure of recipients to the programme activities
- quality of delivery
- responsiveness of participants
- differentiation of participant experience by planned activities only.

Later developments of models may have different or additional components, but in common with the above features, the focus is on the relationship between the planned activities in a programme and implemented activities.

In the study of implementation, there are different views of the value of fidelity, with two positions that can broadly be summarised as pro-fidelity and pro-adaptation perspectives (Century & Cassata, 2016). A pro-fidelity perspective considers it important that effective practices should be implemented without deviation and that any changes should be made in a design phase. In this view, users should be encouraged and supported to implement with fidelity. A pro-adaptation view considers that high fidelity of implementation may be hard to achieve in practice and innovation users will respond to context, and that those implementing innovations are able to add effective strategies or improve the innovation. Such adaptations can mean innovations can be more widely applied beyond any one specific context, and this can support sustainability (Century & Cassata, 2016). For

new research-informed innovations, adaptation in use aligns with a different model of the relationship between researchers and designers and practitioners in which there is collaboration and co-design. Practitioners are positioned as agentic rather than end users.

Underlying the pro-adaptation perspective is an emphasis on the underpinning causal assumptions for a programme or its component parts or the programme theory (Ahl et al., 2022; Munter et al., 2016). 'Theory' is used in multiple ways with nuanced meanings, including when considering programme implementation (Helenius et al., 2023). It is often used as part of a compound phrase, 'Theory of Change', but this term too has different interpretations, often being used to mean the visual representation of programmes casual structure (Boylan, 2023; Chen, 2012). Other terms are used instead of or alongside 'theory' to refer to the same or similar phenomena, such as determinants (Chen, 2012; Helenius et al., 2023). though often used with reference to implementation and contextual determinants (McLoughlin et al., 2021). Others use 'mechanism' to identify causal relationships (Lewis et al., 2018), often drawing on realist social theory (Coldwell & Maxwell, 2018). Conversely, statisticians may more commonly consider 'assumptions' in inferential models (Colnet et al., 2024). However, regardless of language used, these different terms draw attention to how designed programme processes and structure may cause intended outcomes. Thus, fidelity to the casual relationships of a programme or a component is fidelity to programme theory.

From a pro-adaptation perspective, considering fidelity to theory as a separate construct is helpful in addressing what adaptations are acceptable or desirable for each specific innovation or component. Acceptable adaptations support the enactment of the programme theory, and desirable adaptations are those that help to amplify the programme theory mechanisms. In cases where programmes are in a mature stage of development, including when core components and essential fidelity are established, then fidelity to design will often include fidelity to theory, as the theory is embedded in the programme design, process, and structure.

Mathematics education and fidelity

Turning to mathematics education specifically, it is important to consider implementation in connection with the specifics of the discipline and the mathematics education ecology (Koichu et al., 2021). In mathematics education, specifically, adaptation is likely and may be desirable and intended (see, Ahl et al., 2022, for an example). In mathematics education, a central concern is for the interplay between mathematical content, teacher activity, the learner, and the learning environment. While the conceptualisation of this interaction varies in different paradigms, it is significant in arguably all traditions in mathematics education and underscores the significance of responsive adaptation of practice. Adaptation is particularly important in pedagogical approaches that stress the importance of both teacher and learner agency in the learning process. Beyond individual classrooms, similarly adaptive practice is important to the implementation of mathematical education programmes.

For some mathematics education practices, fidelity and adaptation are a false dichotomy. This is because fidelity to the underlying principles of the programme or activity may require adaptation of materials or practice. I take as an example the implementation and evaluation of a professional and curriculum development programme in England for lower secondary pupils—Realistic Maths Education (RME) (Demack et al., 2022). In the RME programme, one aim was for teachers to move

towards greater use of models and representations in teaching than their previous practice. Teachers received curriculum and teaching resources, along with professional development, to encourage the use of bar models, ratio tables, and double number lines. It was thought that if teachers could choose and use different models in different ways, it would first help students learn more and then help students learn how to choose the right models to help them solve problems. Given this, although teacher use of programme materials was important (fidelity to design), the fact that these were used flexibly and with adaptation was also important (fidelity to theory).

A typology of three types of professional learning frequently found in innovations provides a heuristic to identify whether fidelity to design or fidelity to theory, or both, are important specifically for mathematics innovations that include professional development (Boylan & Demack, 2018). Technical professional learning aims for teachers to use new techniques or use new materials in specific ways. Here fidelity to design is most relevant. Pedagogical professional learning focuses on growth and change as a professional through reflective and agentic practice. Here fidelity to theory is most relevant. Curriculum professional development combines professional learning with the use of research-informed curriculum materials. Here, as in the RME programme, it is likely that both forms of fidelity should be considered.

Regardless of the forms of professional learning or the value in the typology, for any given programme or component of a programme, three possibilities are possible in terms of the importance of the two different forms of fidelity (for instances where fidelity is important at all):

- fidelity to design
- fidelity to theory
- fidelity to design and fidelity to theory

The MX programmes as an illustration

I now consider an example to illustrate the application of the different forms of fidelity in practice. This example is a set of four programmes – the MX programmes - funded by the Maths Excellence Fund (n.d.) in England, informed by research on relative attainment of students across their education experience in relation to their demographic characteristics (Noyes et al., 2023). The programmes aim to support disadvantaged students to attain highly at 16 and for more to progress to A-level and university mathematics, with 46 secondary schools participating. The National Foundation for Education Research is evaluating the four programmes, and I advise on the application of Theory of Change to the evaluation. The four programmes are led by several types of organisations.

Each programme is comprised of multiple components (see Table 1), with some types of components common across programmes and some specific to individual programmes. The MX programmes' overall meta-theory posits that addressing systemic and long-standing inequalities in mathematical outcomes requires multiple programme components that can have an additive impact.

Some components involve activities similar to activities often reported on in mathematics education research: parental engagement, teacher training and development, classroom technology use, tutoring, and mentoring. Others are more specific to the programme or to the context in England:

- tracking and monitoring target groups of pupils and collecting data on outcomes

- In-school champions who coordinate and encourage participation
- An extended, more challenging mathematics curriculum for 11- to 14-year-olds
- Additional supplementary maths qualification for 16-year-olds
- Y6-Y7 transition to support pupils' mathematical learning as they move from primary (elementary) to secondary (junior high school) phases
- Maths enrichment through after-school maths clubs or mathematics events at universities
- Interschool competitions between local schools inspired by maths Olympiad competitions.

Fidelity of design and theory in implementation and evaluation

Table 1 summarises the different components for the four programmes and, for each programme, posits whether fidelity to design (d), fidelity to theory (t), or fidelity to design and theory (d & t) is most relevant. Empty cells show that the component is not part of a programme. These ascriptions are an interpretation informed by my analysis of programme implementation plans and logic models and then checked with the team responsible for oversight of the four programmes for the funder. For some components, expected outputs from activities are identified, for example, the number of students participating in additional coaching sessions. For others, the programme design indicates that activities will be developed and modified on specific sites.

We can attribute fidelity to the design, if there are specific indicators of adherence to the design, such as the number of students participating in specific activities with defined processes and structures. Ib the MX programmes, pupil tracking systems most fully exemplify this. Components that demonstrate fidelity to theory are those that allow for significant flexibility in implementation. So, for example, in three programmes, an in-school champion will be identified, but what they will do is not predetermined. In one programme, the in-school champion will be a new member of staff, working closely with the target groups of students undertaking activities that are specified in other programme components. Two types of components are considered to have both fidelity to design and relevance to theory. Some activities have plans for the number of students participating or the number of sessions offered, but programme teams will develop or tailor the details in practice to suit identified needs. Alternatively, the components feature both pre-designed subcomponents and ones that will be developed.

Table 1: Types of fidelity relevant to selected programme components

Programme components	United learning	East Maths Community	MEI	Co-op Academies
Tracking and monitoring	d	d	d	d
In school champion	t	t	t	d & t
Parental engagement	t	d		t
Teacher training and development	d		d & t	d & t

Programme components	United learning	East Maths Community	MEI	Co-op Academies
Community learning hubs		t		
Classroom technology use				t
Extended KS3 maths curriculum	d		t	
Additional maths qualifications	d	d	d & t	d
Tutoring	d	d & t	d & t	d & t
Mentoring			d	d & t
Y6-Y7 transition	t			
Maths enrichment	d & t	d & t	t	d & t
Inter-school competitions		t		

Identifying forms of fidelity that are most relevant to components supports Theory of Change development and evaluation activity. Where fidelity to design is relevant, it is important to consider appropriate fidelity measures (O'Donnell, 2008). When fidelity to theory is considered important, fidelity measures might not be suitable. Instead, when developing Theory of Change models and evaluation activity, the underpinning programme theory relevant to the component under consideration should be examined.

Conclusion

I have considered two forms of fidelity: fidelity to design and fidelity to theory. Fidelity to design corresponds to common meanings of implementation fidelity. Fidelity to theory is important, particularly for programmes in early stages of development where essential components are not yet identified.

It is also important for programmes in which adaptation, agency, and flexibility of mathematics teachers are central to programme aims and important to intended outcomes. Considering fidelity to programme theory. provides a means to assess whether adaptations are potentially useful additions to programmes or should be viewed as a failure of implementation and supports the articulation of causal theory. This may be particularly important when replicating or scaling innovations (Aguilar et al., 2023; Cai et al., 2020). The distinction between these two types of fidelity potentially has wider applicability beyond mathematics education.

Post-funding implementation—Attending to teachers' readiness

Jason Cooper and Boris Koichu

Weizmann Institute of Science, Department of Science Teaching, Rehovot, Israel;
jason.cooper@weizmann.ac.il

Our goal is this article is to contemplate what might happen with mathematics education innovations at a post-implementation stage, when funding for professional accreditation of the participating teachers terminates. To this end, we attended to our experience with running a voluntary mathematics club for teachers that features mathematical problem solving, and analysed one of the meetings of the club in some detail. We found that of four processes under the umbrella of implementation as defined by Koichu et al. (2021), traces of three processes—constructing agency, changing communication, adapting the innovation—can be identified in the club discussions. Furthermore, we provide evidence in support of a hypothesis that these processes can be related to the development of the teachers' readiness to implement the innovation. We conclude by a call to further explore anchoring and sustainability of R&D projects having limited funding periods.

Keywords: Implementation, mathematics teacher knowledge for teaching problem solving, post-implementation, readiness to implement, voluntary professional development.

Introduction

Design and implementation of research-based innovations is often stipulated by funding that the innovation proponents are capable of securing; part of the funding is sometimes designated to support professional-development (PD) accreditation for participating teachers. Not surprisingly, the sustainability of a funded implementation project is challenged when funding ends. This phase of a project brings to mind the term post-implementation, which Misfeldt et al. (2023) define (in one sense of the term) as "attendance to anchoring and sustainability" (p. 5) when adoption and dissemination of an innovation may continue until the innovation ceases to disrupt the system, possibly through general adoption or general rejection.

Misfeldt et al. (2023) do not explicitly suggest that post-implementation begins when funding ends. While this may be a natural assumption, we will argue that at least in some cases, processes identified by Koichu et al. (2021) under the term "implementation" can continue after funding ends, though in different shapes. In particular, the funded stage of an implementation may rely on incentives that do not align with the nature of the innovation as communicated to the funding agencies. For example, a common practice in PD is to require teachers to try out some innovative pedagogy and to report on their experience. This requirement can be justified, for instance, by the need to enhance mutual learning within a community of practice (Graven, 2004). When teachers comply, it is tempting to believe that they do so while recognizing opportunities to learn as planned by the proponents of the innovation, yet it is possible that they are merely doing what is required for professional accreditation. It seems possible that external motivation used to encourage teachers to enact an innovation when funding is available may in fact hinder the construction of teachers' agency over it—a central process of implementation according to Koichu et al. (2021).

We have often asked ourselves what implementation might look like without teachers' external motivation to acquire accreditation. An opportunity to investigate this occurred in 2023–2024. This

was a challenging school year in Israel, fraught with political and military unrest. Teachers, many of whom had experienced personal trauma or loss, were struggling to find ways to engage students who had many things on their minds other than learning mathematics (Koichu, 2023). In late October 2023 we initiated an online mathematics club for middle and high school teachers where we introduced an educational innovation—non-standard problem-based activities—that we felt might engage distracted teachers and students.

Our running of the mathematics club drew significantly on resources developed in the context of a funded R&D program. The 2023–2024 school year was the fourth and final year of a project called Raising the Bar in Mathematics Classrooms (RBMC, for details see Cooper & Koichu, 2021; Koichu et al., 2022). The goal of the project was to encourage grades 8–10 teachers to organize some of their lessons around problem solving (PS), supporting them in this practice in various ways. A collection of thirty problems had been developed and piloted for this project, and teachers were required—for professional accreditation—to enact PS in their classes at least three times throughout the year, and to submit online reflective reports on the lessons. In each PD session teachers worked on a problem and participated in a discussion that attended to both mathematical and pedagogical aspects of the problem (e.g., strategies and solutions, anticipated student approaches and errors, how and when to present the problem, which classes it is appropriate for, possible adaptations, etc). Additionally, teachers shared and discussed their enactment experiences with their peers. As funding for the project was nearing its end, we had been giving much thought to its sustainability. We realized that without the incentive of professional accreditation, which relied on the project's funding, it was by no means certain that teachers would continue to implement PS. In this sense we regard the voluntary (i.e., not for credit) club as a kind of testing ground for investigating models of post-implementation.

Many of the 2023–2024 club meetings were organized around problems from the RBMC collection, and the structure of the meetings drew on experience that we had gained from working with teachers in RBMC. We encouraged teachers to make use of these problems, but they were under no obligation to do so and were offered no accreditation for their participation in the club. Nearly 200 teachers participated in at least some of the club meetings in October and November. As teaching conditions gradually improved in most parts of Israel, less teachers attended each session, yet a core of approximately 16 teachers continued to attend regularly throughout the year and attended most of the 30 club meetings (see Cooper & Badarne, 2024, for details).

In January 2024 we conducted interviews with some of the regular and intermittent participants in the mathematics club (Cooper & Badarne, 2024), and found that the teachers claimed to be participating primarily for the sake of the mathematical activity, which they enjoyed, and that while they considered the problems appropriate for their students, none of them had enacted any of the problems in their classrooms. Our initial response was disappointment, first and foremost with respect to the club itself—we had not met the goal we had set ourselves of supporting implementation of PS activities in classrooms. Our findings also raised concerns regarding prospects of sustainability for the RBMC project. The club members' reluctance to enact problems in the classrooms raised concerns that teachers who had begun to implement the PS innovation might neglect this practice without the incentive of accreditation.

When we had gotten over our initial disappointment, we asked ourselves whether these teachers' voluntary participation in a PS club may nonetheless contribute indirectly to the implementation of

this innovation. While becoming a proficient problem solver is not a sufficient condition for teachers to enact PS in their classes (Chapman, 2015), we have long believed that it is a necessary condition and have organized the PD activities of RBMC around teachers' PS experiences. However, to date we have not explicated in what ways participating in PS may contribute to implementation. It is this that we wish to attend to in the current article.

Theoretical framing

Implementation occurs in interaction between the innovation, its proponents and its adapters, and, according to Koichu et al. (2021), the proponents have ultimate agency over the innovation at the beginning of the process. During the implementation, the adapters should come to experience at least some of the following four processes: "(1) constructing agency over the innovation, (2) gradually changing within-community communication or across-community communication, (3) gradually changing practice so that it accommodates the innovation, (4) adapting the innovation to their needs and aspirations" (Koichu et al., 2021, p. 986). Koichu et al. (2022) proposed an analytical framework—*problem-solving implementation chain*—for investigating implementation of PS as a sequence of interactions between actors en route from proponents to adapters in which adaptations are negotiated. For example, proponents of a problem-based innovation and teachers may interact in a PD setting and negotiate adaptations for the teachers' particular educational contexts and needs. Such negotiation will often include what should change, for what reasons and purposes, and what is lost and gained as a consequence. Adaptation may continue to take place in the teachers' individual planning, and later in their enactments.

A tacit assumption in our work to date has been that interactions along the implementation chain take place with the ultimate goal of classroom enactment with students. Thus, investigations of interactions between proponents and adapters in PD has focused on the third and fourth of the four implementation process mentioned above, namely, *gradually changing practice* and *adapting the innovation*. We now wish to challenge this tacit assumption and consider interactions between proponents and adapters that are not around immediate changes in practice and the negotiation of adaptation. In principle, such interactions might contribute to other processes of implementation.

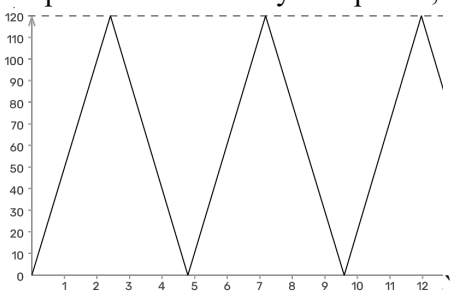
We suggest that our attention should be on the development of teachers' readiness to implement PS, which Zaks and Koichu (2022) have taken to encompass their inclination to enact as supported by relevant knowledge. Zaks (2023) singled out the anticipation of students' responses in PS activity as an important facet of supporting teachers' knowledge for enacting PS and has found five characteristics that constitute the thickness of teachers' anticipation: specificity, detail of mathematical moves, organizational aspects, first person solver's voice, and variety.

Developing readiness to enact has imperfect overlap with the notion of implementation—not all aspects of implementation can be conceptualized as building readiness, and vice versa. However, there is significant overlap. In particular, development of agency (one of the implementation sub-processes) may contribute to an inclination to enact (aspect of readiness), and the development of supporting knowledge (aspect of readiness) can contribute to changes in discourse (one of the implementation sub-processes). In this article we are concerned with this (hypothetical) relationship, and ask accordingly: How may teachers' participation in a voluntary mathematic club that features

PS contribute to changes in agency over the problems considered in the club, in teachers' discourse on PS instruction and in their readiness to enact PS in their classes?

Data sources and analysis

Given the exploratory nature of the above research question and space constraints, we selected one meeting from a later stage of the club (February 2024), by which time there was a core of 16 regular participants. The meeting was selected as typical regarding its structure and interactions. The meeting, led by the first author, took place over Zoom and was recorded. The meeting was transcribed, and relevant parts were translated from Hebrew by the authors. In the data we sought exchanges that could be interpreted as manifesting processes of implementation (constructing agency, changing communication, adapting the innovation) and/or as contributing to teachers' readiness (inclination to enact supported by knowledge of how to enact).



Findings and Discussion

We begin by presenting four excerpts that concern a problem presented in Figure 1, and then discuss these excerpts in terms of the above–mentioned processes and notions.

Out-and-back Trains

The distance between two cities is 120 km. A train line runs back and forth between them all day long (without intermediate stops). The train's maximum speed is 50 km/hr and it can transport up to 900 passengers. At high season the number of passengers wishing to travel on this line is greater than its capacity, and the management is looking for ways to increase the capacity.

1. How many passengers per hour can the train transport between the two cities?
2. The management intends to purchase a new train that can travel up to 120 km/hr and can hold up to 300 passengers. There is a single rail between the two cities so the trains cannot pass each other. In your opinion, should they replace the old train with a new one?

3. Inspector Gabriel had a suggestion: "Each station has a number of platforms, and they can be used to operate the two trains concurrently". Plan a timetable that will allow this. You may use the provided graph, which describes the old train's schedule during part of the day. How many passengers per hour can be transported according to your suggestion?
4. The management agreed to double one section of the track between the two cities to allow the trains to pass each other. Inspector Doron suggested: "If we double the track midway between the two cities, we can build a timetable that will allow us to transport up to 600 passengers per hour". Explain how this is possible.
5. Inspector Hila commented: "I have an idea for some other place between the cities where we can double the track instead of midway, and this will increase the number of passengers per hour even more". Suggest such an alternative place, plan a schedule and calculate how many passengers per hour it will allow. Compare your solution to Doron's.

Figure 1: The problem that teachers worked on and discusses in the club

Excerpt A: Seeking clarifications regarding Question 1 (see Figure 1)

1	Teacher R:	Can I ask a clarification question? How many passengers per hour, does that mean that a train needs to arrive at a destination once every hour? Because the first train to leave will not arrive in one hour.
2	Facilitator:	How long does it take to get from one city to the other?
3	Teacher R:	Two hours and a bit.
4	Facilitator:	And it transports 900 passengers.
5	Teacher R:	It's the same train that runs back and forth?
6	Facilitator:	Yes
7	Teacher R:	There aren't two in opposite directions?

Excerpt B: Features of realistic literacy problems (with respect to Question 2)

1	Facilitator:	The question was, *in your opinion* should they replace the old train. This invites all sorts of answers. It's true that it's less passengers per hour, but each passenger has a shorter ride. Whether that's beneficial or not…
2	Teacher V:	The question is what the goal of the management is.
3	Teacher R:	And who benefits from buying a second train.
4	Teacher G:	Perhaps you can charge twice as much for the faster train.
5	Teacher R:	And maintenance costs [for a new train] are lower too.
6	Facilitator:	One of the things I really like about literacy problems is that they invite discussions that are more interesting than you might think… You need to construct a mathematical model for "beneficial", make some assumptions, like… beneficial is measured in profit for the rail company, construct a formula for "beneficial" that is not given in the problem and justify answers based on this… Sometimes a slightly non-standard question is asked, and suddenly [students who don't normally participate] have something to say.

Excerpt C: A teacher shares her work related to Question 3

1	Teacher R:	I don't mind sharing, but I did something quite simple [shows a drawing, see Figure 2].
2	Facilitator:	It's best to start with the least sophisticated and move on to more sophisticated solutions.
3	Teacher R:	The fast train needs to wait.
4	Facilitator	Where? For what?...
5	Teacher R:	For the other train to pass.
6	Facilitator:	How can it pass?
7	Teacher R:	Ok, cancel my solution.

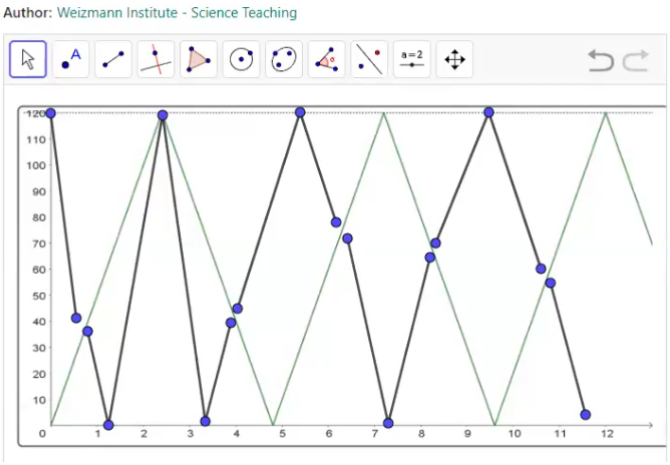


Figure 2: A teacher's flawed solution to question 3

8	Facilitator:	Save your solution. Who knows, maybe there will be a question for which this is a good answer… This is excellent. If I'd known this was your solution, I'd have chosen to begin with it and ask what's wrong with it.

Excerpt D: Teachers proposing adaptations of Question 3

1	Facilitator:	In motion problems, if someone walks part of the time and rests part of the time, and we want to know the average speed, the rest lowers the average speed.
2	Teacher V:	That's right, but when you ask a student what average speed is… [he] understands what average speed is, here [passengers per hour] it's just a calculation.
3	Teacher G:	For me it's more important that students be able to do this [work out passengers per hour] than calculate average speed. This is the use of mathematics in real life…[but] I would add a twist. The problem is there is no single hour of the day when I can say that 500 passengers travelled. If the question were how many passengers per *day* it would be less abstract.
4	Facilitator:	You can adapt the problem. I certainly don't know which is preferable… Sometimes you need to try something, help students if they need it, and do it differently next time.

Readiness to enact: Developing thick anticipations by tacitly simulating students' actions

Often problem solvers ask clarification questions that they could have answered on their own (e.g., line #1 in excerpt A), or present solutions that are flawed (e.g., excerpt C). When the problem solvers are experienced mathematics teacher, one might wonder what purpose the questions and hasty solutions serve. In our experience, teachers in PD often take on behaviours that are typical of their students. We believe that this is a kind of transference (Klein, 2018), a process studied in psychanalysis where an individual's feelings and actions, which are inappropriate in the present context (e.g., PD), are a repetition of significant situations from other contexts (e.g., teachers' classroom experiences with students). However, it is not the psychological interpretation of this phenomenon that is important, but rather its affordances in PD. We posit that such questions are often teachers' implicit anticipations of students' questions. Making these questions public serves the purpose of sharing thick anticipations (Zaks, 2023) of possible responses that are 1. Specific; 2. Presented in first person voices; 3. Varied. Furthermore, the facilitator's responses (excerpt A) offer detailed teaching moves to respond to such questions. This phenomenon was repeated by many teachers, and we present a second example:

Teacher G:	Are trains permitted to stop on the way?
Facilitator:	I don't know. It's a question you need to direct to yourself at this point.

Implementation: Facilitator promoting change in discourse around innovation and its merits

Preceding excerpt B, a teacher replied to Question 2 that the old train should not be replaced because the new one transported less passengers per hour. The facilitator led three teachers to consider alternative answers based on different mathematical models of "beneficial". Making these answers public may help teachers anticipate productive responses from their students, which may increase their inclination to enact. Later (line #6) the facilitator presented some key components of the modelling cycle and discussed merits of the innovation that are not obvious, about the multiplicity of correct answers and the opportunities for all students to participate. In this he was promoting a process of implementation by leading a change in teachers' discourse on PS. Furthermore, teachers often shy away from flawed student solutions for fear that revealing the flaws will discourage these students. In excerpt C the flawed teacher-solution allowed the facilitator to explicate some pedagogical tips:

How to capitalize on errors while valuing the quality of thinking that led to them (line #8), and how to sequence a discussion based on students' work (beginning with incomplete or flawed work).

Implementation: Teachers considering adaptations and constructing agency

Excerpt D was triggered by a teacher's difficulty to deal with units of passengers per hour. We deem it significant that the difficulty served as a springboard to consider adaptations (passengers per day instead of per hour). Of note is that even though the teachers had no intention of enacting the problem in their classes, they spoke of the activity with respect to imagined students (lines #2, #3).

Summary and contribution

In this article, our goal has been to begin contemplating what might happen with mathematics education innovations at a post-implementation stage (Misfeldt et al., 2023) denoted by termination of funding for professional accreditation of the participating teachers. For this, we attended to our experience with running a voluntary mathematics club for mathematics teachers, whose operation relied on experience gained and on instructional materials developed during the funding period.

We have found that of four processes under the umbrella of implementation as defined by Koichu et al. (2021), traces of three processes—constructing agency, changing communication, and adapting the innovation—can be identified in the club discussions. This finding sheds light on the specificity of anchoring and sustainability associated with the post-implementation notion (Misfeldt et al., 2023). Furthermore, we have provided evidence in support of a hypothesis that these implementation–related processes are related to the development of the teachers' *readiness* to implement the innovation (Zaks & Koichu, 2022; Zaks, 2023) even though the circumstances prevent them from so doing in proximity to the club meetings. Namely, we found that the teachers' anticipations of what might happen with the problem of interest in a classroom were specific, varied and alluding to students' first-person voices. To this end, we attribute value to teachers' intensions to implement, and their developing experience as problem solvers and potential enactors of problems that were not easy for them to solve, even when there is no actual implementation in classrooms. We realize of course that this stance is speculative and needs to be tested by following individual teachers' future classroom practices.

Speaking more generally, we suggest that impact of R&D projects having limited periods of funding should be further explored not only in terms of the innovation dissemination with students but also in terms of its effect on teachers' knowledge, worldviews and affiliation with communities of practice (see. Cooper & Koichu, 2021, for elaboration of the notion of *impact*). Needless to say, our study is only a small step on the way to reveal diverse phenomena of post-implementation. Additional research in this direction is desperately needed.

The role of habits in a theory of change: Lessons from an implementation of interleaved practice

Andrew Grant[1] and Johan Prytz[1]

[1]Department of Education, Uppsala University, Sweden; andrew.grant@edu.uu.se;

There has been a growing call for an explicit theory of change to be used within mathematics education implementation research to improve both the coherence of the implementation and its evaluation. This paper uses a pilot study into the implementation of interleaved practice to investigate the role of habits and habit forming within its theory of change. The results showed that the teachers relied heavily on personal and easily applied routines in order to implement interleaved practice. It is recommended that for future iterations, the role of routines is understood within the theory of change with clearer strategies explicitly shared to aid the routine forming and ultimately habit formation. It is argued that the steps towards habit formation would benefit from being explicitly considered in any theory of change.

Keywords: Implementation research, theory of change, habit formation, interleaved practice.

Introduction

There is a call within implementation research to explicitly use a *theory of change* shared between all the stakeholders in order to both guide the process of implementation and evaluate its success (Jankvist et al., 2021; Century & Cassata, 2016). In this paper, we address the role of teachers' habits and routines in a theory of change. In an overview of professional development research, Kennedy (2016) explains when teachers undertake professional learning, they are not simply assimilating new ideas but abandoning an old practice, which has guided them in the past and is likely to be habitual.

The habitual nature of teaching is highlighted by Hobbiss et al. (2021), who emphasise the insensitivity of habits to goals or rewards. This seems important in implementation research, in particular given the difficulty in sustaining a reform after an initial introduction, which leads Coburn (2003) to give sustainability as one of four key dimensions needed for lasting change. In order to understand the efficacy of professional development, Kennedy (2016) questions the traditional process model, calling for more focus on strategies and theories of action. An example in this vein is Lindvall et al. (2022), who analysed the Swedish program of Boost for Mathematics and concluded that the lack of effect of the program could in part be down to the overemphasis of pedagogies of investigation (what to know) at the expense of pedagogies of enactment (what to do).

This paper aims to build on the understanding of *theory of change* by investigating the role that habits play when an innovation in mathematics education is implemented. In our case, the innovation concerns interleaved practice.

Interleaved practice, and its implementation, is a suitable case for several reasons. Interleaved practice in mathematics teaching concerns the sequencing of tasks and exercises, which is an essential part of mathematics teachers' habits and routines. Moreover, it has a growing experimental research base, but there are numerous barriers to implementing the innovation of interleaved practice, see below.

The research question is: How can *routines* and *habits* inform a *theory of change* in the case of implementing interleaved practice?

Theory

This project is within the implementation research tradition of investigating the interaction between an innovation and the real-life settings of its implementation, where an innovation is a practice that is "new to the user" (Century & Cassata, 2014, p. 82). As such implementation research examines "the ways innovations are used in practice, the impact of contextual factors on enactment, and the extent to which particular enactments have strong relationships to desired outcomes" (Century & Cassata, 2014, p. 98). A theory of change has been described as "a systematic and cumulative study of the links between activities, outcomes, and contexts of the initiative" (Connell & Kubisch, 1998) and can be shared amongst all the stakeholders for the effective implementation and evaluation of the innovation (Jankvist et al., 2021). Jankvist and colleagues argue that sharing the desired processes that lead to successful outcomes for the pupils can increase the coherence of the implementation through all its stages as well as enabling a more accurate theory-based evaluation of the implementation, that is how and why it did or did not succeed in its goals. In this paper, we focus on how habits relate to the links within a theory of change.

Teaching is complex with a high degree of repetition which leads to the need to automate tasks in order to reduce the cognitive load for the teacher (Feldon, 2007). Habits are how we characterise this automation and are understood to be structured behaviours which are triggered by environmental cues and are often insensitive to goals or rewards, particularly under stress (Hobbiss et al., 2021). Habits can offer an explanation for the levelling off of teacher performance, where after initial rapid improvement, the rate of improvement decreases or levels off entirely which coincides with habitual behaviours (Hobbiss et al., 2021). The automaticity is double edged as although it can make changing practice more challenging given habits' automaticity despite competing goals, it also reduces the cognitive load for a teacher (Feldon, 2007) and thus make a challenging profession easier. Habits form through repeated actions in response to contextual cues, but deliberate choices can hinder this habit formation (Wood & Rünger, 2016).

In this paper we use interleaved practice as case study to discuss the role of habits in a theory of change.

Interleaved practice

Interleaved practice in its broadest sense defines the practice undertaken by pupils, where the questions answered are rotated between different concepts and is best understood in comparison to the traditional blocked practice where all the questions on one exercise use the same concept and are often very similar in style. For example, a traditional blocked approach to teaching Pythagoras' theorem might have a first practice lesson with plain triangles and substituting the side lengths into the formula and solving; the following lesson would be a set of word problems where the pupils have to construct the triangles themselves before substituting the values into the formula and solving. In both sessions the pupils are practicing the execution of a single strategy (Rohrer et al., 2014). In contrast interleaved practice includes a mix of questions which require different strategies forcing the

pupil to both choose a strategy and practice its execution. For example Mayfield and Chase (2002) asked pupils to choose the correct arithmetic strategy to use from different alternatives when manipulating algebraic exponents and then execute that strategy, while Rohrer et al. (2014) used four superficially different types of problems.

The empirical research on interleaved practice has shown fairly consistent results, with the learners often initially performing better with blocked practice, but this quickly reverses with blocked learners not retaining their knowledge (Mielicki & Wiley, 2022; Rohrer, Dedrick, Hartwig & Cheung, 2020; Rohrer & Taylor, 2007). For example in Rohrer and Taylor's (2007) comparison of interleaved practice (mixers) and blocked practice (blockers), the blockers performed better in the practice with 89% accuracy compared the mixers' 60%. These results were reversed in a test a week later with the blockers at 20% and mixers 63%. In summary, within mathematics education interleaved practice seems to promotes long-term retention over short-term performance.

Teachers, who participated in a trial of interleaved practice, were positive towards the use of interleaved practice (Rohrer, Dedrick, Hartwig & Cheung, 2020). In a survey the majority reported that they believed that it had a positive effect on pupil outcomes and would be easy to assign without changing their teaching routines, even if it took a slightly longer time and the students found it a little harder.

Interleaved practice was initially concieved as an inductive category learning tool, where similar but contrasting concepts are used to foster learning. The interleaving effect was ascribed to either the contrast between the examples (discriminative-contrast hypothesis) or the increased attention paid to the examples when compared to the later problems in blocked practice (attention-attenuation hypothesis) (Firth et al., 2021). However mathematics education research has expanded the concept to include the consolidation of learning with the efficacy of this practice put down to the required conscious strategy choice combined with the known advantages of spacing and retrieval practice (Rohrer et al., 2014). Both inductive and consolidating interleaved practice could be described as a desirable difficulty (Bjork & Bjork, 2019), where the process of forgetting and remembering supports better long-term retention over short-term perfomance.

In all the experiments on interleaved practice researchers have created resources with the questions either blocked or systematically interleaved. For interleaving to become implemented widely, teachers need to have access to such resources, however there is currently a scarcity of interleaved practice in premade resources and textbooks in particular (Rohrer, Dedrick & Hartwig, 2020), meaning that teachers need to create their own. The need for teachers to generate the material brings the challenges of writing resources faithful to interleaving as a mechanism, how to disturb teacher habits to fulfill this process, and finally whether this disturbance overburdens teachers' time and energy. A theory of change which addresses these issues can only aide the implementation process.

Methodology

This paper is based on a pilot study into the implementation of interleaved practice in mathematics education. Six teachers from two Swedish lower secondary school mathematics departments were given a half day's training session, which included a theoretical introduction to understand the

advantages of desirable difficulties and the benefits of interleaved practice over blocked practice, followed by a brief discussion on how it could be implemented in a real-life classroom. The teachers had a mixture of experience from newly qualified to 10 years of experience. To track the implementation and potential habit formation the teachers' use of interleaved practice was monitored over a 2-month period in weekly 6-question questionnaires before interviews were undertaken to understand the mechanisms of change. The interviews were transcribed and then thematically coded in order to understand the usage of interleaved practice, the process of implementation, and potential repeated actions on the road to habitual use.

Results

All the teachers reported that they understood the theoretical advantages of interleaved practice and could relate to the problems of blocked practice as their earlier usage of blocked practice often led to short-term success which was not sustained in the medium or long term. However, this understanding did not lead to an easy or immediate implementation of interleaved practice, rather they all developed their own individual routines in order to embed it into their own teaching. These easily repeated actions were unique in both how they created the resources and how they implemented them in their regular lesson structure.

Newly qualified Teacher 1 described their creation process as follows:

> I was creating worksheets in the beginning but now that I'm doing relationship and change, I'm picking up questions myself. And so, I'm not trying to reinvent the wheel anymore. In the last few days, last few weeks what I did was I picked up summaries from all the [textbook] chapters. We have a test coming up and it's a big one, like some number, some algebra for A-level questions and then relationship and change, the whole chapter. So now I'm using different summaries and it's more flowing through the practice now.

The teacher described how they eventually found a more efficient and sustainable routine to create their resources. The sense of before and after finding their routine was very clear in their weekly usage of interleaved practice. In the weeks before changing the method 36% (n=14) of their lessons used interleaved practice, while afterwards this increased to 73% (n=11) of the lessons.

A second newly qualified teacher at the same school used a different routine for resource creation; they simply started using the textbook more. Although the textbook is split into sections and chapters where each section is predominately concerning a single concept, the questions within a section each addressed its concept from a different angle, for example question 1 might be a pair of simple calculations, question 2 using it in a different context, while question 3 could be slightly harder calculations and so on. This differs markedly from the teacher's previous practice of chiefly giving worksheets on one concept with repetitive problems which only practiced of the execution of that single type of problem. It is noteworthy that the intervention was only partially successful for this teacher as they did stop using blocked practice but instead of interleaved practice, they employed a form variation theory where the same concept is tackled from different angles (Kullberg et al., 2017) as opposed to different concepts in interleaving.

Within the same school the final teacher, with 10 years of experience, used a third routine. They first looked at previous presentations on the topic and the exercises in the textbook, making notes on these before adding ideas from both challenging topics covered earlier in the course and topics which are popular in the national test. Although the first steps here do not differ radically from the first teacher, this teacher then employs their pedagogical experience of teaching the course before and knowledge of the national test, tools unavailable to a newly qualified teacher, to create their own questions, stating "I think if you know the curriculum very well, for us in Sweden it's not a very complicated thing." Similar to the first teacher, this teacher took some time before finding a process that worked for them.

In summary, all the teachers used a unique routine, which they found achievable based on their own situation, experience and old routines. With some teachers this came quicker, while others took time to find a routine which was workable for them.

In addition to the routines in creating the resources there were also individual approaches to incorporating the interleaved practice in their own lessons. Generally, each teacher's individual standard lesson structure did not change, with the exception that the previous blocked practice part had been swapped out for interleaved practice. For example, the second teacher continued to have a single-question warm-up, which was reviewed as a class, before either introducing the new concept and then practice, or direct to practice. The difference now was that the practice now came in a more varied form as opposed to before they "just wasted time by answering four pages of the same question". However, it was commonly reported that this exchange of blocked practice to interleaved practice caused the practice itself to take more time, but they all assimilated this into their standard lesson pattern by adjusting the timings of their typical lesson structure, as they appreciated the advantages for the pupils' long-term learning that they gained from practicing a little longer.

Conclusion – habits in a theory of change

To understand the role of routines and habits in a theory of change we first discuss their role in the pilot, before considering its design and finally proposing a theory of change for the subsequent iterations of the project. For all the teachers in the study to implement interleaved practice, it meant not only enacting a new idea, but also abandoning a prior approach, which they did by replacing an old routine with a new one. A shared understanding that blocked practice did not deliver long term learning was not sufficient for the teachers to start using interleaved practice. To regularly implement it in their teaching they needed to translate the theory into an easily replicable routine. Each teacher had an individual journey to create their process, depending on their experience, current situation and practice, and inclination. However, the commonality amongst all the new routines was the ease of implementation for that teacher within their current situation. Although it was too early to define this routine as a new habit, a habit is formed by repeated actions in response to contextual cues (Wood & Rünger, 2016) and each teacher had found an easily repeatable routine to create interleaved practice when cued to plan the lesson.

When examining the Swedish program Boost for Mathematics, Lindvall et al. (2022) suggest that one of the reasons for its lack of effect on pupil learning was the greater reliance on the pedagogies of investigation (what to know) with less focus on the pedagogies of enactment (what to do). The pilot

study spent most of its instruction explaining the theoretical grounding of interleaved practice and so also had a heavy dependence on pedagogies of investigation whilst being light on the pedagogies of enactment. Despite this, all the teachers were motivated to change their practice, however they did this in diverse ways with all of them finding a defined routine to make the change. When describing their journeys to their new routines, they did not always find it straightforward to create one which fitted the individual circumstances. To aid the teachers in the process of finding an efficient routine, it could be beneficial to present clearer strategies to go with the theory behind the change, thus both guiding their choices of routines and reducing the difficulty in forming a routine.

When introducing these strategies, the experience and situation of each teacher needs to be considered. In the pilot study the third teacher stated how their pedagogical knowledge of the curriculum eased the creation of the resources. Clearly not all teachers have this knowledge and so the chances of success of this strategy depends on the individual teacher's experience and knowledge. To present this to a new teacher could risk either poor implementation, due to insufficient knowledge, or create unrealistic expectations, increasing the risk of not implementing the innovation. There needs to be a balance to the strategies presented which does not overburden teachers with unrealistic strategies for their situation nor presents a simplified version for those who have the greater knowledge or skills. In other words, the strategies need to be appropriate to the teachers and their teaching experience.

By understanding the implementation of interleaved practice in terms of creating new routines and ultimately habits it is possible to describe a theory of change as follows: A theoretical introduction to interleaved practice forms the teachers' understanding and desire for change; within the teacher's standard lesson structures, there must be the opportunity to replace blocked with interleaved practice; a range of appropriate strategies are introduced; each teacher needs to establish a realistic routine either from the strategies suggested, by adjusting one of these, or by creating their own; this personalised routine can straightforwardly replace the old blocked practice and eventually become habitual; and finally the pupils now undertake a more challenging form of practice and this consequently leads to more effective long-term learning for the pupil.

Discussion – the conclusions in a wider context

When considering the implications of this paper for theories of change in general it is worth considering two of Century and Cassata's (2014) five factors affecting implementations, namely the innovation itself and the individual users involved. For the implementation of interleaved practice, the innovation itself is unusual as the largest required change is in teachers' planning, which occurs outside the classroom. After substituting in the interleaved practice, it required only minor adjustments to the norms of lessons in terms of the type and length of practice, these were reported to be overcome quickly. Such adjustments depend also on the characteristics of the individual users, in this case the inclination of the teacher and the pupils who in the study quickly accepted it. In comparison, an innovation that changes a teacher's in-lesson behaviour, for example how a teacher asks questions, can be seen as much more challenging, given it is a far more dynamic environment and potentially involves a larger change to the norms of the classroom. Furthermore, habitual behaviour is stronger under stress (Hobbiss et al., 2021) and so the potentially higher stress levels in

a teaching classroom implies that habitual behaviour is more likely. This automaticity does have the benefit for the teacher of easing their cognitive load of the teacher even though it simultaneously hinders change and leads to potentially suboptimal default actions (Feldon, 2007). Given this, it could be argued that in the more dynamic in-class environment, addressing the role of habits in any theory of change is even more important.

Kennedy (2016) describes how when a teacher implements a new skill, they have to abandon a prior approach, and when this understanding is combined with teacher automaticity it implies that changing habits is core to the implementation of any innovation. It also has the potential to explain how often an innovation is not sustained after the initial intervention (Coburn, 2003); if the new practice is not made a habit, then under stress the old habit will return even if the motivation is to change. Thus we argue that a theory of change must incorporate an implicit strategy to facilitate the innovation becoming habitual. This understanding of individuals as habitual beings adds a dimension to the characteristics of individual users (Century & Cassata, 2016) and any innovation would benefit from having a plan within its theory of change of how it is going to either replace an old habit with a new one, or how it will instigate a new habit.

Teaching for mathematical competence: "Stumbling blocks" in teacher in-service training at scale

Tomas Højgaard

Aarhus University, School of Education, Copenhagen, Denmark; tomas@edu.au.dk

In this paper, I analyse a developmental process in which every mathematics teacher in the municipality of Ishøj in Denmark took part in a three-year in-service teacher training programme. The purpose was to learn to plan, organise, conduct, and assess teaching explicitly aimed at students' development of mathematical competencies. Following a description of the project, the core of the paper is an analysis of the efforts made by and collaboration between stakeholders at various levels of the developmental process. The analysis is structured around the identification of three "stumble blocks" for succeeding with the developmental endeavour.

Keywords: Mathematical competencies, in-service teacher training, development at scale, stumbling blocks.

Introduction

In the course of the latest decades, mathematics teaching in many parts of the world has been subject to curriculum reforms representing a shift from subject matter learning goals related to mathematical concepts and procedures towards learning goals described as combinations of mathematical subject matter and more mastery-oriented ambitions. This overall development in the conceptualisation of learning goals for mathematics education is well covered in the research literature. Many reports focusing on specific countries document this shift (Niss et al., 2016).

Such curriculum reforms create a need for reconsidering many other issues related to educational development. One of these issues is what it takes to teach the new mastery-oriented ambitions. In this paper, I focus on the education of practising mathematics teachers to meet this challenge, guided by the following research question: *What challenges and ways forward can be identified when conducting in-service teacher training at scale in competency-oriented mathematics teaching?*

I address this question by describing and analysing an attempt to conduct such teacher training as part of the Danish *Ishøj Project*. The approaches applied in this project was an attempt to upscale results from previous developmental research projects also focusing on competency-oriented mathematics teaching. Hence, the paper reflects a scaling (Coburn, 2003) and an implementation perspective (Century & Cassata, 2016) on mathematics education research and development, the latter in two different ways: The written curriculum is sought to be implemented as a pivotal part of the operational curriculum (Akker, 2013), and results from previous studies is sought implemented and further developed in new settings.

In what follows, I begin by describing the methodological approach, the core of the Danish competency framework, and the key elements of the Ishøj Project. Then I analyse the project guided by the research question (cf. a Danish version of this analysis in Højgaard & Winther, 2021), before finishing off with some developmental recommendations.

Methodological approach

Methodologically, I rely on what Lincoln and Guba (1985) call human instruments, i.e., that the researcher "elects to use him- or herself as well as other humans as the primary data-gathering instruments" (p. 39). In this case, these instruments are me and the municipal mathematics consultant in the Ishøj Project, throughout this paper referred to as "we". Initially, when applying for funding of the project, I designed the developmental approach to be used. Subsequently, when the municipal consultant was hired, the two of us jointly facilitated the developmental processes in the project and adapted the approach taken along the way, cf. the description below. Hence, we were there throughout the project, discussed it continuously with each other and with the other participants, made all the major decisions about the way things were done, and therefore know the rationale for and reality of what happened.

The above imply that in this paper, the Ishøj Project is used as a case study of the type that Merriam (1998, p. xiii) describes as "an intensive, holistic description and analysis of a bounded phenomenon […]." For two reasons, it also resembles a critical case, "defined as having strategic importance in relation to the general problem" (Flyvbjerg, 2006, p. 229). Firstly, Denmark can be considered something of a best-case scenario for exploring competency-oriented teaching because many circumstances have aligned to make such a teaching approach both possible and wanted, cf. the description of the local context below. Secondly, the main ambition behind the didactical design of the Ishøj Project was an attempt to systematically facilitate the incorporation of mathematical competencies as a key element in mathematics education for grades k-9 in Denmark. As one of the national experts in such an endeavour, I was quite naturally and enthusiastically the driving force behind this design, and my ambition was only met with support and joint efforts by the other key players in the project. Hence, The Ishøj Project was arguably a best-case attempt to facilitate competency-oriented mathematics teaching by means of in-service teacher training, and as such critical for exploring this endeavour. Not as a here-is-how-to-do-it-description, of course not, no such thing exists when it comes to mathematics education. Rather, the project is a critical case for in-service teacher training facilitation of the students' development of mathematical competencies in the sense of being grounded on a very thoroughly developed and research-based design and conducted under very favourable times and conditions, locally as well as nationally.

Exploring the KOM framework in a Danish context

In Denmark, the mastery-oriented curricular ambitions are described by means of a set of mathematical competencies (Højgaard & Sølberg, 2023). The scaffolding of this idea was the hub of the so-called KOM Project (KOM is an acronym for "competencies and mathematics learning" in Danish), conducted in the years 2000-2002 with Mogens Niss as the director and me as the academic secretary. The key steps in the project's analysis were—cf. Niss og Højgaard (2019)

- to move from a general understanding of the concept competence, conceptualised as someone's insightful readiness to act appropriately in response to the challenges of given situations,

- to a focus on a mathematical competency, conceptualised as someone's insightful readiness to act appropriately in response to a specific sort of mathematical challenge in given situations,
- and then identify, explicitly formulate and exemplify a set of mathematical competencies that can be agreed upon as independent dimensions spanning what it means to master mathematics.

In Denmark, the publication of the KOM report (Niss & Jensen, 2002) initiated a developmental approach, where the mastery-oriented curricular ambitions are described by means of a set of mathematical competencies. In 2009, the set of mathematical competencies proposed in the KOM report became a fundamental part of the curriculum for compulsory mathematics education (grades K-9) in Denmark (Undervisningsministeriet, 2009)—and this remains the case in the current curriculum (Børne- og Undervisningsministeriet, 2019). This process of curricular development is thoroughly described and analysed in Højgaard and Sølberg (2023). Hence, Denmark has been and still is a good place to study competency-oriented mathematics teaching head-on by establishing "naturalistic laboratories" where teachers of good will join in on experimenting with this approach. Together with colleagues, among them not least several excellent teachers, I have done so in four longitudinal, 3-10 year long case studies over the last 25 years.

The Allerød Project was a developmental research project conducted in the years 1998-2003. A central part of the project was experimental teaching at an upper secondary school in the years 2000-2002. It involved a class of 25 students, their mathematics teacher and me as the PhD student who initiated, framed, and followed the experimental teaching processes (Jensen, 2007).

KOMPIS is an acronym (meaning "buddy" in Swedish) for KOmpetenceMål i PraksIS, Danish for "competency objectives in practice". It was another longitudinal developmental research project designed to test and document a strong focus on competencies in the teaching of mathematics, Danish, and science in lower secondary school. For each of these three school subjects, a group of 3-6 teachers (from the four participating schools in the same Danish municipality), one of their classes of 20-25 students, a teacher educator and a researcher framed and carried out experimental teaching in the years 2009-2012 (Højgaard & Sølberg, 2019). I was the mathematics education researcher in the project and followed the experimental teaching processes particularly closely in one of the mathematics classrooms.

In the ongoing *Hvalsø Project*, the results and approaches from the KOMPIS Project are being used and further developed when following the mathematics teaching in one class of 20-25 students in grades 1-9 (2016-2025). As opposed to the Allerød and KOMPIS Projects, it is a design feature of the Hvalsø Project to conduct classroom experiments focusing on all the mathematical competencies described in the KOM report (Niss & Jensen, 2002) one by one, and to iteratively carry out such a "competency tour de force" at both lower primary (grades 1-3), upper primary (4-6), and lower secondary level (7-9). Hence, the project investigates and offers examples of teaching experiments focusing on the same mathematical competency (at least) three times over the course of nine grades, and with a focus on and interviews with the same students followed consistently over the years.

The Ishøj Project was conducted in the years 2014-2017, where the Danish municipality Ishøj ran a project involving all their students and all their teachers of science and mathematics in the compulsory

school system, i.e. grades K-9. The aim of the project was to develop the competencies of the students in mathematics and the various science subjects by means of developing the qualifications of the teachers involved. The hub of this development was experiments carried out by the teachers in their own classrooms, framed by bi-monthly school-based seminars for the entire group of mathematics or science teachers at each of the six schools in the municipality (Højgaard & Winther, 2021; Winther, 2017). I was responsible for the mathematics part of the project, explicitly based on the experiences and results from the KOMPIS Project. The main part of this effort was to run the more than 100 seminars (six seminars at each school each of the three year) for the group of 5-15 mathematics teachers at each school.

Collaboration between participants at different levels

Organizationally, the Ishøj Project can be characterised as a municipally anchored, school-based experiment on the development of teacher competencies. The project was established, framed and administered by the school administration at Ishøj municipality, but the developmental process needed to respect the differences between the six participating schools, and therefore had the individual school as an organizational focal point. Thus, there were effectively six parallel developmental projects in the project. Both during the process and now in retrospect, this framing of the project initiated two kinds of considerations and subsequent analysis regarding the conditions for the desired developmental processes: One about the importance of the effort from and cooperation between participants at different levels, and another about how differently such collaborations was exercised at the different schools.

The developmental process–a cooperative utopia

In the analysis of these considerations, I distinguish between the following types of key participants: The students, the individual mathematics teacher, the team of mathematics teachers at a school, the school-based so-called mathematics supervisor, the school leadership, the municipal mathematics consultant, and the municipal school leadership. In utopia, their mutual roles and cooperation can be described as follows:

- *The students* develop solid mathematical competencies because *the teacher* is good at meaningful competency-oriented mathematics teaching.
- *The teacher* is–among other things–good at it because *the mathematics supervisor and/or the municipal mathematics consultant* has taught him or her how that can be done and inspired him or her to remain committed to the developmental process.
- *The teacher feels* supported when it comes to preparation for and evaluation of the teaching, among other things because *the mathematics team* at the school is a well-functioning academic collective facilitating the teachers' development of their individual teaching practices.
- *The mathematics team* is well-functioning because–among other things–the *mathematics supervisor* puts him-/herself in front of a well-established and systematically facilitated collaborative culture within the team.
- *The mathematics supervisor* considers him-/herself well framed and supported because–among other things–*the municipal mathematics consultant* puts him-/herself in front of a well-

established and systematically facilitated collaborative culture among the mathematics supervisors at the different schools.

- *The mathematics supervisor* succeeds in managing the collaborative culture because–among other things–*the school leadership* show commitment in this and establish positive expectations about and room for it.
- *The school leadership* succeed in establishing positive expectations about and room for a developmentally oriented culture with a shared sense og direction among the mathematics teachers because–among other things–*the municipal school leadership* show commitment in this and establish positive expectations about and room for it.
- *The municipal mathematics consultant* keeps the pot boiling by communicating with and mediating between the various levels of development from the teachers to *the municipal school leadership*, among other things because the latter has chosen to employ the consultant with such a communication and mediation need in mind.

With this cooperative utopia as a frame of reference, I will now describe three experienced developmental stumbling blocks. In each case, this is accompanied by a description of what the municipal consultant and I believe are the main problematique behind the stumble stone, and by a description of what we believe may be possible ways forward.

Developmental stumbling block 1: Supervisors responsibilities and qualifications

Qualificational problematique: The municipal consultant and I had the impression that most of the participating mathematics teachers found it meaningful but difficult to teach competency-oriented–both because goal-oriented teaching in itself is demanding and because mathematical competencies are complex ambitions to pursue.

Experienced stumbling block: Mathematics supervisors are typically not qualified to teach competency-oriented mathematics teaching, simply because there is nothing even close to this in the one-year diploma program for mathematics supervisors in Denmark. Consequently, these supervisors rarely want to teach competency-oriented mathematics teaching, which, for example, was the case for all the mathematics supervisors in the Ishøj Project.

Possible solutions: The most direct answer to this challenge is to strive for the mathematics supervisor in the schools typically having the type of competency-oriented in-service education that the Ishøj Project points out is needed. A key element in this will be to develop a new educational program for the supervisors. Alternatively, as was the case in the Ishøj Project, a municipal mathematics consultant can be hired to help bridge the qualification gap. As a last resort, one can hire an external consultant to take care of teaching the supervisors, which was my role in the Ishøj Project. However, in a long-term development perspective it is the least attractive solution, partly because external contributors, as was the case in the Ishøj Project, are often only temporarily involved, partly because the external resources available are far from sufficient for a nationwide effort.

Developmental stumbling block 2: Managerial responsibilities and qualifications

Managerial problematique: In some of the schools, a few teachers opposed development and common direction, and as a result the mathematics team was not homogeneous and well-functioning.

Experienced stumbling block: The school leadership forward the problem to the mathematics supervisor, who, however, has neither formal nor actual managerial competence to handle it, and does not want to take up this role among mathematics teacher colleagues. As we experienced it, mathematics supervisors are typically driven by a subject-specific didactical interest and a desire for a collective collegial approach to developmental processes, not by managerial ambitions.

Necessary resort: The school leadership need to take responsibility for handling such individual obstructional approaches and more generally engage in and provide support and resources for the mathematics supervisor's effort to lead the developmental process of the mathematics team. At some schools, we found this to be largely the case. Among other things this was consistently manifested by the school leader closely following the developmental process and often being present in parts of the associated seminars, and therefore by self-examination being able to observe some mathematics teachers turning their back to it. In other schools the leadership was completely invisible in the development process.

In one school we experienced a remarkable change of attitude during the three years of the project. Two very experienced teachers at the school explicitly told us and the rest of the teachers in the mathematics group that they had no interest in the change of teaching approach that was on the agenda in the Ishøj Project, based on a "don't fix it if it isn't broken"-approach to their teaching. The school principal during the first year of the project had been at the school for many years and had established a tradition of not interfering more than absolutely necessary with the work of the teachers in general and the old and experienced teachers, with whom he had worked for decades, in particular. He explicitly told us this when confronted with the problems arising from the non-participation of the two experienced teachers, which left the mathematics supervisor quite frustrated. After the first year, that school principal retired, and his successor expressed a markedly different approach from day one: At a meeting about the problem, she told us and the mathematics supervisor that she would not accept anyone turning their bag to a decided joint effort, and that the supervisor should come to her if the problem remained. She then showed up at the subsequent project seminar and—following an appraisal of the project and how she looked forward to getting to know more about it—said the same thing to the whole group. The two experienced teachers somehow got the message, which paved the way for a complete change of atmosphere at the seminars, and the school changed from being the most reluctant to the most positive among the six schools.

Developmental stumbling block 3: Time and energy for development

Resource-wise problematique: Competence development of one's own practice requires time and energy for commitment over a longer period with the same focus, and many teachers and mathematics supervisors do not feel that they have these resources.

Experienced stumbling block: We experienced school leaderships forwarding the time and resource challenge to the individual teacher, justified by not wanting to interfere with the teachers' management of their time, which has been one of the burning issues in continuation of a Danish school reform in 2014. This well-meant approach caused a lot of frustration among most of the teachers affected by it and implied a completely individual approach to the preparation of teaching. In some cases, the problem was exacerbated by the leadership taking too many developmental initiatives at the same time, in the initial phase of the Ishøj Project dictated by the municipal school administration.

Necessary resort: The school leadership must actively help direct the developmental efforts by creating space for and the consequent expectation of these efforts, and the municipal school leadership must provide space for and support such a managerial focus. In the Ishøj Project, the approach within the municipal school leadership and within all the school communities developed in this direction during the three years of the project. A key element in this development was the previously mentioned, systematically introduced (by the municipal consultant and me) and managerially supported follow-up organizational meetings in continuation of each seminar for the whole mathematics team.

Developmental perspectives

The analysis of the efforts from and the cooperation between participants at different levels invites for the following developmental recommendations:

- Make sure you have, develop, or get a mathematics supervisor who is competent and would like to take on the role as *the person responsible for teaching the mathematics team competency-oriented mathematics teaching*—by conducting the teaching him-/herself and/or by collaborating with someone else who can and will carry out this task.
- *The school leadership must support and enable the supervisors to succeed,* firstly by dealing with possible individual leadership problems standing in the way of a collaborative approach in the mathematics team, secondly by engaging in and providing support and resources for the mathematics supervisor's effort to facilitate the developmental process of the mathematics team.
- *The school leadership must actively support a shared sense of direction in the developmental work* by providing room for—and the consequential expectations of—the developmental effort, and *the municipal school leadership must provide room for and support of such a managerial focus.*

Implementing PISA research to practice: a design research approach to enhance mathematical literacy

Ingi Heinesen Højsted[1]

[1]University of the Faroe Islands, Faculty of Education, Tórshavn, The Faroe Islands; ingih@setur.fo

This paper provides a theoretical exploration of how design research methodology can translate insights from PISA assessments and implementation research into actionable classroom practices in the Faroe Islands. In response to declining PISA results, the study develops humble design principles aimed at enhancing mathematical formulation skills and the use of digital tools, while integrating Communities of Practice (CoPs) into the design to foster teacher collaboration, professional development, and sustainable implementation. This collaborative approach is designed to positively influence the ecological disruption described in implementation research, facilitating the modification and integration of interventions in alignment with the designers' goals. The findings aim to support national scaling but also to provide broader insights into design research implementation processes in mathematics education.

Keywords: PISA research; implementation research; design research

Introduction

When the Faroe Islands[1] joined the PISA survey for the first time in 2005/2006, the results had a profound impact on both the Faroese education system and the broader community. The performance of students in mathematics, reading, and science was notably lower than that of any other Nordic nation (Egelund, 2006). In the following PISA cycles, Faroese results improved steadily (Højsted et al., 2016; Olsen et al., 2019) until the latest edition of the PISA assessment in 2022, in which results again plummeted (Olsen et al., 2023). Following the results of the most recent PISA assessment, various stakeholders have expressed concerns about the overall state of the education system and the application of research findings into practice (e.g. Olsen, 2024). With the support of the Faroese Ministry of Education, a group of researchers are working on bringing the accumulated research knowledge about Faroese primary school students provided by PISA into practice.

Effectively addressing these challenges demands a methodology that bridges theoretical frameworks with practical classroom application. Design research (DR) (Bakker, 2018), provides such a pathway, offering a systematic, iterative approach to developing and refining teaching interventions that are both theoretically sound and adaptable to local educational contexts.

DR has established itself as a common methodology in educational research, distinguished by its dual focus on advancing both practical solutions and theoretical insights. Conducted *in* and *for* practice, DR ensures that theoretical constructs remain connected to real-world learning environments (Bakker, 2018).

[1] The Faroe Islands is a self-governing nation within the Kingdom of Denmark, with a population of around 54,000 people (Hagstovan, 2024).

A central outcome of DR is the development of *design principles*, which are theoretically informed guidelines that emerge through empirical testing and iterative refinement. These principles act as a bridge between theory and practice, providing predictive insights that evolve from concrete classroom experiences (Prediger, 2019). In their early stages, when principles are primarily theoretical and remain untested, they are often referred to as *humble*, an acknowledgment of their preliminary status and the need for validation through further implementation (Prediger, 2019).

This paper is a theoretical exploration of how DR can strengthen the implementation of educational interventions based on PISA evidence into Faroese classrooms. Using notions from implementation research literature, the paper highlights the role of communities of practice in fostering teacher collaboration, in order to attain a sustainable innovation (Koichu et al., 2021). The guiding research question for this study is:

How can design research methodology support the implementation of PISA based educational sequences in Faroese mathematics classroom practice?

Emphasizing this question allows for an exploration of DR's role in bridging theoretical insights from PISA with actionable classroom practices.

In the next section, relevant notions on implementation research and communities of practice are presented. This is followed by an elaboration of DR methodology and of the proposed humble design principles for the intervention using selected results from the analysis of Faroese PISA data. Afterwards, the outlines of an early-stage research project utilizing these design principles are described as well as the next steps of scaling the project. Finally, concluding remarks are given on the use of DR in the early-stage project and more generally in implementation research.

Implementation research

According to Century and Cassata (2016), implementation research focuses on two primary aspects: understanding the characteristics of educational **innovations** and identifying the surrounding conditions or contextual factors that shape its enactment. The notion of innovation has been conceptualized in multiple ways. Rogers (2003) defined innovation as any idea, method, or object that is perceived as new by its adopters, regardless of its broader societal familiarity. Jankvist and colleagues (2019) proposed that innovations in educational settings should be recognized as changes in practice that are valued by key stakeholders such as teachers, students, or educational policymakers.

Koichu et al. (2021) offered a nuanced perspective of implementation research by conceptualizing it as an *ecological disruption* within the educational system. This disruption occurs as innovations are gradually adopted and endorsed in response to identified challenges or needs. The implementation process, as described by Koichu et al. (2021), involves two primary roles: the proponents of the innovation, who introduce and guide the change, and the adapters, who modify and integrate the innovation into their practices. Over time, adapters engage in four interdependent processes:

1. Developing a sense of ownership or agency regarding the innovation,
2. Adjusting communication practices within and between communities,

3. Modifying classroom practices to align with the innovation, and
4. Tailoring the innovation to address specific contextual needs.

Koichu et al. (2021) description gives rise to the perspective that successful implementation of innovations in education may be fostered by including a focus on teacher collaboration and professional development. Communities of Practice (CoPs), as conceptualized by Wenger (1998), offer a framework for understanding how practitioners learn and grow collectively. CoPs are groups of individuals who share a common interest or concern and work together to improve their practice. They can provide a space for collaboration and knowledge sharing, which can foster sustainable educational change. Hodges and Jong (2014) describe how school-based communities of practice supported an implementation process by providing opportunities for teachers to reflect on and refine their instructional decisions. In contrast, the absence of such communities hindered the effective integration of specific educational materials.

In this study, Koichu et al.'s (2021) perspective and the notion of CoPs are included into the design of the intervention.

Design research

DR is a well-established methodology in educational research, emphasizing the importance of conducting studies both in practice and for practice (Bakker, 2018). Its primary focus is to address real-world educational challenges while simultaneously contributing to practical and theoretical advancements (Bakker, 2018). DR at its core focuses on the creation of educational materials, such as tasks or instructional activities. Typically, this approach involves iterative cycles consisting of three phases: (i) the preparation and design of educational materials, (ii) testing these materials through teaching experiments, and (iii) retrospective analysis of data collected during the teaching experiments. Through repeated testing and refinement of educational materials, DR facilitates both the enhancement of design and the development of new theoretical insights.

In DR, the goal is to advance both practical applications and theoretical understanding. A key outcome of DR studies is often the formulation of design principles, which serve as guiding frameworks grounded in both practice and theoretical perspectives. These principles bridge the gap between research and practice by being informed by real-world implementation while contributing to broader theoretical insights (Prediger, 2019). However, when design principles are still in their early stages, having been developed theoretically but not yet tested or refined through practice, they are referred to as humble principles (Prediger, 2019).

Design principles may have the following structure:

"If you want to design intervention X [for the purpose/function Y in context Z], then you are best advised to give that intervention the characteristics A, B, and C […], and to do that via procedures K, L, and M […], because of arguments P, Q, and R" (van den Akker, 1999, p. 9).

Proposing humble design principles

In order to develop humble design principles, previous analysis of Faroese students' performance in PISA was used, particularly analysis of the 2022 results (Olsen et al., 2023), highlighting several areas requiring targeted intervention.

Faroese students scored significantly below the OECD average and Danish peers in mathematical modeling processes, which are formulating, employing, and interpreting (OECD, 2023). The greatest challenge lies in the process of *formulating*, where students struggle to identify and translate real-world problems into mathematical terms. This gap suggests that current instructional approaches do not adequately emphasize the full modeling cycle, particularly the initial and final stages that connect mathematics to real-life contexts (Olsen et al., 2023). Faroese students reported minimal use of *digital tools* in mathematics lessons, with 40% indicating "never or almost never" using them, compared to just 3% in Denmark. Similarly, 45% lacked experience with spreadsheets, compared to 10% of Danish students. This underuse of technology, including the underuse of spreadsheets, limits students' ability to solve data-rich problems (Olsen et al., 2023). Given the increased emphasis on digital tools in the latest PISA cycle, students' unfamiliarity with technology places them at a disadvantage when tackling tasks that require analysing, organizing, and interpreting data.

Communities of practice (CoPs) can provide essential support, enabling teachers to co-design tasks, share experiences, and reflect on instructional challenges, and to adjusting communication practices within and between communities. Such collaboration may fosters teacher ownership and ensure the effective and sustained implementation. Integrating CoPs into the design may affect the ecological disruption in a favorable manner, i.e. support the modification and integration of the innovation in alignment with the intention of the proponents of the innovation.

Using the structure proposed by van den Akker (1999), three ***humble design principles*** A, B, and C are proposed, followed by procedures K, L, and M, as well as the arguments P, Q and R:

If you want to design an educational intervention to enhance students' ability to mathematically formulate real-world situations and effectively use digital tools [to improve mathematical modelling competency and technology use in Faroese mathematics classrooms], then you are best advised to include the following characteristics:

A: *Support students' mathematical formulation process*

Provide tasks and scaffolding to help students identify mathematical concepts, variables, and relationships. Use structured prompts and realistic, context-based tasks to connect mathematics with real-world situations.

B: *Integrate digital tools for data analysis and problem solving*

Incorporate tasks using spreadsheets and other digital tools to analyse, organize, and visualize data, in order to interpret, and draw conclusions. Engage students with real-world data to enhance their reasoning and efficiency through technology.

C: *Foster collaboration and professional development through communities of practice*

Organize collaborative mechanisms where teachers achieve professional development, share experiences and reflect on the implementation of teaching sequences. Provide structured opportunities for co-designing, adapting, and refining instructional tasks. Support the adjustment of communication practices within and between communities.

To achieve this, follow these procedures:

K: Break down complex problems into smaller, manageable steps to guide students progressively through the formulation process. Provide examples of successful formulation processes as models for students to analyse. Encourage classroom discussions where students reflect on and articulate their thought processes during mathematical formulation.

L: Develop tasks that require students to input, manipulate, and analyse data within digital tools like spreadsheets. Include teacher-guided activities that demonstrate how digital tools can simplify mathematical processes.

M: Schedule regular meetings before, during, and after the implementation of teaching sequences to facilitate ongoing dialogue and reflection. Offer professional development resources to support teachers in integrating mathematical modelling and digital tools into their instruction. Involve teachers in the co-design and adaptation of tasks to align with their specific classroom needs.

This is important because:

P: Students often struggle to recognize mathematics in real-world contexts, which hinders their ability to initiate the modelling process. Providing structured support helps students independently identify and frame mathematical problems, while context-based tasks increase engagement and demonstrate real-world relevance

Q: Limited experience with digital tools, places Faroese students at a disadvantage when solving data-rich problems, such as those posed in the PISA mathematics assessment. Integrating technology aligns with modern mathematical practices, prepares students for technology-driven problem solving, and fosters deeper understanding of data analysis and interpretation.

R: Collaboration through communities of practice supports teacher ownership, improves instructional practices, and supports a sustained implementation by shifting the modification and integration of the intervention towards an alignment with the intentions of the designer.

Project MAC (Mathematics in action)

The proposed humble design principles are the foundation of a design intervention currently in progress in the Faroe Islands. The intervention is taking place in three Faroese lower secondary schools, and it consists of the design of two teaching sequences per year for grade 7 (sequence 1a and 1b), grade 8 (sequence 2a and 2b), and grade 9 (sequence 3a and 3b). Each teaching sequence spans three weeks (15–20 school hours). Sequences 1a, 2a, and 3a focus on mathematical modelling, especially on the process of *formulating*, while 1b, 2b, and 3b include the use of digital tools in this work. The iterative process of design, testing and refinement takes place during a 4-year time period. A community of practice (CoP) is established between mathematics teachers in grades 7-9 at the participating schools.

School A functions as a pilot school that is one year ahead of schools B and C in terms of the implementation process, see table 1.

Table 1: Timetable of implemented teaching sequences and BC´s in project MAC

Timetable project MAC		School A	School B	School C
2024	Autumn	1a		
2025	Spring	1b - **BC1**	**BC1**	**BC1**
	Autumn	1a, 2a	1a	1a
2026	Spring	1b, 2b – **BC2**	1b – **BC2**	1b – **BC2**
	Autumn	1a, 2a, 3a	1a, 2a	1a, 2a
2027	Spring	1b, 2b, 3b – **BC3**	1b, 2b – **BC3**	1b, 2b – **BC3**
	Autumn	1a, 2a, 3a	1a, 2a, 3a	1a, 2a, 3a
2028	Spring	1b, 2b, 3b – **BC4**	1b, 2b, 3b – **BC4**	1b, 2b, 3b – **BC4**

Prior to the introduction of each teaching sequence, the involved teachers participate in a professional development module developed specifically for the teaching sequence. Once during and once after each implementation period, the local CoP is activated in an evaluation and reflection session. In addition, every spring there is a *between communities* (BC) seminar, fostering cross community communication, collaboration, and sharing of experiences.

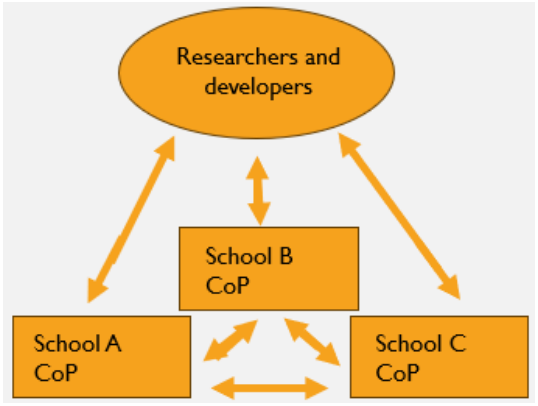

Figure 1. Supporting CoPs within and between communities

Figure 2. Task booklet cover from sequence 1a

The early-stage research project has begun in School A, with the establishment of a CoP and the first iteration of testing of sequence 1a.

The effectiveness of the intervention will be measured using both qualitative (interview with teachers and school principals) and quantitative methods (student questionnaires and tests), with a key measure being the PISA 2029 results. The full participation of the Faroese student population in the PISA

assessment enables rigorous comparisons and accurate tracking of progress in the three selected schools, leveraging the unique small-scale dataset for precise evaluation.

The project aims to scale up the intervention to the entire Faroese education system, contingent on the successful implementation of the initial phases. With funding and support from the Faroese Ministry of Education, the refined teaching sequences and professional development modules will be extended to all schools nationwide.

Concluding remarks

The paper has highlighted how DR can provide a systematic and iterative framework to support the design of educational interventions aiming to alleviate identified deficiencies in mathematical literacy. By bridging theory, practice, and teacher agency, this study addresses the specific challenges within the Faroese educational context while also offering broader insights into the application of DR and CoPs in implementation processes within mathematics education. The integration of iterative design cycles, teacher collaboration, and targeted interventions demonstrates how DR may drive meaningful educational change by aligning humble design principles with classroom realities. CoPs provide support by enabling teachers to co-design tasks, share experiences, and reflect on instructional challenges, while also facilitating adjustments to communication practices within and between communities. Such collaboration fosters teacher ownership and ensures the effective and sustained implementation of interventions. By integrating CoPs into the design, the ecological disruption described in implementation research may be influenced in a favorable manner, supporting the adaptation and integration of innovations in alignment with the intentions of the designer.

Based on a literature review, this paper investigates the challenges and strategies involved in scaling educational innovations in mathematics education. The study focuses on small, medium, and large-scale implementations, highlighting the necessity of maintaining core innovation ideas, the determinants, during adaptation processes. It highlights that small-scale implementations succeed due to close contact between developers and users. In contrast, medium and large-scale implementations face complexities due to reduced developer involvement and varied material supports. The study emphasizes the critical role of voluntarism and sustained support in medium-scale projects. Furthermore, it questions the feasibility of large-scale reforms, particularly those requiring shifts in teaching practices, without significant resource allocation and structural support.

Keywords: Mathematics education, innovations, implementation, scale.

Introduction

In mathematics education, the successful implementation of innovations is often marked by adaptation challenges within diverse educational contexts. These challenges are particularly pronounced when scaling from small, localized projects to broader, more extensive implementations. Innovations in education, while necessary for addressing persistent issues such as the gap between curricular goals and student outcomes, require careful consideration of the context in which they are implemented.

Drawing on insights from a systematic literature review of implementation research in mathematics education (Ahl et al., 2023), where the results reported here can be considered to be serendipity findings outside but close to the second research question asked in the review "Which innovations from research in mathematics education have received such attention that they have been implemented in teaching practice and reported in implementation research?" (Ahl et al., 2023, p. 139). This paper narrows down on the question and asks: *What are the characteristics of innovations implemented successfully on small, medium, and large scales, respectively?* We use our insights about scaling at different levels, where we have identified characteristics of studies that can be classified as medium-scaled projects concerning the contact, material, and organizational factors for the implementation (Aguilar et al., 2023) to categorize the characteristics in relation to scale. The novelty of this paper is thus that we provide insights into the practicalities and challenges of educational reform for different innovations across varying implementation scales.

IR theoretical constructs applied

We depart from a pro-adaptability perspective (Century & Cassata, 2016); that is, we recognize that any innovation will be adapted to the educational context in which it is implemented. Adaptations are

necessary and expected, but they must be made without losing the innovation's core ideas (Ahl et al., 2022). The core ideas can be described in a set of norms called determinants (Chen, 2012). The determinants must continue to apply when the innovation is adapted to the context. If the determinants are lost, the idea with the innovation is lost.

To categorize the studies in our review, we adopt a classification framework for small, medium, and large-scale studies, as presented by Aguilar et al. (2023). Our understanding of scaling is aligned with Coburn's (2003) definition. Coburn outlines four critical dimensions necessary for effectively scaling educational reforms: depth, which entails profound changes in classroom practices and teacher beliefs beyond surface-level modifications; sustainability, which focuses on the enduring nature of reforms despite evolving circumstances; spread, which involves both the expansion of reforms to additional schools and their deep integration into existing systems; and the shift in reform ownership, which emphasizes transferring control from external parties to local educators and institutions to ensure that reforms are ingrained and maintained internally.

To move away from a model where the innovation designer continues to play a central role in enacting innovation, we consider three key factors: the interaction between developers and users, the nature of material support, and the organizational structure (Aguilar et al., 2023). These elements help distinguish between small-scale and large-scale projects. Typically, small-scale projects involve direct developer involvement, less sophisticated material support, and a central role for developers within the organizational framework. In contrast, large-scale projects generally feature limited direct contact between developers and users, more advanced material supports that enable independent operation, and organizational structures that do not centralize the developers' roles.

An emerging concept is the medium-scale implementation project, combining features of small-scale and large-scale projects (Aguilar et al., 2023). In medium-scale projects, responsibility for adapting the product shifts to the user, with developers potentially serving as training multipliers to support broader dissemination. Various scenarios for medium-scale projects exist, such as leveraging existing resources to scale up within a specific locality or using trained personnel to launch new projects elsewhere, possibly maintaining close contact to ensure implementation fidelity. As illustrated in Table 1, these examples demonstrate the diverse nature of medium-scale projects, which bridge small and large-scale efforts.

Table 1: Classification of implementation projects according to the contact, material, and organizational factors at different scales (adapted from Aguilar et al. 2023, pp. 18-20)

	The contact factor	**The material factor**	**The organizational factor**
Small-scale implementation projects	Participants in the project have direct contact with the innovation designers.	The material support structures for participating in the project are not yet so developed that it is possible to start working on the project	The organizational support structure is set up in a way that involves the developers in a central position

		without direct contact with the innovation developers.	
Medium-scale implementation projects,	Participants in the project have direct contact with the innovation designers or other experts assigned by the developers, mainly for monitoring purposes.	The material support structures for participating in the project have been developed so that it is possible to start working on the project without direct contact with the innovation developers. These structures might be complemented with locally produced instructions. When new teachers start working on the project, the material support structures for participating must be accompanied by expert developer support.	The organizational support structure includes experienced implementation teachers as advisors in a position where fidelity to the implementation ideas can be overseen and enforced. Organizations that do not involve developers in central positions but use developers or persons assigned by the developers as experts can set up an organizational support structure.
Large-scale implementation projects	Most participants in the project have no, or at most, sporadic direct contact with the innovation designers.	The material support structures for participating in the project have been developed so that it is possible to start working on the project without direct contact with the innovation developers.	Organizations that do not involve developers in central positions can establish an organizational support structure.

Method

The literature review commenced by utilizing the ERIC database as the primary source. The structure of our review adhered to the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines (Moher et al., 2009). We searched for manuscripts containing the term "implement*" within the title and/or abstract across the top 20 journals in our sample, as identified by Williams and Leatham (2017). To ensure thoroughness and that no relevant articles were missed, we replicated the search for "implement*" in the title and/or abstract directly on the websites of each of these 20 journals. This process resulted in identifying 1,093 peer-reviewed articles that met our inclusion criteria. The selection process followed PRISMA's four key steps: (1) identification, (2) screening, (3) eligibility, and (4) inclusion (Moher et al., 2009). The literature search was conducted on February 4-5, 2021. We conducted an additional follow-up round where we incorporated articles that met our search criteria from the newly established journal *Implementation and Replication Studies in Mathematics Education (IRME)*, as well as from a special issue on implementation in *ZDM—Mathematics Education* that was published after our initial systematic search.

We revisited our search across the 20 journals initially included in our review to identify any new studies published between February 4, 2021, and August 26, 2022. In May 2023, we repeated this search for IRME and the 20 journals, focusing on articles published after August 26, 2022, with an official publication date of 2022. This approach was intended to ensure we covered complete publication years rather than partially including articles published in 2023. The review process management was facilitated by the software Covidence.

Each article underwent a two-stage screening process and was reviewed by two independent reviewers. Papers were included based on their alignment with Century and Cassata's (2016) definition of Implementation Research (IR). According to this definition, innovation refers to the practical application of ideas derived from research to enhance education. The final sample included 103 papers.

Data extracted from these papers included general information such as the authors, title, purpose statements, country of the study, research questions, methods, target group, and results. Specific information regarding the implementations covered aspects such as the type of innovation in mathematics education, the goals (whether short-term or long-term), the phase of implementation being studied, the stakeholders responsible for the implementation, and factors identified as influencing the outcomes. Due to space limitations, it is impossible to include 103 references. We refer to Ahl et al. (2023) for complete information on the review methodology and a full reference list. This paper refers to articles showcasing trends we have identified in our review.

Results

Implementing innovations at small scale

Innovations implemented on a small scale generally work and positively affect teachers' and students' learning of the content and/or teaching model the innovation addresses. The close contact with innovation designers ensures that the teachers' adaptations align with the determinants. We have chosen Stylianides and Stylianides (2009) as an illustrative case for this category. The authors develop and implement an instructional sequence designed to help students recognize the limitations of empirical arguments in validating mathematical generalizations and the need for proofs. It is based on a 4-year design experiment in an undergraduate mathematics course, focusing on cognitive conflict to achieve learning goals. The first author, G. Stylianides, conducted the last research cycle reported in the article, describing a close match between the classroom community's hypothetical and actual learning trajectories. The innovation designers developed and implemented the innovation and ensured that the adaptations made in the design process aligned with the determinants.

Implementing innovations at a medium scale

Innovations implemented on a medium scale are generally successful when participation in the project is voluntary. We have chosen the TRIUMPHS project (Barnett et al., 2022) as an illustrative case for successful medium-scale projects based on voluntary participation. The TRIUMPHS project integrates primary historical sources into undergraduate mathematics instruction through Primary Source Projects (PSPs), which combine historical materials with curricular resources to enhance students' understanding. These PSPs offer flexible, open-source content for instructors and are

designed to replace traditional textbooks. The success of the TRIUMPHS project was significantly influenced by its innovative structure, adaptable materials, detailed instructor guidelines, and ongoing support from experts assigned by the developers. As Aguilar et al. (2023) highlight, the strong collaboration between creators and users, which evolved into a co-production model, is a key factor in TRIUMPHS' success alongside the high adaptability of the materials.

Often, medium-scale projects based on something other than voluntarism have mixed outcomes regarding innovation implementation (Alarcon & Stoudt, 1997; Beswick & Jones, 2011). While some teachers find sufficient support for innovation enactment, even though innovation designers are not in direct contact or have little direct contact, the support is insufficient for others. Not surprisingly, it seems that teachers who do not voluntarily participate in the implementation project generally need more support than teachers who do participate voluntarily.

Implementing innovations at large scale

When it comes to large-scale innovations, we see that what works is changing the content of curricula and the sequencing of tasks in teaching materials as long as it does not require changes to teaching practice (Prytz et al., 2022). Both Stylianides and Stylianides (2009) and Barnett et al. (2022) implementation projects had not worked to implement on a large scale in their current project organization, according to Aguilar et al. (2023). For Stylianides and Stylianides (2009), the close contact with the innovation designs is impossible to maintain on a larger scale. For Barnett et al. (2022), the voluntariness factor is difficult to maintain on a large scale. Having established this, we want to convey what else we found does not work concerning large-scale projects.

Implementing so-called Process Standards on a large scale is very difficult. Process Standards mean that the innovation aligns with or is inspired by the National Council of Teachers of Mathematics (NCTM) recommendations for K-12 education, outlined in the *Principles and Standards for School Mathematics* (NCTM, 1989). These standards emphasize problem-solving, reasoning and proving, communication, representation, and making connections, reflecting a shift from teaching mathematical facts to focusing on the processes involved in doing mathematics. Overall, it appears difficult for teachers to change their routines. Even when teachers say they are positive about reforming their teaching practice, they fall back to the more traditional teaching they are already used to. We illustrate this phenomenon with Stickles (2011). She found three broad categories in her study of 50 elementary school teachers enacting a new Standards-based curriculum. The vast majority, 80%, are categorized as *Growing reformists*. They are positive about a changed teaching practice but do not succeed in thoroughly changing it. There are some superficial changes, but the determinates (Chen, 2012) of the innovations are not implemented with depth (Coburn, 2003), so-called benign positive appraisal (Gregoire, 2003).

Reformed teaching in line with NCTM Standards is also of great interest in teacher training courses. A significant research issue in teacher education is the disconnect between the practices endorsed by university credentialing programs and the methods teachers use in K-12 classrooms (Gainsburg, 2012). Specifically, mathematics credential programs often advocate for reform-oriented practices, yet mathematics instruction continues to follow traditional methods. Various explanations have been suggested for the limited adoption of university-endorsed teaching practices, including new teachers'

challenges in navigating the 'two worlds' of university and school, the complexity of reform-based teaching, and the shortcomings of the conventional teacher-preparation model, which emphasizes general pedagogy before specific instructional techniques.

Conclusions and hypotheses

In Aguilar et al., 2023, we coined the term medium scale from the size of the project organization. In this paper, we change the starting point and consider the characteristics of the innovation in relation to the scale of the implementation. For small-scale implementations of innovations, close contact with the innovation designers ensures that the teachers receive sufficient support to implement the innovation without adaptions violating the determinants. However, the critical question for all mathematics education research is how to plan and scale successful innovations so that they reach large groups of teachers and students. We hypothesize that if small-scale studies are used in a pilot phase before a more significant scale-up, authentic situations with representatives of the large-scale target group are needed to try out the innovation. The innovation designers need to create a small-scale authentic situation with support for the teachers similar to the support planned for the large-scale implementation if the small-scale project is to provide information on whether the teachers can implement the innovation without making adaptations that conflict with the determinants.

We doubt that close contact with designers who teach models to teachers, as in the project by Stylianides and Stylianides (2009), can work on a medium or large scale because it requires, by definition, a distance from innovation designers.

In the medium-scale implementation, where contact with the innovation designers is carried out through facilitators who mediate between innovation designers and the teachers' enactment, voluntariness is a success factor. While teachers who are optimistic about the innovation and the changes in practice required succeed well even when the contact with innovation designers is a step away, teachers who are not initially optimistic about the innovation need more support for enactment than is usually offered on a medium scale. However, it is also possible that positive teachers in medium-scale projects exhibit what Gregoire (2003) calls benign positive appraisal, which means that only superficial changes to teaching practice occur. The teacher is convinced that the teaching is entirely in line with the innovation, which puts obstacles in the way of change. Despite the danger of benign positive appraisal, we hypothesize that teachers with a well-functioning practice can handle a lower degree of support than those who already struggle with their teaching routines.

For large-scale projects targeting all teachers in a district or country, we hypothesize that the only innovations with prospects of success are innovations that concern changes in subject content and the order in which mathematical content is taught (without demands for changed practice). These innovations can be implemented in detail through curricula.

Innovations aiming to implement process Standards do not seem possible to implement with significant effect at scale through curricula alone. We hypothesize that the kind of support and contact with innovation designers described for small and medium-sized implementation projects is required. This, in turn, means that it is very resource-intensive to implement innovations that require changes

to teachers' routines. However, if the goal is to implement reformed teaching, teacher education must also work toward changing practices.

Regarding teacher training, our review has shown that future teachers are told that teaching must be done through problem-solving, classroom discussions, reasoning, and inquiry-based practices. However, they rarely get to practice these practices. We hypothesize that we will not see an impact of Standards-based teaching practices if the students are not taught according to these principles and are allowed to practice these teaching models during their education. Then, we can mix up the existing staff of teachers with recent graduates who can carry out Standards-based teaching. These may also function as support for the large majority of teachers who are positive about change but fall back to traditional routines for teaching.

In conclusion, after delving into 103 articles on implementation projects, we cannot emphasize enough how difficult it is for teachers to change their classroom routines regardless of good intentions to change practice. Gaps may exist between the teacher's intentions and her routines, most of which are too automatic to be controlled (Sfard, 2023). The consequence of the strength of teachers' established routines is that determinants are often lost in favor of adaptations that align with the teacher's established routines rather than the innovation determinants.

Implementability of programming and computing education: Accommodative and assimilative approaches to turtle geometry

Morten Misfeldt,[1] Jack Kallo,[1] Cecilie Carlsen Bach,[1] Raimundo Elicer,[2] Uffe Thomas Jankvist,[3] Andreas L. Tamborg[1]

This paper explores the challenges and opportunities of integrating programming and computing into mathematics education through two approaches: computational thinking (CT) and computational literacy (CL). Using a turtle geometry activity as a case study, we compare their potentials and challenges in relation to supporting implementation efforts. We introduce a distinction between assimilation and accommodation to illustrate how CT and CL differ. The results shows that CT adds new methods to existing practices (assimilation), while CL transforms mathematical concepts (accommodation). In that sense CT aligns with current practices, while CL requires a deeper conceptual shift. We discuss the challenges of implementing programming and computing in mathematics and the value of differentiating between assimilative and accommodative innovations.

Keywords: Computational thinking, computational literacy, turtle geometry, implementation.

Introduction

In recent years, there has been an increased emphasis on integrating programming and computing in mathematics teaching, a shift that has proven challenging to implement effectively (Tamborg et al., 2024). While computing holds potential to enrich the learning experience, its integration often encounters significant obstacles. For instance, tools like Scratch, which can be used to draw geometrical figures, tend to confuse students by requiring an understanding of external rather than internal angles, thus complicating rather than clarifying mathematical concepts (e.g., Elicer & Tamborg, 2023). This has led to critical voices arguing that computing adds little to the existing curriculum (Kilhamn et al., 2021). The value of using computational methods for working with tasks that are already part of the traditional mathematics curriculum is in large a matter of perspective. Some even contend that computing is not inherently mathematical and therefore should not be a part of mathematics instruction (Kilhamn et al., 2021). Moreover, the competency gap in relation to computing education further hinders its effective implementation (Bocconi et al., 2022; Wilson et al., 2010).

One potential reason for these challenges is that current efforts to incorporate programming and computing into mathematics are unclear about disciplinary stability and boundaries. Often, we assume that both school mathematics and programming/computing are stable and well-defined. But for Seymour Papert—one of the earliest and most influential proponents of programming and

computing in relation to mathematics teaching, the entire idea is to challenge and transform a flawed "paper and pencil mathematics" (Papert, 1980).

In this paper, we use the Piagetian concepts of assimilation and accommodation to explore different approaches to integrating programming and computing into mathematics, and how these approaches influence the implementability of this effort. Specifically, we investigate the difference between viewing programming as merely adding new and foreign phenomena into the mathematics classroom and viewing programming and computation as something that alters the underlying concepts and phenomena of classical mathematics. We look at two frameworks/concepts that view the interplay between programming and mathematics in slightly different terms: Computational Thinking and Computational Literacy (CL). CT emphasizes that certain new practices related to decomposition and algorithmic thinking are incorporated into mathematical problem-solving practices, whereas CL emphasizes the development of new ways of thinking and understanding through computational practices. Based on this, we ask in which ways do CT and CL potentials for implementation differ? In which ways do CT and CL differ regarding implementability? By analysing these two frameworks in the context of a classical mathematics activity—turtle geometry—we seek to contribute to the discussion of implementation and implementability, by showing how a difference in framing and theoretical understanding can greatly matter to the way a specific type of activity is received in mathematics education practice.

Computational thinking and computational literacy

Originally introduced by Papert (1980) in the book *Mindstorms* from 1980 and revitalized by Wing (2006) in the influential short paper from 2006, *computational thinking* (CT) emphasizes "thinking like a computer scientist" through abstraction decomposition and problem-solving. In recent years, research on CT in mathematics and science teaching has expanded, resulting in multiple definitions such as the framework of Weintrop et al. (2016) and of Pérez (2018). Weintrop et al. (2016) focus on four practices: data practices, modelling and simulation practices, computational problem-solving practices, and systems thinking practices. Pérez (2018) focuses on integrating computational thinking (CT) dispositions—tolerance for ambiguity, persistence, and collaboration—into mathematics learning.

Before Wing's (2006) paper, and long before the broader push for CT as part of the school system, diSessa (2000) introduced the concept of computational literacy, focusing on the broader transformations to cognitive and social structures that computational technologies provide, rather than just on developing technical skills and thinking like a computer scientist. Later, diSessa (2018) defines literacy as a significant cultural achievement, and views CL as a new form of literacy that emerges when digital technologies reshape how people think and learn (diSessa, 2018). Unlike Wing (2006), diSessa (2018) argues that computational literacy should not have a specific affinity to computer science and computer scientists; instead, it should be seen as an important way of *being* and *learning*, adaptable to various disciplines and contexts.

Implementation and Implementability

According to Koichu et al. (2021), implementation in mathematics education can be conceptualised as a "disruption to a particular mathematics education system, through the gradual endorsement of innovation in conjunction with an action plan" (Koichu et al., 2021, p. 986). Further, Koichu et al. (2021) argue that implementation in mathematics education takes place in an interaction between the proponents and adapters of an innovation (Misfeldt et al., 2023). This interactive approach to understanding implementation highlights the importance of the ideas, beliefs and conceptualisations that all involved stakeholders have about the purpose and nature of the innovation. This also includes how much an innovation is invited into a reshaping of the practice it is intended to support. Sometimes implementation of innovations can lead to radical changes to practices that can be hard to grasp from a perspective as deeply embedded in an existing practice (Misfeldt & Aguilar, 2024). We do see the introduction of programming and computing in mathematics teaching as very unclear in relation to how disruptive this innovation is, and CL and CT views the transformative potential in very different ways.

With a metaphor from Piagetian psychology, the integration of programming and computing into school mathematics can be seen as either an *assimilative* or *accommodativ*e process (von Glasersfeld, 1995). Assimilation refers to incorporating new information connected to existing knowledge without altering these. On the other hand, *accommodation* is the process in which new information requires a restructuring of previous knowledge. We use this distinction to describe how CT and CL interact with the establishedpractice of mathematics teaching. Assimilative approaches adapt computing content to fit within our pre-existing understanding of mathematics, preserving the discipline as we (as well as teachers and students) know it. In contrast, accommodation describes a situation where new ideas necessitate a fundamental rethinking of school mathematics. These concepts have previously been used to discuss technology adoption in organizations (Reinking et al., 2000), highlighting that accommodative changes are often much more difficult to reach than assimilative. However, accommodative approaches are sometimes necessary to reach the benefit from radical innovation.

Context and case

At the Danish Knowledge Centre for Digital Technology Comprehension, we explore how children and young people can critically and constructively co-create the digital technologies shaping their lives. Our ambition is to ensure everyone, regardless of gender or background, understand digital technology to participate as democratic citizens in a digitized society. The TC curriculum includes digital empowerment, digital design, computational thinking, and technological agency, with a focus on both integrating TC into subjects like mathematics and developing TC as a topic on its own.

Turtle geometry activities are designed to integrate elements of both geometric understanding and basic programming in primary school mathematics education, specifically aimed at students in grades 7–8. This type of activity was originally created by Seymour Papert, who used a digital "turtle" to help learners explore triangles and angles. By programming the turtle with commands like `FORWARD 50` and `RIGHT 120`, students can draw equilateral triangles and experiment with different angles to create various types of triangles. This hands-on approach deepens understanding

of geometric properties, such as angle sums and symmetry, while also developing problem-solving skills and creativity in line with Papert's constructionist learning philosophy.

Through this activity, students can apply their geometric knowledge, first in a physical context and then translate this understanding into a Scratch programming framework, providing them with deeper insights into both mathematical and computational concepts.

Results

One way of looking at turtle geometry activities is as a way of accessing geometry through algorithmic, step-by-step actions. This aligns with a CT approach. Students work with geometric figures such as triangles by following sequential movements based on established mathematical geometry knowledge/concepts, such as angles and lines, and these concepts remain stable and unchanged. This part of the activity is assimilative, as both the mathematics and CT competences are familiar and unchanged. Students apply their existing knowledge of geometry and algorithmic thinking in a new context, but their fundamental understanding remains intact.

But one could also tell another story about turtle geometry. A geometry building on movements (such as *forward* and *turn*) rather than gestalts (such as *lines* and *polygons*) is, in a sense, a *different* geometry. Building curves from inner movements, using recursion and iteration as key building blocks leads to different geometrical insights that are difficult to see from the perspective of computational thinking.

When the perspective on the activity shifts to a CL perspective, students are introduced to a curve and movement-based approach to geometry using Scratch. In contrast to looking at this through the lens of CT, where geometric concepts are applied in a familiar and stable form, the Scratch infrastructure enables a new way of interacting with geometry. Students now work with a sprite that has an orientation in space, and they define geometric figures based on vector-based understanding, where direction and movement in space are central. This vector- and movement-based geometry represents a change in how students understand and manipulate geometric phenomena. Although mathematical concepts such as angles remain the same, this digital approach requires students to restructure their cognitive schemas to integrate the new technology and the understanding of vector-based geometry. Therefore, this part of the activity is accommodative.

One activity that highlights the difference between classical geometry and turtle geometry is finding the sum of the angles in polygons. In classical geometry, the sum of the angles in a triangle is always 180°. As the number of sides in a polygon increases, the sum of the interior angles also increases. This can be proven by adding a triangle to an existing polygon: for example, a quadrilateral (4 sides) has an angle sum of 360° because it can be formed by adding a triangle to a triangle. To form a pentagon (5 sides), another triangle is added, increasing the angle sum by 180°, and so on.

In turtle geometry, instead of counting the interior angles of a polygon, we measure the change in direction as we move around the shape. This approach leads to a remarkably simple result: all polygons, regardless of the number of sides, have a total angle sum of 360°. This is because the total change in direction for a complete loop around the shape is equivalent to a full circle, or 360°.

In our own work, we have also seen this phenomenon and the problems it can lead to. We examined the work of an expert teacher, who co-designed and implemented an innovative task integrating block programming into a sixth-grade geometry lesson (Elicer & Tamborg, 2023). While the teacher effectively adapted the innovation to align with her expertise and pedagogical values, the outcomes were mixed, highlighting challenges in combining computing and programming with mathematics teaching. Despite her efforts to balance change and continuity, her revisions sometimes led to unintended learning outcomes, suggesting a need for an integrated expertise in both programming and mathematics education (Geraniou et al., 2024).

From a CT perspective, the task draws on familiar school-level geometry content and competences from CT on algorithmic stepwise actions and part/whole relations. Both mathematics and CT are stable and unchanged. The task of the teacher would be to articulate and make sense of the interdisciplinary relations between CT and mathematics. From a CL perspective, the task introduces curve-based geometry. Contrary to the CT perspective, the scratch infrastructure provides a way of interacting with geometry based on a sprite with an orientation in space. Students define outer and not inner angles of geometrical figures.

The different approaches to programming and computing in mathematics teaching and learning described in the case above show that the CT here acts in an *assimilative* manner respecting the nature of school mathematics. Furthermore, few new mathematical insights are provided when working with turtle geometry, but it allows students to enact CT in a mathematical context. On the contrary, the CL approach challenges the existing school mathematics allowing students to develop entirely new perspectives on geometry. However, the latter is difficult. Especially at scale (Aguilar et al., 2023).

Discussion: Difficulties implementing programming and computing

To understand the difficulties in implementing computing and the differences between a CL and a CT approach, we will describe a historical development and show an example from the ongoing work implementing computing and programming.

A historical account of computing and programming can be seen in two waves (Misfeldt, 2022). The first wave in the 1980s saw the integration of technology into classrooms, particularly in mathematics education, promoting creative approaches. Abelson and diSessa (1980) and Papert (1980) were driving figures in this movement. However, interest waned by the 1990s due to mixed results and a shift toward task-oriented software use.

Currently, a second wave of technology education is underway. Beginning in the mid-2000s, rather actively building on CT and Wing's (2006) work. This second wave, unlike the first, is driven more by political decisions, requiring significant educational capacity building and consideration of the balance between STEM career preparation, equity, and citizenship.

In brief, the first wave of computing and programming in mathematics teaching was in large shaped by the progressive and radical ideas by Papert and diSessa. And in that sense, this approach was based on a less developed version of what is now referred to as CL, whereas the second wave was very directly related to CT. And history is a hard judge, CL did not work, but CT did.

From the above description, it becomes evident that the way computing and programming are framed within mathematics teaching significantly impacts their integration into the curriculum. A focus on computational literacy and a radical reform of school mathematics may appeal strongly to a small group of scholars and educators who are already aligned with these ideas but are likely to fall short in engaging a larger group of mainstream teachers. Table 1 below illustrates the differences in CT and CL in terms of who are likely to be proponents of the two innovations, adaptors/adopters, the ownership one could expect, and the type of transformation the innovation will lead to. In contrast, when we frame computational thinking in terms of problem-solving and competence development while emphasizing its relevance for the labour market, it appears to offer a more accessible approach for mainstream mathematics teachers. Hence, this perspective may facilitate broader acceptance and smoother integration of programming into the standard mathematics curriculum.

When applying the theoretical framework by Koichu et al. (2021) on implementation to the context described, we see clearly why this has been the case and why it might not need to be like this. The framework highlights that the implementation of innovations in mathematics education, such as programming and computing, depends on stakeholders' beliefs and perceptions of the innovation's purpose and potential for disrupting existing practices. In Table 1 we compare the two approaches on parameters relevant for implementation according to Koichu et al. (2021).

Table 1: Proponents, adaptors, adopters, ownership and transformation as key differences in the implementability of computing and programming in mathematics education depending on if you build upon a CT or a CL style of thinking

	Proponents	**Adaptors and adopters**	**Ownership**	**Transformation**
CT	Political system and industry	Teachers Teacher trainers and educational institutions	Mainstream – high among many	Low
CL	Scholars	Teachers and non-profit organizations	High among few	High

The table shows how the different factors draw in the same direction. Apart from being assimilative toward school mathematics, our initial impression is that the CT approach also has more influential proponents and a much broader base of ownership than the CL approach (Bocconi et al., 2022). This full understanding of the implementation ecology around CL and CT will require further research, but Table 1 suggests that several factors influence this.

Conclusion

In this paper we have introduced the Piagetian concepts of assimilation and accommodation to explain the difficulties that transformative educational ideas can meet in implementation. We have further discussed how CT and CL as two approaches to computing and programming exemplified this difference. To do that, we have analyzed the case of turtle geometry and shown that CT acts in an

assimilative fashion towards school mathematics, adding a new topic but stabilizing central elements such as problem-solving and algebra. On the other hand, CL acts in a much more accommodative fashion, questioning and transforming key elements of school mathematics. More research is needed to understand the actual reasons why CT is more successful than CL in mainstream implementation, but this paper has shed light on the transformative nature as one factor in the question of implementability.

Success in implementation in early mathematics education - Fidelity and/or adaptation?

In this paper, the tension between fidelity and adaptation is elaborated on within the context of a large-scale implementation of a preschool mathematics innovation. We elaborate on how fidelity and adaptation can be understood in relation to depth, sustainability, spread, and shift in ownership. The results show that fidelity may hinder ownership while adaptations, when they are productive, may indicate depth, spread, sustainability, and ownership and thus be empirical evidence of successful implementation. The challenge in implementation research, then, becomes to clarify what adaptations that may be productive as they do not distort the core elements of the innovation. These results must, however, be seen in the context of Swedish preschool, where preschool teachers are qualified and expected to make productive adaptations in relation to the children they teach.

Keywords: Implementation, fidelity, adaptation, early mathematics, preschool.

Introduction

According to Century and Cassata (2016), implementation research is the endeavour to understand whether and how educational efforts to implement an innovation accomplish their goals. This paper focuses on how we in implementation research know if we have accomplished our goals. To elaborate on this, we use as an empirical example a study in which preschool mathematics education developed within one study was scaled up in a subsequent study. The first study was an intervention where mathematics education for the youngest preschoolers was developed in collaboration between two researchers and three preschool teachers. This study showed both qualitative and quantitative developments in the use of numbers by the children in the intervention group compared to those in the control group (Palmér & Björklund, 2024). Based on these positive results, a new study was initiated with the aim of implementing the innovation large scale. However, implementation research has demonstrated that successful interventions are not easily transferred to a larger community of teachers and that all interventions undergo changes when implemented in new settings (Century & Cassata, 2016).

In the large-scale implementation, Coburn's (2003) framework was used. This framework was developed as an alternative to implementation studies that focus on the number of teachers, schools, or districts involved rather than on the quality of the implementation. The argument for developing an alternative framework was that numbers provide limited insight into the nature of the envisioned or enacted changes, as well as the degree to which any observed changes are sustained. Coburn developed a framework comprising four interrelated dimensions: depth, sustainability, spread, and shift in ownership.

Regardless of the framework used in implementation research, adaptation and fidelity are two important notions. Fidelity implies that implementations should adhere closely to the original model, while adaptation considers adjustments of innovations essential to reproducing positive outcomes from one context to another (Century & Cassata, 2016). In this paper, we build on Coburn's (2003) framework to elaborate on tensions between fidelity and adaptation with reference to the large-scale implementation of an innovation in preschool mathematics education.We ask the following research question: How can fidelity and adaptation be understood in relation to depth, sustainability, spread, and shift in ownership in a large-scale implementation of preschool mathematics education? Elaborating on this question will contribute with knowledge on how to know if implementation is successful.

Literature review

Based on a review of implementation research, Century and Cassata (2016) conclude that improving education requires processes for changing individuals, organizations, and systems. In line with this, Maass et al. (2019) emphasize that instructional improvement involves substantial teacher learning, which requires systematic support.

> […] implementation research [is the] systematic inquiry regarding innovations enacted in controlled settings or in ordinary practice, the factors that influence innovation enactment, and the relationships between innovations, influential factors, and outcomes (Century & Cassata, 2016, p. 170).

Implementation can be conducted and studied at a micro level with a few teachers (e.g., from one school), at a meso level with several teachers (e.g., from different schools within a region), or at a macro level (e.g., a district or nation) (Maass et al., 2019). However, this division of scale may emphasize a focus on quantities instead of qualities. Coburn (2003) argues that definitions of scale have traditionally had a restricted scope, focusing on increasing the number of schools or teachers reached by an implementation rather than on the depth of change achieved through it. In line with this, Century and Cassata (2016) emphasize that studies that isolate, decontextualize, and simplify issues regarding the complexity of education decrease the applicability of the results from implementation research. Coburn (2003) offers an alternative definition of scale that places less emphasis on quantities and more on the nature and quality of the implementation. This definition emphasizes a focus on depth (the nature and quality of change), sustainability (the persistence of change over time), spread (within each setting), and ownership (the autonomy of teachers).

In implementation, not all elements of an innovation are regarded as equal; some are considered core components (the essential and indispensable elements of the intervention), serving as key contributors to outcomes of interest and primary mechanisms for change (Century & Cassata, 2016). Therefore, to succeed with implementation, we need to identify which elements of the intervention being essential to replicate – and for how long and with what intensity they should be implemented – and which elements can be modified or eliminated entirely (Coburn, 2003). This is in turn connected to fidelity and adaptation. Jankvist et al. (2022) conclude that the notion of fidelity, both inside and outside of mathematics education research, is diverse, in terms of both definition and measurement aspects. For example, they highlight that fidelity may be considered in relation to the pedagogy, the

content, and/or the cognitive dimensions of an innovation. Regardless of the dimension in focus, according to Durlak (2010), fidelity refers to the degree of correspondence between the intended and actual outcome of implementation (Durlak, 2010). Measuring fidelity of implementation is, according to Century and Cassata (2016), based on the view that once an innovation is found to be efficacious, future implementations should not deviate from the established model. Adaptation, on the other hand, refers to the nature and degree of changes made to the original innovation; the focus is on the reasons for adaptation and the relationships between adaptation and innovation outcomes (Durlak, 2010). While some argue that adaptation undermines fidelity and thus must be avoided, others argue that a blend of fidelity and adaptation can yield positive results (Century & Cassata, 2016). Since educational contexts differ both within and between regions and countries, it is important to understand how innovations can be adapted to local conditions. However, adaptations must be in line with the core components of the innovation (Maass et al., 2019). When adaptations respond to the demands of the context while remaining consistent with the core components of the innovation, Debarger et al. (2013) refer to these as productive adaptations.

The study

Maass et al. (2019) emphasize that scaling up means different things in different countries due to variations in school systems. For example, the presence of a national curriculum, the content of that curriculum, and the education of teachers have an impact on implementation. The large-scale implementation focused on in this paper was conducted in Swedish preschools. In Sweden, approximately 87% of all children aged 1-5 are enrolled in preschool (Swedish National Agency for Education, 2023). Two professional groups work in the preschool: preschool teachers, who have a three-year university education, and childminders, who have a three-year high school education. The national curriculum emphasizes both care and learning. Sometimes the term *educare* is used to emphasize that learning must always be seen in relation to care (Bass & Good, 2004). Although the curriculum does include mathematical goals, these are not achievement goals but goals to strive towards. While the curriculum determines the experiences children should be offered in preschool, it does not dictate how these experiences should be implemented, allowing preschool teachers a great deal of autonomy in their teaching practice.

The implementation focused on in this paper was an innovation developed within this context. In a combined research-development project conducted in collaboration between researchers and preschool teachers (financed by the Swedish Institute for Educational Research, grant no. 2018-00014), mathematics education aimed at providing the youngest preschoolers the best conditions for learning mathematics was developed and tried out in authentic preschool settings (see for example Björklund & Palmér, 2022; Palmér & Björklund, 2023). The aim was partly to investigate how ongoing preschool activities could become the starting point for mathematics education, giving toddlers the opportunity to distinguish necessary aspects of numbers, and partly to investigate how such activities can advance toddlers' development of numerical skills. In the study, teaching activities were developed in accordance with three design principles (Palmér & Björklund, 2023). First, the context of the activities ought to be based on children's experiences, needs, and interests, and they should be familiar so that the children can participate in, relate to, and reason about the content based on their previous social and cultural experiences. At the same time, in line with variation theory

(Marton, 2015), interference from irrelevant aspects ought to be minimized. Second, the activities ought to make it possible for the children to discern essential aspects of numbers (i.e., representations, cardinality, ordinality, and part–whole relations). Third, the activities ought to allow the children to express different ways of understanding and allow a variety of experiences and expressions. The intervention was successful, indicating quantitative as well as qualitative differences in how children in the intervention group and control group used numbers (Palmér & Björklund, 2024). Based on these positive results, a subsequent study on how the successful intervention could be implemented on a large scale was initiated (financed by the Swedish Institute for Educational Research, grant no. 2022-00010).

The first step in the subsequent study was to identify the essential and indispensable elements of the intervention, that is, to identify the core components of the innovation to be implemented. These core components were to comprise the content of a guiding material to be used in the implementation (Century & Cassata, 2016; Coburn, 2003). The guiding material was developed in collaboration between researchers and the same preschool teachers involved in the initial research-development project. The innovation was described in the guiding material as consisting of five parts, where each part focused on one of the core components: part 1: mathematizing; part 2: contrast and generalization; part 3: representations; part 4: cardinality; and part 5: part-whole relationship of numbers. Each part consisted of one text to read, one video illustrating the content of the text in authentic teaching situations, questions to discuss with colleagues, one scripted activity to be carried out with children, and finally, one activity to be planned and carried out by the preschool teacher.

The subsequent study was conducted in line with educational design research, which implies implementation in cycles, where new preschools are successively included in an increasingly broader implementation. In the first cycle, the guiding material was implemented in two preschools. After that, in the second cycle, six new preschools were involved, and finally, in the third cycle all preschools from one municipality implemented the guiding material. The data generated were individual interviews (12), focus group interviews (28), and video documentations (219) from the teaching at the preschools. Also, delayed interviews (after 6 and 12 months) were conducted, and video documentations of teaching were generated. The interviews focused on the guiding material and how it was used and experienced by the preschool teachers. The video documentations made visible how the theoretically driven new forms of instruction were adopted by the preschool teachers. These video documentations were also used during the interviews as a form of stimulated recall.

These empirical data were analysed with a focus on whether the core components were visible in the teaching and, if not, how the guiding material needed to be developed. The analysis was grounded in depth, sustainability, spread, and shift in ownership in accordance with Coburn (2003). Based on the findings from each cycle, the guiding material was revised.

Depth, sustainability, spread, and shift in ownership

The question to be explored in this paper is how fidelity and adaptation can be understood in relation to depth, sustainability, spread, and shift in ownership in a large-scale implementation of preschool mathematics education. First, in this section we describe how depth, sustainability, spread, and shift in ownership became visible (or not) in the large-scale implementation of the preschool mathematics

innovation. After that, we elaborate on how fidelity and adaptation can be understood in relation to these four interrelated dimensions.

According to Coburn (2003), depth implies "deep change" (p. 4), which means that the change goes beyond surface structures or procedures such as materials, classroom organization, or the addition of specific activities. Deep change includes change of teachers' norms, views on the subject, and pedagogical principles as well as their assumptions about how students learn.

In our analysis, we searched for depth in both interviews and video documentations. However, since we did not have data on the teaching in the preschools before the implementation, the focus of the analysis was not on the nature and quality of change but instead on the nature and quality of the core components of the innovation. Depth was particularly visible in the video documentations of the activities planned by the preschool teachers themselves, along with their reflections on these video documentations during the interviews. This is in line with Coburn (2003), who argues that capturing depth requires in-depth interviewing and classroom observation. In the interviews, we searched for statements about the content, pedagogical principles, or young children's learning that aligned with the core components of the innovation. In the video documentations, we observed whether the core elements were visible in the teaching. We found that, regardless of whether the scripted activities were conducted in line with the innovation, the core components of the innovation were sometimes visible in the teachers' own planned activities and sometimes not. We interpreted this as an indication of whether the preschool teachers' learning went beyond the surface (i.e., they were able to plan their own activities in line with the core components) or if they remained superficial (i.e., they were not able to plan own activities in line with the core components).

The second element of scale is sustainability as implementation must last over time and not fall into disuse. This was investigated through the delayed interview and video documentations of teaching based on the same logic as above. According to Coburn, depth plays an important role in sustainability as teachers with a deep understanding of an innovation are better able to respond to new demands and may also continue deepening their understanding of the innovation over time. However, we found this hard to investigate as the delayed interview and video documentations of teaching were not carried out unprepared. The teachers themselves chose what teaching to document on video, and they knew when they would be interviewed and what the interview would be about. Thus, for example, they could have read the guiding material again. Therefore, the documented teaching and what was said in the interview may not show true sustainability of the intervention. What the delayed interview and video documentations could show was non-sustainability; that is, they could show whether and when the intervention was not visible. To investigate sustainability, observations would probably provide more reliable data.

When Coburn discusses spread, she refers not only to expansion outward to more schools and classrooms but also to spread within schools and classrooms. This can become visible if teachers begin to draw on innovation beyond specific innovation-related activities. In our study, this was apparent in the video documentations and interviews. Similarity between the scripted activities and the teacher-planned activities (when core components are kept) may indicate spread. For example, a scripted activity that focuses on ordinality and that uses a song about elephants might be changed so

that the song is instead about cats. Such a change might not indicate spread in the same way as changing the scripted activity into a completely different one but still with ordinality as the core components. Further, in the interviews, how the preschool teachers talked about the innovation may indicate spread, for example, if they talked about the innovation in connection to situations and activities other than specific innovation-related activities.

The final dimension of scale from Coburn is ownership. This implies that the ownership of the innovation is no longer external but internal, which means that teachers have the capacity to sustain, spread, and deepen the core components themselves. Similar to sustainability, this can be studied through the delayed interview and video documentations of teaching. Thus, the same pros and cons of the study's data apply.

Fidelity and adaptation

How do fidelity and adaptation relate to the above? Coburn (2003) highlights that there is a tension between ownership and fidelity, particularly if the implementation strongly emphasizes fidelity. In line with this, we quite quickly concluded that pure fidelity to the scripted teaching was not something to aspire to. This is because when the teachers were conducting an activity from the guiding material exactly in line with the script, the teaching became artificial and disconnected from the children's experiences, needs, and interests, which thus contradicted the core components of the innovation. Therefore, some adaptations were needed. We also realized that all included preschool teachers made adaptations to the intervention, but not all adaptations were productive (Debarger et al., 2013).

Adaptations were observed in both the scripted teaching and the teachers' own planned activities. In the interviews, the preschool teachers talked about their adaptations. When focusing on productive adaptations we realized that these could be understood as indicating depth and spread; that is, to be able to make productive adaptations and to transfer these adaptations between teaching activities, the teachers had to really understand the core components of the innovation. Productive adaptations were also visible when following the preschool teachers over time, where some of their own planned activities developed in line with the different parts of the guiding material while others did not. This was interpreted in terms of sustainability. Further, ownership was apparent in the interviews when the preschool teachers talked about how they made productive adaptations but without distorting the core components. Similarly, Coburn (2003) writes that ownership exists when the decisions about what and when to adapt are made by the preschool teachers themselves rather than imposed by the implementers.

Discussion

The question explored in this paper is how fidelity and adaptation can be understood in relation to depth, sustainability, spread, and shift in ownership (Coburn, 2003) in a large-scale implementation of a preschool mathematics innovation. To summarize, we found that adaptations, when they are productive, may indicate depth, spread, sustainability, and ownership and thus be empirical evidence of successful implementation. This insight gave us a new lens in the analysis of the implementation of the innovation, that is, it prompted us to search for productive adaptations. To understand which adaptations are productive, we found that the core components of the innovation needed to be clearly

identified and documented. In our case, that entailed clearly documenting valid signs of the core components of mathematizing, contrast and generalization, representations, cardinality, and part-whole relationship of numbers. The more precisely these valid signs are documented beforehand, the more precisely productive adaptations can be separated from non-productive ones. And, if identified, non-productive adaptations can be addressed in the guiding material as examples of how not to teach the innovation.

The positive view on productive adaptations presented in this paper must, however, be understood within its national educational context (Maass et al., 2019), that is, in connection to the Swedish preschool. As mentioned, Swedish preschool teachers have a three-year university education and a significant degree of autonomy in their teaching practice. Thus, they are both qualified and expected to make adaptations in relation to the children in their preschool why productive adaptions of core components can be considered within reach if understanding the core components. Similarly, productive adaptations have been found in other implementation studies involving Swedish teachers. For example, in a study by Ahl et al. (2022), the two studied teachers attended to the intended organization of the mathematical content, but their attendance to the intended classroom interaction patterns differed. In our study, no explicit interaction pattern was promoted; instead, it emphasized mathematizing, which entails making mathematics necessary for the situation from the child's perspective. We found this to be the hardest core component of the innovation to implement. Thus, like the teachers in the study by Ahl et al. (2022), the teachers in our study more easily implemented the mathematical content than the context in which this content was to be taught. This may indicate that the three dimensions of pedagogy, content, and cognitive dimensions of an innovation often connected to fidelity (Jankvist et al., 2022) could also be addressed in connection to productive adaptations.

Acknowledgment

The study was funded by the Swedish Institute for Educational Research, grant no. 2022-00010.

The Middle-school Mathematics and the Institutional Setting of Teaching (MIST) project was a successful development project conducted across four US school districts. Central to the project's contribution is the development of a Theory of Action, which provides actionable strategies for professional development in mathematics instruction. In this paper, we analyze the MIST project through the lens of implementation research, focusing on key factors that influence its success. Our material consists of semi-structured interviews with people involved in MIST. The analysis suggests that while the MIST project has the potential to be reproduced in other contexts, specific contextual factors must be carefully considered to ensure successful adaptation and implementation.

Keywords: MIST project, implementation research, innovation, influential factors.

Introduction

The Middle-school Mathematics and the Institutional Setting of Teaching (MIST) project, conducted in the US from 2007 to 2015, stands as a notable successful development initiative. The research team produced numerous publications, including a book, to disseminate their findings. Their book, *Systems for Instructional Improvement: Creating Coherence from the Classroom to the District Office*, represents the project's culmination in the field of mathematics education. In this work, the authors present a Theory of Action (ToA), which offers "…actionable recommendations about potentially productive instructional improvement strategies." (Cobb et al., 2018, p. 7). The MIST researchers themselves have described their project as a Design-based Implementation Research (DBIR) initiative (e.g., Cobb et al., 2013). Given the success of MIST, it is highly relevant to develop methods for reproducing it.

In this paper, we examine the MIST project from a traditional Implementation Research (IR) perspective. We aim to gain insights into the possibilities of reproducing the MIST project, that is, implementing it in different contexts. An important step in this process is understanding the nature of MIST—the object to be reproduced and implemented in a specific context. To achieve this, semi-structured interviews were made with key people involved in MIST. Based on IR theory, concerning four types of factors influencing the successful adoption of innovations, we posed a research question: What are the characteristics of MIST in relation to:

- the innovation itself,
- the users,
- the organizational setting,
- and the external environment?

These four categories and their theoretical background are explained in the next section. Following are sections covering the MIST project (background information), our method, and our results and findings. The final section, titled Discussion and final remarks, addresses the possibilities of reproducing the MIST project based on our results and findings.

Theoretical constructs

In this section, we present a literature review on implementation research and outline the theoretical construct we used for data analysis.

Implementation research

Century and Cassata (2016) offer "a working definition for implementation research as a systematic inquiry into the enactment of innovations within controlled environments or typical practices, exploring the factors that influence such enactments and the interconnections between innovations, influencing factors, and outcomes" (p. 170). According to them innovation is the object of implementation (Century & Cassata, 2016). Century and Cassata (2016) define "innovations as programs, interventions, technologies, processes, approaches, methods, strategies, or policies that involve a change (e.g., in behavior or practice) for the individuals (end users) enacting them" (p. 170). According to Rogers (2003), innovation is "an idea, practice, or object that is perceived as new by an individual or other unit of adoption" (p. 12); what matters in human behavior is not whether an innovation is objectively new but whether it feels new to the individual. Jankvist et al. (2021) argue that innovation needs to be novel for the stakeholders, not necessarily for the end users. In all three definitions, there is a common core of what is innovation, which we agree with. We argue, however, that Jankvist et al.'s (2021) concept of multiple users is more suitable for understanding the innovative features of MIST. We return to the issue at the end of the paper.

Exploring implementation research reveals the key factors influencing the successful adoption of innovations, as highlighted by Century and Cassata (2016). These factors span four areas: the innovation itself, the users, the organizational setting, and the external environment. The specific characteristics of these factors vary depending on the context, such as healthcare, sports, manufacturing, or, in this case, educational institutions, with a focus on school systems. Key factors related to the innovation include its adaptability, relevance, and alignment with operational practices. Educators, especially teachers, play a crucial role as change agents in schools. Their understanding of innovation shapes their effectiveness in implementing it, as well as their expertise in relevant domains, prior experiences, organizational skills, classroom management, and personal traits such as beliefs, attitudes, motivation, self-efficacy, and openness to new approaches (Century & Cassata, 2016). Organizational factors influencing implementation arise from decisions made by educational institution stakeholders, including those related to class sizes, resource allocation, infrastructure, scheduling, and the broader organizational structure that guides instructors. These factors also encompass administrative procedures, management practices, and policy decisions specific to the innovation. On the other hand, external environmental factors encompass opportunities and constraints that are beyond the institution's control, such as economic conditions, infrastructure limitations, and shifts in political priorities. Examples include poor network connectivity hindering instructor development and budget changes resulting from shifts in political leadership.

About the Middle-school Mathematics and the Institutional Setting of Teaching (MIST) project

The MIST project was an eight-year initiative conducted between 2007 and 2015 in collaboration with four urban school districts in the United States. This was some years after the No Child Left Behind Act had been established in 2002. MIST was implemented in two distinct phases. All four districts participated during the first phase, from 2007 to 2011. Two of the original four districts continued their involvement in the second phase, which took place from 2011 to 2015.

The primary goal of MIST was to support the development of ambitious, inquiry-based instructional practices among middle-grade mathematics teachers in ethnically diverse urban districts. The initiative sought to develop a Theory of Action that could be broadly applicable to Research-Practice Partnerships across various academic fields (Cobb et al., 2021). The project was conducted as a design-based implementation research (DBIR) study, spanning four cycles. Like other DBIR studies, MIST had two key objectives. First, to provide timely feedback to district leaders on their instructional strategies, offering recommendations for improvement. Second, to develop a scalable, generalizable Theory of Action for instructional improvement in mathematics (Henrick et al., 2015).

Prior to partnering with the districts, the research team formulated preliminary conjectures based on relevant literature in mathematics education, teacher development, and educational policy and leadership. These conjectures addressed various elements of instructional support, including instructional materials, resources, professional development sessions, teacher collaboration, school instructional leadership, and district leadership (Cobb & Jackson, 2021). The study was structured to allow researchers to examine, refine, and expand upon these conjectures iteratively. After each cycle, recommendations were provided to district leaders to enhance their instructional strategies. By the end of the project, the research team had developed a comprehensive Theory of Action (ToA) aimed at supporting system-wide improvements in mathematics instruction. The ToA created through the MIST project consists of three key components: a coherent instructional system (key components similar to NCTM Common Core Standards) designed to improve teachers' instructional practices, the instructional leadership of school leaders in mathematics, and district leaders' efforts to build school-level capacity for instructional improvement (Cobb et al., 2018).

Method

We conducted semi-structured interviews, each lasting 60 minutes, via Zoom with four key people (KPs) of the MIST project and one district leader from each of the four districts that participated in the MIST project. The key people are the members of the research team of the project. The interviews were conducted in November 2023. The interview protocol consisted of six themes, each accompanied by probing questions designed to elicit comprehensive information through the deliberate use of open-ended questions. The six themes were background, planning of the MIST project, implementation of the MIST project, evaluation, identification of supporting and limiting factors of influence, and the role of mathematics education theories. The interviews were transcribed using Zoom's transcription feature and manually reviewed for clarity. For this paper, we analyzed the responses to the interview questions using influential factors as the theoretical construct. We coded the transcripts to identify the influential factors: the innovation itself, end users, organizational

setting, and external environment factors. Additionally, we referenced the project's final output (Cobb et al., 2018) alongside the interview transcripts to gather precise data figures. We used the pseudonyms KP# for KPs and DL for the district leader for anonymity.

Focusing on influential factors, we found that KP1 and KP2 provided the most relevant responses, likely due to their integral roles throughout the project. In contrast, KP3, an applied statistician, and KP4, an expert in professional learning communities, contributed specialized expertise. While all four KPs and the DL provided valuable data, KPs 1 and 2 offered the most pertinent insights.

Results

In this section, we present the results of our analysis of the MIST project, focusing on the influential factors suggested by Century and Cassata (2016).

Innovation

A central focus of Implementation Research (IR) is innovation. However, the nature of the innovation in the MIST project is somewhat ambiguous. When we reviewed the publications associated with the MIST project, one key question emerged: What is the core innovation of the MIST project? As a result, we specifically included this question — What is the core innovation in the MIST project? — in our interviews. KP1's immediate response was, 'I don't know if we had a core innovation.' According to KP1, the MIST project differs from typical implementation research initiatives.

> KP1: I would say… In the work after MIST, it was implementation research. I wouldn't classify MIST implementation research.

KP1 added:

> KP1: One thing I want to clarify … I've got a sense from reading the questions that it was, so you had this idea on how to make things better. What was it [the innovation]? And did it work? Sort of thing? That's not what the MIST project was about. It was about learning. … what I viewed the project was about, because it was funded as a research project, not as a make the world better project, was to figure out what it takes to improve the quality of math teaching and learning, going all the way from the classroom to system leadership. And to figure that out.

KP1 further described the intention of the project to provide details as to why it is not an ordinary IR project:

> KP1: Sadly, in the United States, principals have typically given a very active role in leading instructional improvement. Whether that's a good idea is something that's up for debate… But it's deeply institutionalized here; that's not going to change. So, the question then becomes what should principals who don't have a background in mathematics, let alone in ambitious or inquiry into math teaching be doing, specifically doing to facilitate, encourage, contribute to improving the quality of math teaching, and learning. …

KP2 emphasized the creation of their innovation rather than its implementation, stating: "In terms of innovation, I believe one of our achievements is the development of a theory of action that addresses classroom dynamics on such a scale." This view is shared by KP1, who also highlighted their contribution through the book that presents the Theory of Action. However, KP1 expressed uncertainty about whether this truly constitutes an innovation. KP1:

KP1: And I would say what came out of it. I think you know that at the end there we wrote, we tried to put everything together in a book. What I would say that book, if it makes a contribution, …Is just it gives us a portrait or a model of what a high-functioning district can look like and should look like if you are aiming for rigorous learning goals and ambitious and equitable instructional practices in math. …what high-quality coaching or what high-quality principal instructional leadership looks like. So, I do not know if that counts as an innovation. But that's what I view as our contribution from that work.

As a design study, however, the MIST project began with "… an initial, tentative, and eminently revisable theory of action by formulating conjectures about both supports for teachers' learning and accountability relations that press them to improve their practices." (Henrick et al., 2015. p. 502). This preliminary ToA was developed based on the existing literature in mathematics education, learning sciences, educational leadership and educational policy (Henrick et al., 2015).

End Users

The MIST project engaged various stakeholders as users, including district leaders, principals, coaches, and teachers. The researchers collected data through interviews with these individuals and by video recording several of the teachers' lessons. The transcripts from the interviews and the video recordings were analyzed to produce a document containing recommendations for the district leaders. KP2 detailed the role of school principals in implementing the project.

KP2: Principals, I would say, we interviewed them every January. And we were analyzing what they were saying about how it is that the instructional improvement strategies were playing. Hang out in their schools. The support they felt they had, what they were accountable for, [and] the challenges they were facing. That was all part of the interview. … So, we would produce those feedback reports that would go to the district leadership in May. But then, in August, in most of the districts, we also had a session where we shared that feedback with principals and got their reactions. So, in that sense, we were getting again more information from them in terms of did what we say resonates with them or not. What did it mean for their practice? We were involved and then co-designing and co-leading professional development for the principals. So, they were an integral part of the project.

KPs described the involvement of both district leaders and teachers in the process of data collection.

KP2: In that first phase, especially at the beginning, … we would interview the leadership in the fall so that we could document what their theory of action was. And then, we were generating/collecting data to find out. How [or] in what ways were those instructional improvement strategies playing out as the leaders had intended or not? And so that was through the interview data. It was also through observation of teachers' teaching. Assessment assessing teachers' mathematical knowledge for teaching was that improving over time, there were the survey measures that KP3 is referring to.

KP2 further described:

KP2: In terms of evaluating teachers' enactment, that was primarily through each year, each teacher who participated in this study, there was a video recording of 2 days of instruction where what they were asked to teach a lesson organized around a cognitively demanding or rigorous task that included a whole class discussion of students' ideas. … So, we use that to evaluate teachers' instruction and changes in instruction over time. The teachers also took the mathematical knowledge for

teaching assessment out of the University of Michigan. We use that to assess teachers' mathematical knowledge for teaching and any change in that over time.

There are four distinct types of users involved in the MIST project: district leaders, principals, coaches, and teachers. Although the MIST project collected data from four types of stakeholders, the recommendations were directed toward the district leaders. Thus, the primary users of these recommendations were the district leaders.

Organizational setting

The US school districts have unique organizational settings. The researchers of the MIST project demonstrated an understanding of these settings and designed and executed the project with careful consideration to enhance teachers' professional development (PD) opportunities. They did not interfere with the selection of curriculum resources or materials but instead provided recommendations to improve the strategies that district leaders incorporated into teacher professional development. As per KP2:

KP2: So, I would say the design was very much informed and responsive to the challenges that were arising as we engaged with the districts. We did not prepare curricula for teachers. The districts had selected curriculum. We were not involved in any curriculum design in terms of what happened in the classroom. What we were involved in, I would say, is curricular for the professional development of teachers. We contributed to that, but not the classroom curriculum design.

In summary, the intention of the MIST project researchers was "to support districts in making it happen" (KP1), where 'it' refers to the plans each district had for providing support for teacher PD.

Aligned with the organizational settings of school districts, the MIST project's organizational structure is also distinct (see Figure 1). In Figure 1, arrows labeled with 1 represent the PD initiatives conducted by district leaders (DL). The diagram illustrates the flow of PD support from the DL to the principals (P in the diagram), then to the coaches (C in the diagram), and finally to the teachers (T). Data were collected from all the stakeholders—DL, P, C, and T—denoted as 2 in the diagram. Recommendations were subsequently provided to the district leaders, labeled as 3.

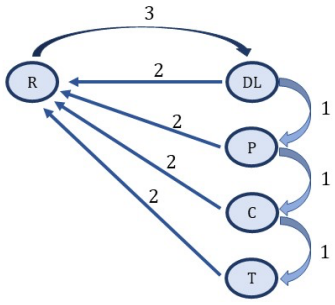

Figure 1: Organizational structure of the MIST project

External Environment

As mentioned, the content of MIST followed the general trend concerning Common Core Standards. The project can be seen as a response to the federal No Child Left Behind Act. However, in other

respects, the influences of the external environment appear small. The political and administration authorities within the districts seemed to have had minimal impact on the MIST project. During the interview, we asked a probing question:

R: Did politicians or school administrators have any influence on the project design in some way, or did they interfere in some way?

KP2: Within the districts, I would say we worked most closely with people who are in district leadership positions, so the curriculum specialist for mathematics would support all of the schools in the district. The principal supervisors, so the people who were in charge of the actual principals are the school leaders. [they are] the academic officers who would oversee all of what was happening for curriculum and instruction, not just math, but all of the content areas. That tended to be the level at which we worked, and they very much shaped the design. So, particularly moving into the latter part of phase one and what phase 2 became, was very much shaped by conversations with people at that level. … And then in terms of other politicians like, for example, school board members. They were not. … I don't think they were involved at all. I know that, for example, the chief academic officer or the superintendent would sometimes share what they were learning with a school board, but the board wasn't shaping what was happening in the project. It was very much, I would say, kind of the bounds were at the district leadership. … I don't think we had any cases of that.

The conclusion regarding minimal influence adds to the finding about the MIST's organization (Figure 1). Information in MIST was not only circulated; it appears to have been a closed circulation.

Discussion and Final Remarks

Despite the challenges faced by district leaders during implementation, 67% of the recommendations made by the project team were attempted by these district leaders (as noted by KP1 during the interview). This indicates a degree of success, suggesting that the MIST project may be worth reproducing. Consequently, the paper focuses on evaluating the project from an IR perspective and exploring how it might be adapted for other contexts. From an IR perspective, the project does not represent a traditional form of innovation. Instead, it developed an innovation—a Theory of Action—that district leaders can use in designing and implementing PD programs for teachers. Thus, the primary target audience for the ToA is district leaders or others responsible for designing teacher PD programs. The research team developed the ToA based on insights gained from various districts.

We suggest that the primary users of the ToA should be district leaders or those responsible for organizing PD programs, with teachers as end-users. Thus, we find Jankvist et al.'s (2021) definition of innovation, which emphasizes change for several users, to be more relevant, especially with respect to reproducing MIST, which requires the existence of an equivalent to district leaders (primary users) in terms of responsibilities and powers. It is not sufficient to have teachers as the only end users.

Regarding organizational settings, we observed that the structure of the US school system is complex, involving numerous different stakeholders. Similarly, the organizational structure of the MIST project involved several stakeholders (see Figure 1). This indicates that the researchers played a vital role in collecting data from various stakeholders and delivering recommendations, integrating theory from existing research with practical insights. Our analysis suggests that this role should be considered when reproducing the MIST project. Thus, if the innovation of MIST—the Theory of

Action (ToA)—is to be reproduced, a variety of stakeholders with different areas of expertise must be involved to ensure the necessary circular flow of information, a dynamic essential to the ToA.

Lastly, the design of the MIST project and the Theory of Action were closely aligned with the structure of the US school district system. Much of the information in the circular motion could flow through existing channels between different bureaucratic levels—district leaders, principals, and teachers—who held formal responsibilities and authority. This also involved an established culture of information sharing, including the types of information that teachers felt they could or should share with researchers, which would eventually reach their district leaders. It is important to note that the US school system, one of the most established and oldest systems of mass education in the world, operated within a democratic society and had long integrated educational research. Hence, we cannot assume that information sharing would function as effectively in countries with younger or less developed school systems. We argue that the innovation of MIST, particularly its Theory of Action, is deeply tied to the specific characteristics of the US school system and its culture. Therefore, when considering a reproduction of the MIST project in a different context, it is crucial to account for the organizational structure of the local school system as a key influencing factor.

Research-designed, teacher-refined: making sense of teachers' adaptations of an instructional innovation

Julia Tsygan

Gothenburg University, Faculty of Education, Gothenburg, Sweden; julia.tsygan@gu.se

How do secondary school mathematics teachers adapt a research-based instructional model designed to improve students' mathematical communication skills? In this case study involving a team of four experienced teachers, data from a school year of regular team meetings was analyzed using a hybrid inductive-deductive approach, combining the deductive application of the Professional Obligations framework with inductive analysis of emergent themes. The findings reveal that teachers made productive adaptations based on three main clusters of factors: individual student needs, institutional constraints, and didactic concerns about the model itself.

Keywords: Mathematics, Program implementation, Design research

Introduction

To study the transposition of a research model from the theoretical or controlled research context to real-world educational settings, both researchers and implementers often consider implementation along a spectrum ranging from pro-fidelity to pro-adaptation stances (Century & Cassata, 2016). This unidimensional approach focuses primarily on the degree of adherence to the original model design. In this paper, we instead adopt the more nuanced integrity approach to implementation (Meland & Brion-Meisels, 2023). This approach posits that implementation should be evaluated not only in terms of fidelity versus adaptation but also in terms of which parts of the intervention are adapted and how. The integrity approach thus allows for a more comprehensive assessment of implementation processes. In this context, integrity represents

> ...the degree to which an intervention was implemented maintaining its core active ingredients, while authentically and fully integrating the assets and needs of the local community. (Meland & Brion-Meisels, 2023, p. 2)

When informed by the needs teachers see in their community or the challenges they encounter during implementation attempts, changes in the teaching model may be necessary or beneficial. When this is the case, one may follow DeBarger (2013) and call these adaptations *productive*.

Practitioners' decisions about whether and how to adapt an innovation during implementation are influenced by a complex interplay of factors. Research across various sectors, including healthcare and education, has identified several key categories of these influencing factors. In the healthcare sector, Moore et al. (2013) found that logistical factors, particularly time constraints and resource availability, play a crucial role in implementation decisions. They also noted that philosophical factors, such as the perceived alignment of the innovation with established cultural values, exert some influence, albeit to a lesser extent.

In mathematics education, Handal and Bobis (2004) found similar patterns with domain-specific nuances. Their study on implementing thematically organized mathematics teaching confirmed the

significance of logistical constraints like time and resources. However, they also highlighted philosophical factors unique to educational settings. Teachers perceived misalignment between the thematic approach and institutional assessment practices, hindering implementation. Additionally, teachers questioned the didactical soundness of thematic organization over traditional topic-based approaches. These concerns, rooted in personal experience and established praxis, may significantly influence which aspects of an intervention teachers implement, adapt, or abandon.

Here, we investigate the implementation of a specific innovation: the MUSK[1] teaching model for developing students' mathematical communication. The teaching model is founded on three core ingredients (Teledahl et al., 2023): the model separates problem-solving from the formal communication of the solution, the model includes spending time discussing the merits of student-produced communications, and the model posits an imaginary or actual absent peer as the intended audience, encouraging students to write clear, convincing solutions for a peer who is unfamiliar with the problem. These principles have been operationalized into four possible teaching sequences, each spanning two lessons with 5 to 7 distinct phases (see Figure 1 for one such sequence).

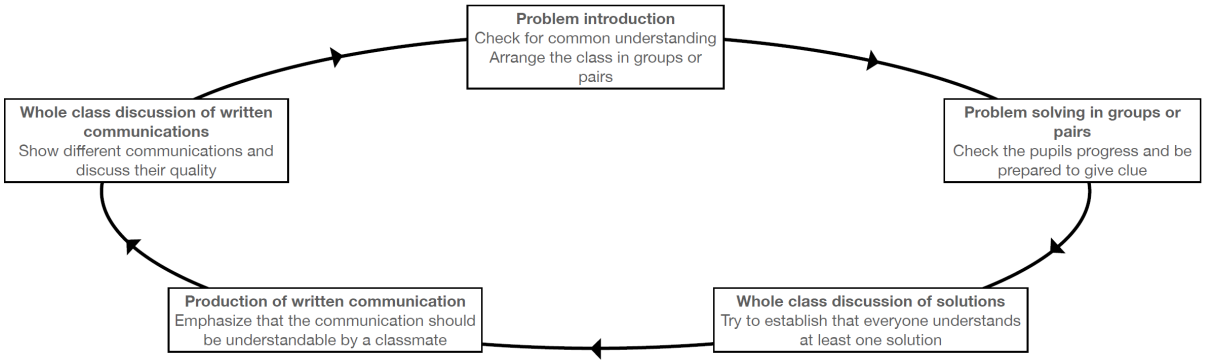

Figure 1: one version of the MUSK teaching model

In this paper, we are interested in how and why teachers adapt the MUSK model. An analysis of the changes teachers made or intended to make may reveal how teachers navigate potential tensions between the model and the teachers' specific context.

The teachers' regular documented meetings over a full school year provide a *useful heuristic case study* (Thomas, 2011) for examining adaptation processes in implementation of researcher-designed educational innovations. Heuristic case studies are representative of some general phenomenon and help to identify relationships between factors within those phenomena. In Thomas' (2011) terminology, the *subject* (the example that is being studied) of the case study is the group of teachers' implementation of MUSK. The *object* (that which the case serves to explicate) is the set of adaptation processes made by teachers implementing a research-designed innovation.

This paper thus seeks to answer: What contextual factors influence teachers' adaptations of research-based teaching models?

[1] "Modell för Undervisning av Skriftlig Kommunikation" [Model for Teaching Written Communication]

Background Research

In analyzing how teachers implement and adapt the core components of MUSK to their local contexts, we draw upon the Professional Obligations framework (Herbst & Chazan, 2012). The Professional Obligations framework posits that teachers' actions and choices in the classroom are shaped by four key obligations: disciplinary, individual, interpersonal, and institutional. The disciplinary obligation refers to the teacher's responsibility to accurately represent mathematics as a discipline. The individual obligation pertains to addressing the needs and characteristics of each student. The interpersonal obligation involves managing classroom dynamics and relationships, while the institutional obligation encompasses the teacher's responsibilities to the school, district, and broader educational system.

Research using the Professional Obligations framework has illuminated the complex nature of mathematics teaching and the tensions that arise between different obligations. For instance, Webel and Platt (2015) examined how institutional pressures, such as standardized testing, influence teachers' instructional decisions and potentially conflict with their perceived duties to individual students or the discipline. In the context of implementing the MUSK model, we anticipate that teachers might experience tensions between, for example, the model's emphasis on communication (aligning with the disciplinary obligation) and assessment demands (part of the institutional obligation).

When adopting a research-based teaching model, teachers could be said to face a fifth obligation: fidelity towards the core components of the teaching model. This obligation is distinct yet intertwined with the other four, influencing how they are fulfilled. The case study seeks to explore whether teachers perceive such a new obligation, and, if they do, how they integrate it with the others.

Method and Results

This section presents the method of analysis together with the results. The results are incorporated here to illustrate the analytical process and to avoid redundancy that would occur if a separate Results section were provided.

The four teachers, all working in secondary school at an international school in Stockholm, Sweden, came from four different national educational backgrounds (only in Western Europe and the U.S.A., however) and had a minimum of 10 years of teaching experience. The teachers met regularly, roughly every two or three weeks, during one school year and had in total 11 meetings of 90 minutes each. Each meeting was documented using careful meeting notes, most often but not exclusively by one of the participating teachers who was also the team leader and is the author of this paper.

The meeting notes were analyzed using a hybrid of inductive and deductive content analysis (Fereday & Muir-Cochrane, 2006). A hybrid approach allows one to approach the data deductively, based on themes that stem from prior research such as the Professional Obligations framework, while also allowing for unforeseen themes to emerge, in our case themes pertaining to the MUSK instructional model. The process was sequential, following the sequence outlined in Fereday and Muir-Cochrane (2006), and is explained below.

First, two coding manuals were developed. One focused on the challenges teachers perceived and adaptations that they suggested or made to the teaching model. Challenges were defined as discrepancies between desired and actual outcomes, identified in the text where teachers expressed complaints about unexpected events, competing priorities, or lack of resources or competency. Adaptations were changes to the given teaching model, recognized in suggestions or reports of instructional choices not explicitly stated in the original instructions. The second coding manual was based on the Professional Obligations framework, comprising four categories. Disciplinary obligations were identified in references to mathematical norms, reasoning validity, and notation. Individual obligations were recognized in mentions of personal needs, behaviours, and differentiation strategies. Interpersonal obligations were recognized in references to group behaviour, spatial orientation, and student-teacher interactions. Lastly, institutional obligations were identified in mentions of assessment demands, regulations, value systems, and resource availability.

In the second step, the coding manual was tested on a sample of data from one meeting in October 2023. It was straightforward to identify themes from both coding manuals, so the codes were deemed to fit well. However, this initial coding process revealed the importance of tacit knowledge shared among the teachers. Actions like assigning homework or reusing test questions were often motivated by multiple factors, including time constraints, assessment alignment, and individualized student support. These motives were rarely explicitly stated, as they are tacitly understood by the group. A brief follow-up interview with the teachers confirmed that these modifications were intended to save time by addressing multiple objectives simultaneously.

In the third step, raw data theme related to MUSK implementation were extracted. For example, an extract from the meeting notes was this:

> M7 work - simplifying tricky algebraic expression - interesting distinction between arbitrary / conventional rules, and deduced and therefore valid or invalid. What about 1m = m?

The extracted raw data theme of this extract became: “distinction made between arbitrary / conventional and deduced rules”.

The fourth step involved coding extracted raw data themes using Challenge and Adaptation themes, followed by Professional Obligations themes. Coding was guided by the manual while allowing for inductive elements. Lower-order themes were identified within each theme. For instance, *Time* and *Assessment demands* were categorized under the *Institutional obligation* theme. Inductive coding was applied to data not fitting the Professional Obligations framework. For example, teachers’ uncertainties about the MUSK model’s task-suitability were coded under the inductively derived theme *Didactic concerns about MUSK*, which involves teachers’ considerations of instructional choices within the model. This theme emerges from questions about language precision, individual vs. group text production, and MUSK instruction specifics. It also includes efforts to refine the model by addressing task suitability.

The fifth step was to connect Challenges and Adaptations with the Professional obligations and the inductively arrived-at themes. I explored code co-occurrence of challenges and adaptations with the four professional obligations, and with the inductively extracted themes, as seen in Table 6.

Table 6: Challenges and Adaptation connected to each of the Professional Obligations and the inductively found theme of didactic concerns.

Theme	Challenges	Adaptations
Disciplinary	Students struggle with valid justifications in their written solutions	Explicit teaching of mathematical reasoning
	Student choice of representations may not be consistent with mathematical norms	Explicit teaching of mathematical notation
Individual	Students do not participate equally in analyzing communication	Asking students to give feedback to peers
	Students have different individual needs in communication and mathematical reasoning	Instructing students to set improvement goals based on feedback
Interpersonal	Students do not participate equally in groups, with some being less active than others	Assigning roles in group work
Institutional	Students prefer teachers to set standards	
	Students do not transfer new communication skills to assessment situations	Including assessment of communication in summative assessments more frequently than before Communicating assessment expectations to students
	Limited time for lengthy problem-solving and communication exercises	Giving problem-solving or writing as homework, reusing tasks that students have previously solved
Didactic concerns about MUSK	Cohesive group norms do not form	Documenting and returning to lists of good qualities identified by students
	Repetitive discussions showing lack of progress	
	Tension between students', teachers', and assessment instruments' expectations	
	Some problem-solving tasks are not useful for MUSK	Choosing problems that elicit a variety of communication approaches
	How to handle students' incorrect solutions	Including incorrect solutions in discussions
		Using MUSK with tasks other than problem-solving

The teachers found adaptations that helped them meet most but not all of the encountered challenges. No adaptations were found that would remedy the sense of repetitive discussions nor the existence of tensions between individual students', teachers' and assessment instruments' interpretations of quality. Additionally, one adaptation (using MUSK with other kinds of tasks than it was designed for) stemmed from an opportunity rather than a challenge. For the most part, however, adaptations could be understood as attempts to address challenges.

In the final step, the connections found between the codes were thematically clustered as seen in Table 7.

Table 7: Higher-order clusters of themes

Cluster	Challenges	Adaptations
Individual student needs	Students vary in readiness, ability, and engagement.	Teachers use peer- and self-feedback to tailor tasks for individual students Teachers teach those skills students are lacking
Institutional constraints	Time constraints make it difficult to devote as much time to MUSK tasks as is necessary Assessment demands specify forms of communication not necessarily aligned with student opinions.	Teachers reuse tasks from other contexts and assign homework rather than spend class time Teachers tell students about assessment demands and ask students to evaluate based on these
Didactic concerns about MUSK	Teachers perceive the MUSK model as lacking in some areas.	Teachers develop the MUSK model and apply it to novel tasks

Finally, a member check was carried out by emailing the teachers tables 6 and 7, together with the descriptive text before and after the tables, and asking whether they feel that this analysis captures their experience of the implementation process. All agreed that it did.

Discussion

The adaptations made to the MUSK teaching model are possible to understand through the concept of programme integrity (Meland & Brion-Meisels, 2023). The core elements, separating communication from problem-solving, positing an absent peer, and orchestrating student discussions of qualities of communication, were preserved. Peripheral elements, such as the kinds of problems students worked on and how student opinions were collected and documented, were adapted in response to challenges teachers encountered.

In addition to changing peripheral elements, teachers adapted the model by introducing new elements: the use of feedback and rewriting (to ensure individual development) and explicit teaching of necessary reasoning and notation skills. The adaptations could therefore be said to be of two types: changes to elements included in the model and adding new elements to the model.

The findings of this study are coherent with Moore et al. (2013) and Handal and Bobis (2004) because logistical concerns (such as time) and institutional concerns (such as assessment) were important influences on teachers' adaptations in this as well as in the earlier studies. In particular, assessment constraints stood out as especially important in this study and in Handal and Bobis (2004). Didactic considerations also played a role in both studies. Teachers used their professional judgement to decide what parts to implement as intended by the model designer, and what parts to adapt or abandon. It is, however, difficult to gauge the influence of philosophical factors in this study, since the teachers agreed to implement the MUSK model precisely because it fit so well with the student-centered teaching and learning of the IB programmes and the participating teachers' preferences.

From the Professional Obligations framework, adaptations were made based on each of the four obligations, but to varying extents. MUSK has student discussion as a core element, so the Interpersonal professional obligation was met with little need for adaptation. Other obligations, such as towards individual student needs and growth, are not as central in the MUSK model, and teachers consequently made more adaptations in those areas. Finally, the data contained themes pertaining to an obligation towards the instructional model itself. Didactic concerns about the instructions led to multiple adaptations of the model.

The teachers' adaptations of MUSK could be said to be productive (DeBarger, 2013) in the sense that they make the model more practical within the context in which MUSK was implemented. Because this study did not measure the impact on students' communication development, we cannot say whether the adaptations made the model more effective. Practicality is, however, a necessary condition for effectiveness, because teachers must find it meaningful and realistic to implement a teaching model for it to be used at all and, ultimately, for it to have any effect on student learning.

A reliability check was intended but not carried out in the third step of the data analysis because the concise nature of the meeting notes made it difficult for someone outside of the group of teachers to understand the notes. This limitation was mitigated by carrying out a member check which is an established method for assessing the credibility of findings (Cutcliffe & McKenna, 2002).

This study suggests some tentative recommendations for design and implementation research. To avoid difficult challenges that give rise to potentially unwanted adaptations, innovations should not conflict with teachers' professional obligations. Ideally, an innovation should serve multiple purposes simultaneously. Finally, teachers and students care about assessment. The innovation is more likely to be implemented with programme integrity if it can be made to align with assessment expectations.

Conclusion

This study demonstrates how teachers tailored the MUSK model to their specific context, guided by their professional obligations and concerns about the model's didactic soundness. Based primarily on the contextual factors of heterogeneous classes and institutional constraints on time and assessment

criteria, they adapted the model to better suit individual student needs in a timely way while preparing students for success on assessments. The Professional Obligations framework, with the additional obligation to the MUSK model, proved valuable in analyzing teachers' implementation choices.

Acknowledgement

This study would not have been possible without the kind generosity, open-mindedness and patience of the participating teachers: Ashton Green, Wilhelm Tunemyr, and Afnan Hashemi-Zadeh.

Young students' proportional judgements: A replication study

Julie Vangsøe Færch

University College Copenhagen and DPU, Aarhus University, Denmark; jvaf@kp.dk

This paper describes a conceptual replication of a set of tasks developed by Spinillo and Bryant, incorporating extensions in terms of population, time period, and classroom implementation. Despite notable methodological differences in how the tasks were implemented in the two studies, students' reasoning patterns remain largely similar to those observed in 1991. While the new study allowed students to collaborate in small groups, unlike the individual work in the original study, the analysis reveals that this collaborative approach only serves to support the initial findings.

Keywords: Replication study, proportional judgement, first- and second-order comparisons.

Introduction

Previous research has concluded that children have significant difficulty performing proportional reasoning (see, for example, Spinillo & Bryant, 1991). Experiments on proportional reasoning typically involve tasks in which children assess relative size by examining relations between relations, also known as second-order relations. According to Spinillo and Bryant (1991), prior research in proportional reasoning had attributed students' difficulties to their inability to compare two proportions. The authors sought to explore whether students' challenges might not stem from second-order comparisons but rather from insufficient understanding of the two underlying first-order relations, such as assessing how full a glass is. They approached this by selecting first-order relations that children as young as 4 years old can understand, specifically *greater than* elations. By designing tasks in which the only proportional reasoning needed was based on *greater than* comparisons, they aimed to determine whether children aged 4–8 years could make proportional judgements. Their argument was that if a child could identify whether one figure contained more blue than grey, remember this information, and later distinguish it from another figure containing more grey than blue, the child would have successfully executed proportional discrimination.

Spinillo and Bryant (1991) concluded that cases where one figure is divided vertically and the other horizontally are especially crucial for determining whether students are genuinely making second-order comparisons – typically by comparing part–part (ratio) relations – or if their reasoning depends on perceptual judgement. Notably, the concept of half plays a critical role in these judgements, as it represents a key boundary in children's proportional judgements, making comparisons easier when ratios are on opposite sides of a half rather than on the same side (Spinillo & Bryant, 1991).

To determine whether the findings of the original study can be generalised to a different context, it can be essential to conduct a replication study. This paper undertakes a conceptual replication (Aguilar, 2020) of Spinillo and Bryant's (1991) research on proportional judgements, extending it in terms of population, time frame, and classroom implementation. By examining whether the original results hold true for Danish students more than three decades later and within a distinct educational environment, this study aimed to assess the transferability of Spinillo and Bryant's (1991) findings. Additionally, the replication study was intended to gain insights into the strategies employed by

Danish students when engaging with tasks involving proportional judgement. Consequently, the research questions guiding this investigation were as follows:

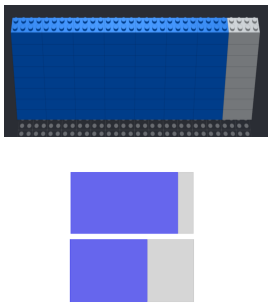
1. What strategies do Danish second-grade students use when solving tasks related to proportional judgement, and how do these strategies compare to those used by 8-year-old students in Spinillo and Bryant's (1991) study?
2. What insights into students' proportional judgements can be gained through a conceptual replication study of Spinillo and Bryant's tasks, conducted with a different population in a different setting?

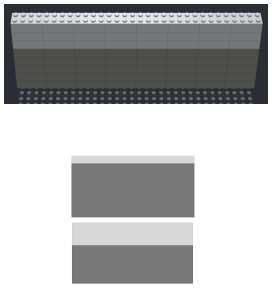
Theoretical constructs related to replication studies

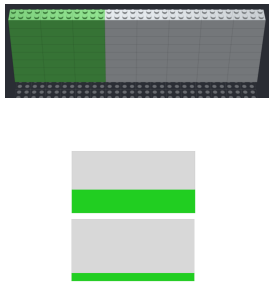
Replication studies play a crucial role in verifying the reliability and validity of original findings, thereby enhancing the credibility of a field. By adhering to rigorous scientific methods and transparent research practices, replication efforts demonstrate a commitment to the robustness of social science research. These studies contribute to building a cumulative and dependable body of evidence, which is essential for the development of sound theories and the formulation of effective practices and policies. Moreover, conducting replications in different settings, populations, or time periods can uncover variations in social phenomena, thus providing valuable insights into the complex and context-dependent nature of human behaviour and social processes (Schoenfeld, 2018; Thanheiser, 2018).

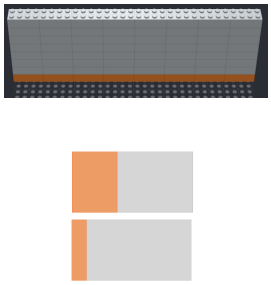
This paper presents a conceptual replication, defined as a replication of a test, hypothesis, result, or, as in this case, a task, but with the use of different methods (Aguilar, 2020). Additionally, the study qualifies as an extension study, as the replication was conducted within a different population (Danish rather than American) and at a different time (the year 2023 and not 1991). This approach allows for an examination of whether the findings of the original study hold true outside the context in which they were reported (Aguilar, 2020).

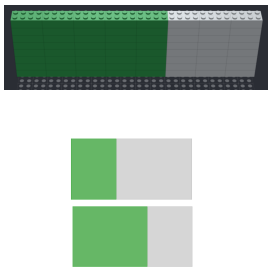
The original study

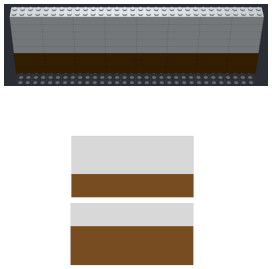


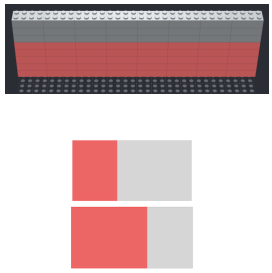


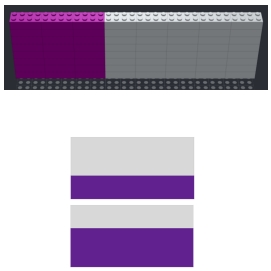


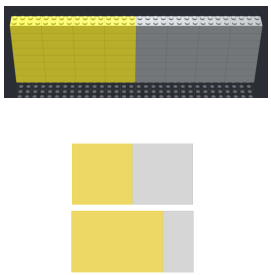


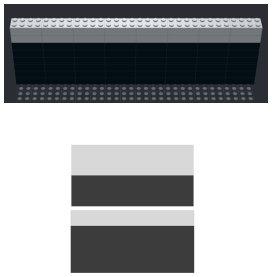


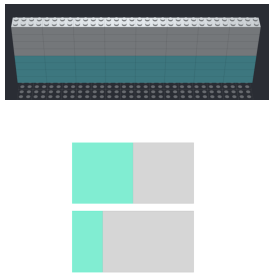


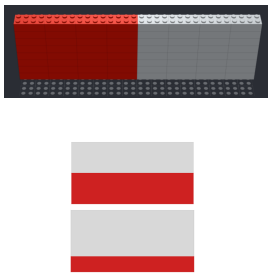












The theoretical foundation for this paper is based on Spinillo and Bryant's (1991) study, which investigated the development of proportional judgements in children aged 4–7 years as described in the introduction. In the original study, the students were shown one figure – the comparison figure – and then asked which of two boxes had the same amount of grey to coloured as the comparison figure (see Table 1). The authors hypothesised that proportional judgement that crosses the half boundary should be easy, and those that do not should be difficult for children. Furthermore, the authors predicted that children would solve proportional judgement problems on the basis of part–part relations, e.g. by comparing one part of the whole with another part of the whole.

Method

In designing the tasks for the experiments in Spinillo and Bryant (1991), care was taken to ensure that children could not base their judgements on the absolute size or shape of the figures. Therefore, the comparison picture was smaller than the two boxes, and the boxes were not subdivided into bricks, so counting was not an option either. The authors included two kinds of comparisons: cross-half and within-half comparisons. While the cross-half comparisons entailed fewer coloured bricks than grey

bricks in one box ($\frac{3}{8}$) and more coloured than grey in the other ($\frac{5}{8}$) (or the other way around), the within-half comparisons had either more coloured than grey in both boxes ($\frac{5}{8}$ vs. $\frac{7}{8}$) or less coloured than grey in both boxes ($\frac{1}{8}$ vs. $\frac{3}{8}$). Furthermore, the authors discriminated if the boxes were in the same or a different orientation than the comparison picture. For each of the four combinations of comparisons and orientations, two tasks were administered to the children in experiment 1. In experiment 2, four tasks were included: two using half comparisons in the same orientation, and two using half comparisons in a different orientation (see Table 1).

Table 1. Presentation of the 12 tasks

	Same orientation		Different orientation	
Within-half comparison				
Cross-half comparison				
Half comparison				

Results

The results of the two experiments showed that even though 4–5-year-olds used the *greater than* relation, they did not use the half as a boundary as older children did. The older children were, however, more likely to use the half boundary in tasks involving a different orientation than they were in those depicting the same orientation. There were no significant differences between the

within- and cross-half conditions in the same orientation. Many more 6–7-year-old children scored above chance level in the cross-half compared to the within-half comparisons. In particular, the 7-year-olds found the cross-half comparisons easier than the within-half comparisons when the orientation differed. There were no significant differences in children's answers when comparing cross-half and half comparisons. The authors concluded that some proportional judgements are made by children from the age of 6 years who discriminate between more than and less than half, thereby indicating that children's initial understanding of proportion involves both simple first-order relations and relations between relations (second-order relations). Children's ability to compare part–part relations was reflected in the justifications the children gave for their answers. Spinillo and Bryant (1991) identified five categories of justifications. While the first two categories did not involve any comparative relations, and the third category involved justifications using single relations, the fourth and fifth categories involved relations between relations. In either of the two latter categories, orientation had no effect on the justifications used by children at any age. However, the fourth category was generally seen in cross-half comparisons, while the fifth category was largely seen in within-half comparisons. In this paper, no distinction will be made between categories 4 and 5.

The replication study

Method

The 12 tasks (see Table 1) were administered to 20 students (one second-grade classroom) in Denmark in January 2023. The students were 8–9 years old. The first task was introduced to the class by their regular mathematics teacher. That task was answered collectively by the students with support from the teacher. The comparison figure was shown in Lego-building blocks, and a picture of the figure was shown on the blackboard together with the two boxes. The students were then split into groups of 2–3, randomly chosen by a picker wheel. All groups were handed cards with comparison pictures and cards with boxes, first for tasks 1–8 and, later in the lesson, for tasks 9–12. The students were then asked to choose the box where the proportion of coloured to grey was the same as in the comparison picture and give a justification to the other group members.

One camera filmed the students' group work during the lesson. The author and an assistant teacher participated in the classroom, answered questions if the students had any, encouraged the students to argue for their choice of box, and took notes of the students' discussions. The excerpts used in this paper comprise a mixture of these notes and transcripts from the videorecording.

Methodological deviations from the original study

This replication study introduced several key differences from the original research, reflecting both an extension of the original study and a conceptual replication. One significant extension was the shift in population and timing: the original study was conducted with children aged 4–8 years in the United States, while this study involved Danish students aged 8–9 years and was carried out 30 years later. Although the Danish students had not received formal instruction on fractions before the lesson, their age group differed from that of the original study (as children aged 4–7 years did not take part).

Another important difference lies in the method of task administration. In the original study, each child was individually given one task at a time. In contrast, this study involved students working in a

whole-class setting where they collaborated in small groups to complete several tasks. This shift from individual to group work represents a conceptual replication, as it explores the same tasks through a different approach.

Additionally, the materials used in this study were adapted from the original. While the original study used blue and white boxes, the current study modified the materials to enhance clarity. The white parts of the boxes were changed to light grey to distinguish them more clearly from the background, and each of the 12 tasks featured different colours instead of the consistent blue used previously. These changes were made to facilitate the students' ability to reference specific tasks while being video-recorded, thereby improving the data collection process.

Results

In order to analyse the students' justifications, all of the justifications in the transcripts were colour-coded based on the four types of justification identified by Spinillo and Bryant (1991):

1. No comparative relation: mention colour without quantification (red)
2. No comparative relation: mention of quantity but no comparison (orange)
3. First-order (single) relation: comparison of quantities of both colours in one box only (part–whole comparison) or comparison between boxes using only one colour (green)
4. Second-order relation (relation between relation): comparison between colours within and between relations across the picture and the box (blue)

All the colour-coded justifications were arranged in a table corresponding to the tasks in Table 1, as can be seen in Table 2. Only justifications where the specific task was clearly identified in the students' justifications are included in this table.

The first four tasks involved two boxes where the proportion of the coloured section fell on the same side of half (within-half comparisons). Since the student groups quickly agreed on the correct box with minimal discussion, this indicates that they found it relatively easy to identify the correct option. The students predominantly used terms such as *more*, *most*, and *less* in their reasoning. None of the students used the term half in their justifications. When possible, they used the comparison figure to measure against, for instance by rotating the comparison figure, especially if they were asked to justify their choice. In tasks with different orientations, many students attempted to rotate the figure. The next four tasks given to the students involved cross-half comparisons. In these tasks, 2–3 students used the term half to argue which box had as much coloured as the comparison image. In the final four tasks, one box had exactly half its area coloured, while the other either had more or less than half coloured. Here, more students employed the term half in their reasoning.

The analysis revealed that in tasks in both *Same* and *Different orientation*, students described the size of the different parts in the boxes by positive degrees such as *much*, *thick*, or *thin*, and by using comparatives such as more/less of, *thicker* or *thinner*, or *equally big*. The use of positive degrees is however only seen in *Within-half comparisons*, whereas students' only used comparatives or the term half in the *Cross-half comparisons*. In the *Half comparisons*, however, the use of positive degrees was repeatedly observed. In Table 2, positive degrees are marked in *italics*, while comparatives are marked in **bold**. Use of the term half is <u>underlined</u>.

Table 2. Colour-coded student justifications

	Same orientation		Different orientation	
Within-half comparison	"The one on the left, because the one with the *small* grey piece resembles the LEGO figure the most. The other one has **more** grey."	"You can see that there are **more** lines on the LEGO figure, so it matchesthe one with the **most** grey."	"This one is really *thin* . The other one is a bit **thicker**. You can see on the LEGO figure that the green is *thick* , so it matches best with 3a."	"It's because there's **more** grey compared to orange [4b], and there's also a lot of grey compared to the orange on this one [figure 4]. Here [4a], there's **more** than on that one [4b]."
	"I think it's the one on the right, because there is **too much** grey on the other one."	"It's because, look. Here there's a very *thin* line [2a], but here there's a much **thicker** line [2b], just like in the picture [figure 2]."	"Because, there's **more** green here [3a] than here [3b]. And there's **less** grey [3a], because it's not just like this [rotates figure 3 to match with 3b]. I can't explain it."	"I think it's because there's **more** grey here, og **less** orange here [4b]"
Cross-half comparison	"It's easy. They're the **same** size."		"That's way too little. Then it would be less than half."	"I think this one matches with this one because if you turn it this way, they would be the **same** lenght."
	"I think it's 5b because the green is the **same** lenght."			"Shall I tell you why? It's because here there's **more** purple than grey, and here there's **more** grey than purple. Can you see it?
Half comparison	"I think it's this one. Look. Half is grey. Half is yellow." "I think it's the other way around. Look, if we flip it, then it's half here."	I think this one matches with that one. This one has *a bit* of grey and *a lot* of black, and here it's also *a bit* of grey and *a lot* of black	"I think it fits here [11a] because there's an **equal** amount of green and grey"	"So, for example, it could be that there's *a bit* of red and *a lot* of grey here, and here red and grey are **equal**, and it's the same here, so it matches well with this one."
	"The grey one has *a bit* of colour. The yellow one has *a lot* ."			"*A bit* of red and *a lot* of grey. Here, it's **equal**"
	E1: "I think that one [9] matches there [points] because there's an **equal** amount of grey and yellow, and it's the same here, but not there."			
	E2: "Here there's *a lot* of yellow, and here there's **mostly** grey."			

While none of the students' justifications were identified as belonging to the first type of justification, types 2–4 were frequently seen. For tasks in the category *Same orientation*, most student answers contained either single relations (category 2) or first-order comparisons (category 3), whereas justifications related to tasks in the category *Different orientation* were based on either first-order (category 3) or second-order (category 4) relations. In the last category, more students used first-order comparisons when the tasks were related to within-half comparisons, while more second-order justifications were seen in cross-half and half comparisons. *Half* was used in one of the justifications related to a task in *Cross-half comparison*, *Different orientation*, but was otherwise only identified in *Half comparison* in *Same orientation*.

Based on the student responses in Table 2, it is not clear whether they found tasks in the *Same orientation* easier or more difficult than those in *Different orientation*. However, several student quotes from the video recordings indicate that tasks in the *Different orientation* category were perceived as more challenging:

Student 1: I thought 1 was easy because the box looked like the one in Lego. Number 3 was the hardest because it's facing the other way.
Student 2: I thought 5, for example, was easier than 3 because in 3, it's facing the wrong way. In 5, it's just the same.
Student 3: 11 is the hardest because the green line [11b] looks like the green line on the Lego figure, but when you turn it, there's an equal amount of green and grey, so it's that one [11a].

The third student response also highlights that students found it easier to compare the boxes with the comparison figure by rotating one of them, despite the figure appearing significantly different. However, this did not seem to confuse the students. In a dialogue with a classmate, one student articulated that even when the figure was rotated, the proportion of coloured sections remained the same, as the student perceived the coloured sections as a liquid that can adapt to another form.

Student: And if you think of this as water, it just flows down here, so it doesn't matter.

Discussion and conclusion

The findings indicate that the Danish students found it relatively easy to make within-half comparisons. Unlike in cross-half comparisons, where a significant number of students referenced half in their justifications, students did not use half as a boundary in their reasoning for *Within-half comparisons*. The use of half and *equal parts* was more prevalent in *Half comparisons*. Additionally, the students' justifications revealed that they perceived tasks with the *Same orientation* as easier than those with a *Different orientation*. The concept of half was used as a justification in *Different orientation* tasks for *Cross-half comparisons*, but not in the *Same orientation*. Conversely, in *Half comparisons*, half was used in the *Same orientation*, while equal was used in *Different orientations*.

Unlike the original study, this one did not conduct a comprehensive count of all students' responses across all tasks. Therefore, it is not possible to determine whether Danish students found *Cross-half comparisons* easier or more difficult than *Within-half comparisons* to the same extent as reported in the original study. However, it is possible to compare the findings regarding the older students in the original study with the Danish students, where the ages overlap. The results in this study are therefore not an indication that an equal proportion of students found cross-half comparisons easier than within-half comparisons. Instead, this study explored whether the same types of justifications observed in the original study were also present in a different population at a later time, and whether students who had not yet received formal instruction in fractions would use half as a boundary when making proportional judgements.

Given the different methodological approach used in this study, this conceptual replication (Aguilar, 2020) offers new insights that were not captured in the original study, where the children worked one-on-one with a teacher. In this study, the students worked together in a setting that more closely resembled their regular mathematics classroom, allowing them to learn from one another and to provide justifications to their peers. This collaborative environment, however, became problematic

in tasks where the students quickly reached a consensus, making further justification unnecessary. Many students were willing to justify their choices when prompted, but particularly in *Within-half comparison* tasks, where they could not use half as a boundary, it became difficult for them to articulate their reasons for choosing a particular box. This finding underscores the importance of the half boundary in students' proportional judgements (Spinillo & Bryant, 1991), indicating that students in this age group are able to distinguish between more than and less than half.

One finding not reported in the original study is that when students were given tasks to be completed in small groups, they attempted to shift the orientation so that the boxes and the comparison picture had the same orientation, even though this made the boxes look significantly different. A key point that supports the notion that students were indeed using part–part relations in such cases is that they focused on the relative amount of the coloured part in one figure compared to the coloured part in the other. Even though the figures looked markedly different, several students in the present study employed the idea that the coloured part were like a liquid that could shift within the box, so that even if the boxes no longer appeared identical, a certain proportion of the box would remain coloured. Although this was not observed in the original study due to the different methodology, it supports Spinillo and Bryant's (1991) argument that students can solve proportional judgements based on part–part relations.

The conceptual replication described in this paper largely supports the original findings despite the methodological differences and extensions (Aguilar, 2020) made: namely, that the tasks were given to Danish students as part of classroom instruction more than 30 years later. To make a closer comparison with the original study's results, it would be relevant to conduct the study with younger students, as was done in the original study. Additionally, more systematic data collection of all students' responses to all tasks, ideally involving a larger population, would be beneficial. Moreover, this analysis did not discriminate between categories 4 and 5 in the analysis, as it was challenging to differentiate between the two codes when analysing students' answers.

Critical speculative implementation discussion: Future scenarios on technology and mathematics in schools

Cecilie Carlsen Bach[1], Jack Jalal Kallo[1], Daniel Spikol[1], Adrienne Traxler[1], Mads Brink Müller[2], and Morten Misfeldt[1]

Keywords: Technology comprehension, implementation, tarot cards, future scenarios.

Implementing technology comprehension into mathematics

Implementing technology comprehension (TC) into mathematics provides students with prerequisites to participate in a digitalized society and to create and act using digital technologies (DT) (Danish Ministry of Education, 2019). Yet, research on TC and computational thinking (CT) highlights the challenges of introducing new subject areas (e.g., Benton et al., 2017; Slot et al., 2021). In Denmark, a national center for digital TC in K-12 education investigates how to develop TC as a new subject and how to implement TC into the mathematics and Danish (L1) curriculum. This poster presents a novel approach aiming to foster discussions with mathematics teachers in design-based research. Drawing on Bayne and Ross (2024), we developed 12 "tarot cards" that offer speculative scenarios related to technology and education, aiming to support teachers in shaping their ideas for implementing TC into mathematics.

Tarot cards presenting future scenarios of technology and education

Our 12 cards were heavily inspired by Baynes and Ross' (2024) cards. However, we were also inspired by trends in mathematics education research. For instance, Card 2 concerns CT (Wing, 2006). In August 2024, the tarot cards were tested in a workshop with three teachers from primary and lower secondary schools at the beginning of a design-based research process. During the workshop, the teachers evaluated the cards by discussing whether the scenarios were "dangerous" or "cool," and "realistic" or "unrealistic." At the end of the workshop, the teachers created their own vision cards to outline their hopes when implementing TC in mathematics. See Figure 1. Four of the cards are presented in shortened versions below:

Card 1: Back to the Analog Past: *What if the school became completely analog again?* We need to go back to the time when DT didn't have a place in schools. Students' learning and well-being were much better before the use of DT.

Card 2: A Necessity for the Job Market: *How can we prepare students for the job market of the future?* The school must help educate the next generation of the workforce. Therefore, we need to focus on developing students' technological abilities and computational thinking.

Card 4: AI Academy: *Why shouldn't students' learning just be taken over by artificial intelligence?* There is no longer a need for trained teachers in schools. In school, there are adults to take care of the children, but all learning is controlled by DT, particularly AI.

Card 10: Computer science is the new mathematics: *Why shouldn't mathematics be replaced by informatics?* Mathematics, as we know it today, must be replaced by informatics. Thus, our students must become more technically competent!

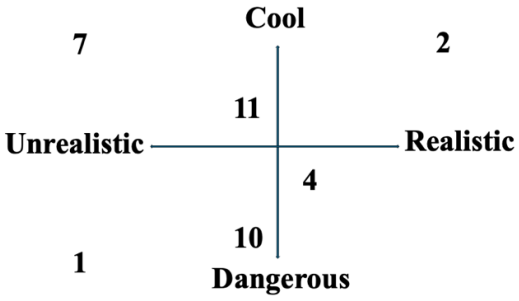

Figure 1: An overview of how the teachers valued Cards 1, 2, 4, 7, 10, and 11

The tarot cards were used in discussions before we designed teaching aiming to implement TC in mathematics. We hypothesize that implementing our tarot cards may ease the implementation of TC as teachers become aware of their aims for implementing TC into mathematics. Potentially, discussions involving our cards could lead to a stronger relationship between teaching aims, and how the teaching is carried out.

At the CERME conference, we bring a printed A0 high-format poster as well as our tarot cards.

Using structured reporting guidelines for intervention research to set up a program theory: The case of Algebra Monday

David Nordqvist[1], Tina Åkegård[1], Linda Marie Ahl[2]and Ola Helenius[2]

[1]Katedralskolan, Skara Municipality, Sweden; David.Nordqvist@edu.skara.se

[2]University of Gothenburg, Gothenburg, Sweden

Keywords: Implementation, Algebra, Scaling.

Introduction

In a recent working paper by Hill, Lynch and Polanin (2024) the authors argue that a reason for the educational research field's lack of ability to build an accumulated evidence base is the inconsistent reporting of critical facets of classroom interventions. Building on research reviews as well as on other analytical work, the authors suggest a set of structured guidelines for reporting intervention research concerning the five dimensions: Program provider and intervention content for students; Program content for teachers; Program professional development; Program curriculum materials; Program support for implementation, as well as a specific category for Setting-Level Resources, Contexts, and Barriers. Within each dimension, several specific descriptive categories are suggested.

This poster proposal and the associated poster has the purpose of bringing the discussion of such guidelines into the field of implementation research in mathematics education. As a background for such a discussion, we apply the suggested guidelines to an implementation case, the case of *Algebra Monday* (described further below) and compare with established ways of discussing implementation variables, as for example described by Coburn's scaling factors (2003) and the role of the innovation, user, organization and external environment as described by Century and Cassata (2016). A goal with the poster and the discussion we hope it can spark, is to examine if the framework Hill et al. suggests is helpful when designing a program theory (Chen, 2012) in addition to being useful when reporting research.

Background

The *Algebra Monday* program is based on the premise that all mathematics teachers from grades 1 to 9, as well as those teaching upper secondary courses, engage with content related to algebra and structured arithmetic once a week, following a specific whole-class instructional design. It is developed in the municipality where the two first authors are working. Using conclusions from a review of implementation research (Ahl et al. 2023) we have decided on a cascading scaling type of design, where we in the planning, designing and piloting phases work with 3 teachers for grades 1-3, 4-6, 7-9, and upper secondary school respectively. Together with these groups we will develop and pilot curriculum materials for Algebra Monday, as well as a professional development design, where the pilot teachers will act as PD leaders in accordance with the medium-scale deliberate multiplier design suggested by Aguilar et al. (2023). This means that Algebra Monday is a complex enough case for examining the feasibility of using the reporting guideline scheme (Hill et al. 2024) as a tool for planning and design. It concerns specific content for students and teachers, a PD component and a

curriculum material component, both developed within the project, as well as support for implementation.

Poster format

The poster contains a description of the background of the Algebra Monday project and brief introduction to the concepts of innovation, user, organization and external environment (Century & Cassata, 2016) as well as the four scale factors described by Coburn (2003). The main part of the poster will be a description of Algebra Monday following the table structure used by Hill, Lynch and Polanin (2024, appendix). In a conclusion section we compare what aspects of the implementation of Algebra Monday that are captured by the structured reporting framework relative to typical implementation aspects described by Century and Cassata (2016), Coburn (2003) and Aguilar et al. (2023).

The main contribution to implementation research will be a suggestion that the reporting guidelines is not only worthwhile when reporting a researched project but can also serve as a planning and design tool. Since the planning and design stages of implementation projects are under-reported in the literature (Ahl et al. 2023), the poster can serve as an inspiration on how to report the planning and piloting stages, using Algebra Monday as a case.

[4]University of Georgia, USA; katherine.obrien1@uga.edu

This paper explores the discussions and findings from Thematic Working Group 24 (TWG24) at the CERME14 conference, focusing on the role of representations in mathematics education across teaching, learning, and research. We examine how representations function as cognitive and communicative tools in various educational contexts and explore theoretical perspectives that inform the use and study of representations. Through a synthesis of the discussions and presentations, we highlight emerging themes, key challenges, and future directions in research and practice.

Keywords: Internal vs. external representations, Multimodal representations, Representations, Realizations, Semiotic registers of representation, Representations of data.

Introduction

Mathematical representations play a crucial role in teaching, learning, and research. They enable learners to visualize, conceptualize, and communicate mathematical ideas effectively. The CERME Thematic Working Group 24 (TWG24) *Representations in Mathematics Teaching, Learning and Research* brought together researchers and educators to discuss theoretical perspectives, pedagogical practices, and methodological challenges associated with representations in mathematics education. This paper synthesizes the group's discussions, presenting key insights into how representations function in classroom instruction, student learning, and research methodologies.

The group consisted of 21 participants and reviewed 17 research papers addressing diverse aspects of representations. The sessions followed a structured format, including short presentations, critical peer discussions, and collective analysis. The discussions centred on how representations support mathematical reasoning, problem-solving, and conceptual understanding in different learning environments.

We organize the following discussion in three main sections: representations in teaching and learning, representations in mathematics research, and theoretical perspectives used.

Representations in teaching and learning

Several papers introduced and discussed the role of representations in mathematics education, arguing that representations are fundamental tools serving multiple pedagogical purposes. These include facilitating communication of mathematical ideas, particularly in inclusive settings (e.g., Angeloni et al.); illustrating mathematical structures, making abstract concepts more accessible (e.g., Copperman et al.; Kadan-Tabaja; Lisarelli et al.); supporting problem-solving and modeling, allowing

students to express and refine their reasoning (e.g., Cosci; Lemrich; Lobnig; Köhne; Wendelborg et al.).

Authors presented various examples of representations in classroom practice, including several innovative approaches to using representations, such as bodily representations. For example, physical movement was used to explore line symmetry, engaging learners in embodied cognition (see Hölzer & Vogel). Sonified representations in the form of sound-based function representations were introduced to support visually impaired learners and emphasize covariation perspectives in function learning (see Manolino et al.; Piroi et al.). Graphical representations, including explorations of the role of graphs, dynagraphs, and symbolic representations in understanding functions were also examined. This research emphasized the need for seamless transitions between different forms (see Aviram et al.; Poli & Macchioni; Lisarelli et al.).

Some contributions presented studies about the roles of representations of mathematical objects, such as expressions, linear equations, functions or fractions, created in digital environments (e.g., Aviram et al.; Lisarelli et al.; Manolino et al.; Poli & Macchioni), also focusing on potential and pitfalls of their affordances including the feedback offered (e.g., Köhne; Kadan-Tabaja).

Our working group also discussed representations in teacher decision-making: Recognizing that different representations highlight different mathematical properties, how can educators select and sequence representations to optimize student learning? (see Weingarden).

Representations in mathematics research

In response to our novel call for papers which explore how representations are used by researchers to analyze and present their data, some contributions discussed the use of representations in research methodologies. Indeed, representations are integral to data collection, analysis, and interpretation in mathematics education research. The following key methodologies were discussed: eye-tracking analysis, gesture-based coding, and discourse analysis. Two papers analyzed eye movements when solving non-linear geometry problems, identifying fixation points, gaze patterns, and areas of attention (see Schroeder & Götze; Volbers et al.). In another contribution to our working group, color-coded visual representations were used to segment and categorize gestural and verbal interactions in video data (see Hölzer & Vogel). Finally, realization trees were employed to track the evolution of mathematical discourse in classroom and research settings (see Weingarden).

A common challenge in research is the static nature of representations in academic papers, which limits the ability to capture dynamic, multimodal mathematical interactions. The group discussed the potential of video-based representations, interactive data visualizations, and multimodal transcripts to improve research communication. While these ideas raise new technical and ethical issues related to the communication of research, they could support research audiences in accessing the more lively and mobile role of representations in both learning and researching.

Theoretical perspectives on representations

To understand the cognitive and communicative functions of representations, studies by various participants made use of a variety of theoretical frameworks, which were then carefully discussed and examined by the group to better understand the perspectives and insights provided by each. Such

discussions focused especially around; 1) commognition (Sfard, 2008), which defines representations as realizations of mathematical objects (e.g., Aviram et al.; Baccaglini-Frank et al., 2022); 2) Duval's semiotic registers (Duval, 2006), which focuses on the transitions between different representational systems (e.g., Wendelborg et al.) and Bruner's modes of representations (e.g., Hölzer & Vogel); 3) Rabardel's Instrumental Approach (Rabardel, 2002), which views representations as tools that mediate mathematical thinking (e.g., Kadan-Tabaja); 4) Peirce's diagrammatic reasoning (Peirce, 1965), which examines the role of diagrams in mathematical reasoning (e.g., Piroi et al.), 5) Goldin's internal versus external representations (Goldin & Shteingold, 2001), which differentiates between internal cognitive structures and external mathematical expressions (e.g., Wendelborg et al.), and 6) Fischbein's intuitive models (Fischbein, 1987), which explores how intuitive mental representations shape mathematical learning (e.g., Cooperman et al.). Other papers developed theoretical frameworks driven by concepts drawn from mathematics education literature. For example, productive irritations (Nührenbörger & Schwarzkopf, 2015, as cited in Schroeder & Götze); Tall and Vinner's (1981) notions of concept image and concept definition (in Lobnig); Polya's (1973) conceptualisation of problems, as opposed to routine tasks (in Volbers et al.).

Our discussions highlighted the need to bridge different theoretical perspectives, particularly in understanding how learners transition between representations and how external representations support internal cognitive processes. However, the efforts to align, interlink, and differentiate between the theoretical concepts that we use to conceptualise thinking, learning, and interacting can be quite challenging (e.g., Hölzer & Vogel). A diverse set of theoretical approaches is important to broaden our research questions and methods related to questions of representation. But the special languages of these theories can silo our research findings, making them meaningful to only those who speak a specific theoretical language. Especially because papers tackle a wide range of mathematical and pedagogical issues, finding common theoretical ground can be important. Similarly, working to understand tensions between specific theoretical approaches drives our work to become both more complex and precise.

Conclusion and future directions

In response TWG24 emphasized the central role of representations in mathematics education, both in practice and research. Key takeaways include the following:

1) The importance of promoting flexible transitions between different representations to enhance mathematical learning,

2) The need for multimodal representations, such as auditory, gestural, and interactive tools, especially because this approach supports the inclusion of a wider group of learners,

3) The current limitations in representing dynamic mathematical interactions in research, and the desire to explore the potential of interactive and video-based representations to address these issues,

4) An interest in understanding how the range of theoretical approaches used to study representation in mathematics and mathematics education can be aligned or debated,

5) An interest in investigating how researchers use representation, not only to communicate results, but also as a part of the research process.

Future research should focus on developing new representational tools and further investigating how representations mediate learning and reasoning in diverse educational contexts. By continuing to explore the intersection of theory, practice, and technology, we can advance both mathematics pedagogy and research methodologies.

Boxes and matches as a model for introducing variables in a sign language-oriented mathematics class

Flavio Angeloni[1], Christian Hausch[2] and Annika M. Wille[1]

[1]Leibniz Universität Hannover, Germany; angeloni@idmp.uni-hannover.de

[2]Universität Klagenfurt, Austria

Sign languages possess characteristics that differ from those of spoken languages and these differences can influence mathematics learning and teaching. In a signed discourse, concepts are typically organised syntagmatically, with a topic in the centre and other topics around it. The study presented here investigates how the "shell aspect" of a variable can become the topic in the centre of the mathematical discourse about the introduction of the variables concept in a sign language. To explore how the students handle mathematical sign language communication, a learning environment was designed and realised with a small group of students. The result is a learning environment that has been shown to be an effective means of introducing the concept of variables in a sign language.

Keywords: Sign Language, algebra, variables, equations.

Introduction

Signed and spoken languages have a different modality: visuo-gestural in sign languages and audio-verbal in spoken languages. Sign languages offer a different kind of access to mathematical concepts (Krause & Wille, 2021). Therefore, modality-related differences should be considered in mathematics teaching that employs a sign language (Grote et al., 2018). For example, Healy et al. (2021) states that "the ways in which movement is incorporated into the signs […] perhaps serves as an effective means of enacting meanings for" (p. 153) algebraic symbolism. This is consistent with the preference for simultaneous signing of information (Krause, 2023). Dessbesel et al. (2023), in a study on algebraic thinking in deaf education, stated that sign languages need to be valued not only in the translation of content from a spoken language to a sign language, but also in communication and search for strategies to achieve learning. Their study, however, does not focus directly on variables, which is what will be done here. Indeed, the study presented in this paper focuses explicitly on introducing variables in a sign language-oriented mathematics class. Linguistic tools are used to develop a learning environment for sign language-oriented teaching to introduce the concept of variables. Such an approach has already been used by Nordheimer et al. (2024), who adapted linguistic tools in geometrical learning contexts to develop learning environments in German sign language. In the study presented here, the learning environment – understood as a teaching and learning offer (Barton, 2023) concerning different methods, learning materials and media (Reinmann & Mandl, 2001) – was developed, discussed and is available in Austrian sign language (ÖGS).

Theoretical framework

Sign languages in the mathematics class – some essential properties

Sign languages organize content differently than spoken languages (Grote, 2010). It has been observed that deaf signers tend to initiate communication with a particular content aspect and give

further contextual information so that all the aspects are in relation to each other (simultaneous-circular structure). In a spoken language, content is typically organised in hierarchical manner starting with something general (sequential-linear structure) (Grote et al., 2018). Therefore, the conceptual development that is typically based on the characteristics of spoken languages often does not match the conceptual understanding of signing students (Krause & Wille, 2021). Healy & Fernandes (2014) explored algebraic expressions of deaf students signing about the notion of variable in the context of solving tasks about constructing sequences. One of their conclusions was that there is a need "to attend more closely to the practice of communicating mathematics" (Healy & Fernandes, 2014, p. 55) in sign language. When considering communication in sign languages, a linguistic distinction between syntagmatic and paradigmatic relation is central. A paradigmatic relation is a hierarchical relation with terms and sub-terms. For example, "car" is a sub-term of "vehicle". A syntagmatic relation, however, exists when terms are usually used together – i.e., "car" and "road". Terms can also be signed simultaneously, whereas in spoken languages terms are always spoken linearly. Grote (2010) stated "the use of sign languages has an effect on the strength of syntagmatic relations in the conceptual system, i.e. on conceptualization" (p. 317). A reason is that *simultaneity* is typical for sign languages and is only possible for terms that are syntagmatically related. Preferring simultaneity tends to strengthen semantic relations between syntagmatically related concepts. The study presented here focuses on syntagmatic relations because of their relevance to concept for learning. In addition, *centring*, which is another property of sign languages, is considered in this paper. This means that a topic is placed at the centre of a discourse and a syntagmatic context is built around it. Such a context can be created by changing the perspective, switching from one specific concept to another to describe it in more detail. In the mathematics class, this would mean that a specific topic should be placed at the centre, around which other "knowledge units […] are placed" (Grote et al., 2018, p. 430).

Aspects of variables in Austrian Sign Language

Fig. 1a Fig. 1b Fig. 1c Fig. 1d Fig. 1e Fig. 1f Fig. 1g

Fig. 1h Fig. 1i Fig. 1j Fig. 1k Fig. 1l

Figure 1: EMPTY$_1$ (a), EMPTY$_2$ (b), NOT-YET (c), CONTENT$_1$ (d), TO-SUBSTITUTE$_2$ (e), IX-No:THREE (f), X-No:THREE (g), TWO-TERMS$_1$ (h) , DO-NOT-KNOW (i), CONTENT$_2$ (j) (Angeloni &Hausch, accepted), BROSHURE-STACK (k) (Angeloni, 2023, p. 531), TWO-TERMS$_2$ (l)

Variables can be considered in different ways. The following section considers the semantic aspects of variables according to Malle (1993) and Wille (2008) and the results of previous studies in the

context of sign languages in relation to the aspect. According to the *object aspect* (Malle, 1993), a variable represents an unknown number. A variable under this aspect can be signed by the signs EMPTY_1 (Figure 1a) and EMPTY_2 (Figure 1b). Both signs express "that the variable does not contain a number" (Angeloni & Hausch, accepted) – the number is unknown. The sign NOT-YET (Figure 1c) conveys that the number is temporally unknown (Angeloni & Hausch, accepted). There are other signs that can be used to sign a variable under the object aspect. They depend on the iconic properties of the reference object. The sign in Figure 1k is an example of this. It expresses, with the movement of the right hand up and down, that the number of brochures on a stack is unknown. According to the *substitution aspect*, a variable acts as a placeholder for numbers (Malle, 1993). For example, this can be addressed by the sign in Figure 1e: a value from a table is substituted for the variable. The information about the table and the equation were previously placed in the signing space with the corresponding signs. According to the *calculus aspect*, a variable is a symbol with which one may operate according to certain rules (Malle, 1993). Under the *shell aspect*, a variable is like "a cover or a box for the number but it is still here" (Wille, 2008, pp. 422–423). Signs in relation to this aspect are CONTENT_1 (Figure 1d) and CONTENT_2 (Figure 1j). Both signs express "that a variable is like a container that can contain a number" (Angeloni & Hausch, accepted). Moreover, the shell aspect of variables can be also identified in the signs in the Figures 1f and 1g. The sign in Figure 1f is used to point to the location of the term in the sign language space where three is to be substituted for x, and, sometimes, to point to the individual locations in the sign language space where x was previously placed. The shell aspect is visible in the Figure 1g with the sign No:THREE behind the sign X: "[…] X acts as a placeholder into which the number [three] is inserted and remains" (Angeloni & Hausch, accepted). The research of Angeloni & Wille (submitted) explores a possible syntagmatic framework between the signs presented here and other signs about variables and operations with them, and consequently, between the different aspects of variables. In the sign language communication studied in Angeloni & Wille (submitted), the shell aspect was often addressed, with the signs presented above, to sign about a variable from the perspective of the other variable aspects – such as in the following phrase from the study: […] CONTENT_1 X_1 X_1 NOTHING_1 NUMBER EMPTY_2 CONTENT_1 PLUS_1 No:THREE *(the content of x is not a number, it is empty, but we calculate plus three)*. Here, the perspective changes repeatedly from the shell aspect (the variable has a content) to the object aspect (the content is unknown) and the calculus aspect (we calculate with the symbol x for the variable). So, the shell aspect is centred in the network and syntagmatically connected to the other aspects.

Research interest

For introducing the concept of variables, the following questions arise: *RQ 1) How can the shell aspect be centred in a learning environment to introduce variables in sign-language-oriented teaching? RQ 2) How do students handle mathematical sign language communication in such a learning environment?*

Methods

A group of three deaf secondary school students (aged 12 to 14) took part in a series of 50-minute mathematics lessons about variables. The lessons addressed the aspects of variables described above. Two students were in the 8^{th} grade, so they should already have been familiar with the topic of

variables. One student was in the 6th grade and, therefore, should have more basic knowledge – such as setting up "simple" linear terms. The regular mathematics class of these students was spoken language-oriented and they were accompanied by a special education teacher who summarizes the content of the lessons for these students. Students' knowledge about variables was not previously tested so as not to interfere with their participation in the regular class. The first two lessons of this series included the introduction of variables. According to the aim of the learning environment (RQ 1), the focus was on the shell aspect of variables. To address this aspect, matchboxes were used to represent variables and matches were used to represent numbers. Each box has a colour so that different variables can be distinguished and there must always be the same number of matches in the boxes of the same colour. This representation can address the object aspect of variables: if the box is closed, we do not know how many matches are in the box. The number of matches can also be changed. Therefore, a box can stand for any (positive integer) number. With these representations, variables can be introduced without notations like x or y. Boxes and matches can be strung in a row to form an expression. Two such expressions can be set equal and form an equation, here called a "box-equation". The shell aspect can be directly addressed: a box is still here when matches are added. Therefore, as described below, the learning environment is based on "boxes and matches". The participant should have achieved the following learning objectives by the end of the two lessons: 1) they are able to explain that a variable can represent an unknown number using appropriate signs – such as CONTENT$_1$, NOT-YET and EMPTY$_1$; 2) they can transform box-equations into linear equations with two variables; 3) they can find solutions of box-equations with two variables by substitution with numbers. To investigate question RQ 2, the students solved the tasks set within the learning environments according to the principle of "think, pair and share". In this way, they should become active in signing. The students were interviewed individually at the end of the series of lesson to obtain further information about their knowledge of mathematical signs and feedback on the lessons. The interviews included questions such as: Was the topic new to you? What signs did you know before? Did you understand the signs in the lesson videos? The lessons and the interviews were held in ÖGS and were videotaped. The video data (from the lessons and interviews) and the written students' solutions to the tasks were analysed using qualitive content analysis (Mayring, 2014).

Findings

The first section addresses the research question RQ 1 about a learning environment that focuses on the shell aspect of variables. The research question RQ 2 is discussed in the second section.

A learning environment for introducing variables in sign-language-oriented teaching

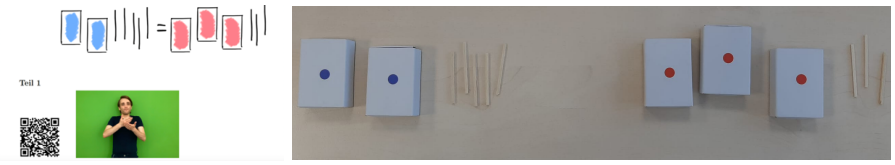

Figure 2: Exercise 1, part 1 of the worksheet (left) and an arrangement of boxes and matches (right)

The learning environment includes a worksheet, blue and red boxes with matches, has a duration of 90 to 100 minutes and it is designed to teach in ÖGS. In this learning environment the concept of variables is introduced from the perspective of the shell aspect by using the sign CONTENT$_1$ (Figure

1d). To centre the shell aspect, a syntagmatic context should be constructed by changing the perspective. Therefore, the perspective changes multiple times during the learning environment, for example to the object aspect, and, every time, the specific signs for the variable aspects presented above are used. The worksheet contains two tasks which are given as videos in ÖGS. It also contains an explanatory video in ÖGS. To watch the videos, the students scan the QR-codes. Each student is equipped with a tablet with internet access, blue and red boxes, matches, paper and pencils. The signs that are signed in the videos are the results of previous studies (Angeloni & Hausch, accepted). The first task consists of three parts and addresses the learning objectives 1 and 3 as follows: 1) The box-equation in Figure 2 is presented in the video: "There are boxes without content and there are two colours – red and blue boxes. There are also a lot of matches. Place the boxes and matches on the table as follows". The box-equation in Figure 2 is now signed. The students must set up this box-equation as in Figure 2 and compare it with the picture above. The signs CONTENT_1 and EMPTY_1 are signed in the video. At this point, the shell aspect is addressed by CONTENT_1 and the object aspect of the variable represented by a box is addressed by EMPTY_1. 2) The question is signed: "How many matches are there in a blue or red box?". The information that the sum number on the left and the sum number on the right of the box-equation must be the same is given by the equal symbol on the picture (Figure 2, left). Nevertheless, the teacher can sign it using the sign in Figure 3d. According to the "think, pair and share" principle, the students should think about a possible solution and discuss them with each other. 3) Finally, the students are asked to set each other similar tasks and solve them.

Fig. 3a Fig. 3b Fig. 3c Fig. 3d Fig. 3e

Figure 3: Signs NOT-A-NUMBER (a), EQUAL_3 (b), TIMES (c), RESULT_3 (d), PLUS_1 (e)

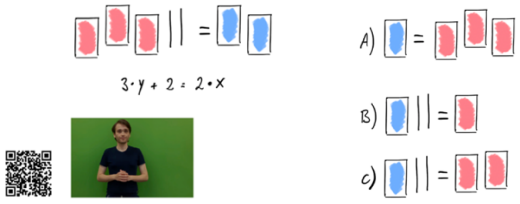

Figure 4: Explanatory video (left) and exercise 2 (right)

In the explanatory video, learning objectives 1 and 2 are addressed by explaining the relationship between box-equations and algebraic equations. The content of the video is the following: The box-equation in Figure 4 (left) is first signed. After that, the signer signs that we do not know how many matches are in a blue box, therefore we need to set x for the unknown number. This occurs using CONTENT_1 (Figure 1d) and the sign in Figure 1i. The location in the sign space is relevant to express the relation between the blue box and the variable x: the box is placed on the right and the variable is placed on the left. The box-equation is no longer present. The relationship between x and the blue box is signed once again. The signer explains, additionally, that "the content of x is not a number. It is empty." The signs COTENT_1, NOT-A-NUMBER (Figure 3a) and EMPTY_1 (Figure 1a) are signed

here. The perspective moves to the object aspect and the variable is described in more detail, but the syntagmatic relation to the shell aspect is still there. Indeed, the signs CONTENT_1 and EMPTY_1 occur in the same sign phrase and at the same place. Similarly, the signer introduces the variable y, related to the unknown number of matches in a red box. The box-equation is taken back and signed once again: its left (resp. right) side is placed on the left (resp. right) side of the sign space. This is relevant in the next step, when the equation is introduced with the question: IX.left TOTAL HOW-MUCH IX.right TOTAL HOW-MUCH WRITE WHAT *(What do we write for the total number on the left and the total number on the right side?)*. The signer signs now the equation $3 \cdot x + 2 = 2 \cdot x$. EQUAL_3 (Figure 3b) is used for the equal symbol, TIMES_1 (Figure 3c) resp. PLUS_1 (Figure 3e) for the multiplication resp. addition symbol and TWO-TERMS_2 (Figure 1h) is signed for the equation. The explanatory video, with the mentioned signs, addresses learning objective 1. The explanation of the transformation of a box-equation into a linear one addresses learning objective 2. This is also addressed by the second task (Figure 4, right), which consists of two parts described as follows: 1) First, the picture in Figure 4 (right) is signed above in the sign space. The students are then asked to transform the box-equations into equations with x and y. The sign TWO-TERMS_2 (Figure 1l) for "equation" is used and signed below in the sign space "under" the box equation. 2) The students must transform the box-equations that they have created in the first task. The learning environment presented here centres the shell aspect of variables and can be used to introduce the concept of variables in a sign-language-oriented class. This answers to the first research question.

The handling of mathematical sign language communication in the learning environment

Fig. 5a Fig. 5b Fig. 5c Fig. 5d Fig. 5e Fig. 5f

Figure 5: Signs from the data of the lessons

Regarding the signs signed by the students, EQUAL_4 (Figure 5a) was not signed in the videos or by the teacher, was used introduced by the students themselves for the equal symbol. EQUAL_1 (Figure 5b) for "equal" or "it is equal to" was never used to sign the equal symbol. The equality (resp. the inequality) of two terms was signed on the vertical axis of the sign space (Figure 5e) with the sign in Figure 5c resp. 5d. CONTENT_1, CONTENT_2, and EMPTY_1 were also signed by the students, as explained in the videos of the worksheet. Moreover, the students used the construct in Figure 1f, but also with other numbers, to express the substitution. This occurred in both representations of variables with boxes or letters. It was also observed that the students expressed the substitution by placing the number sign at the place where the variable was in the sign space. Regarding the use of the sign space, the students often signed in the vertical plane (Figure 5f), even when the referred object was on the horizontal plane. For example, they resigned the picture with the boxes and matches – which they drew on the paper – on the vertical plane. In summary, the students achieved most of the learning objectives at the end of the two lessons: 1) they signed CONTENT_1, CONTENT_2 and EMPTY_1 while communicating about variables, but they did not explicitly explain that a variable represents an

unknown number or that numbers can be "put" into a variable; 2) they found different solutions of the box-equations by adding some matches in the boxes; 3) they transformed the box-equations into equations with x and y. Additionally, task 2 was extended: each student invented a box-equation, signed it to others and they transformed it into an equation with x and y. The signing student placed the terms of the box-equation in the same way as in the videos of the worksheet and as the teachers had signed during the lessons, i.e., the left (rep. the right) term of the equation was signed on the left (resp. right). In the interviews the students' main comments were that the task videos of the lessons were too complicated at first, but understandable. They also said that they were not familiar with all the signs in use and that they would like to have more content in ÖGS.

Discussion

The learning environment centres the shell aspect for introducing variables in a sign-language-oriented class, constructing a syntagmatic network with the other variable aspects. However, the construction of the syntagmatic network is not yet complete with this learning environment. The occurrence of EQUAL_4 indicates that the possibilities of signing about variables and operating with them should be further investigated. This should be considered in research, in teaching mathematics, and in designing learning environments for a sign-language-oriented classes. The students have achieved most of the learning objectives. With the deliberate choice of signs from the syntagmatic network, the explanatory video addresses learning objective 1. Such videos are important for sign language-oriented students to be able to find mathematical information in ÖGS outside the mathematics class. Moreover, it can contribute to the development of technical sign language by the students. Therefore, the representation with "boxes and matches" can be a suitable way to introduce the concept of variables and to centre the shell aspect. The symbolic representations, such as letters, has been partially implemented in task 2 of the worksheet, but it will be considered in more detail in further studies. These studies will also explore learning environments that focus on other variable aspects. Bimodal-bilingual mathematics teaching should also be considered more intensively, as this can be particularly important for teaching signing and non-signing students. The representation with boxes and matches and the centring of the shell aspect can be used by both groups of students.

A Pair of algebra beginners working in a spreadsheet environment: Commognitive perspective

Tamar Aviram[1], Michal Tabach[1] and Einat Heyd-Metzuyanim[2]

[1]Tel Aviv University, School of Education, Tel Aviv, Israel; tamar.aviram@gmail.com

[2]Technion - Israel Institute of Technology, Israel

The purpose of the current study is to identify the mechanisms by which a spreadsheet environment can facilitate learning. We examined the work of a pair of seventh-grade low achieving students as they engaged in a mathematical activity in a spreadsheet environment. Using the commognitive theory, we analysed the routines the students enacted, seeking for changes in their performance. We found that at the beginning of the process the students did not same between the realizations given in the task and performed the routine in a ritual way. As the process went on, they developed saming between realizations and performed the routine in an explorative way, meaning there was a de-ritualization process. We conclude that working in a spreadsheet environment can strengthen developing of saming between realizations and this could be one of the mechanisms by which a spreadsheet fosters students learning.

Keywords*: De-ritualization process, commognition, saming between realizations.*

Introduction and Literature Review

Studies have documented obstacles students are facing while taking their first steps in entering the algebraic discourse at the beginning of middle school (e.g. Rojano, 2002), especially for low achieving students. This transition from arithmetic to algebra is particularly important due to the central role algebra plays in middle school and beyond. One approach that was suggested to help students enter the algebraic discourse is learning in a spreadsheet environment (e.g. Tabach et al., 2013). Spreadsheets are marked by a dominance of numerical representation. This representation is strongly linked with students' arithmetic discourse, which was developed in elementary school mathematics lessons. Indeed, it is possible to type numbers into spreadsheet cells. Yet, early on students learn that they can write symbolic expressions that make use of another cell, and the spreadsheet will present the number which is the result of the expression calculated for a certain value of the variable. When dragging the expressions to other cells, the spreadsheet presents the appropriate numerical values in these cells. In that sense, working with a spreadsheet has the potential to encourage students to use symbolic representations, as was found in several studies (e.g. Tabach & Friedlander, 2008). Yet, less is known about the specific mechanisms that seem to promote students' learning in a spreadsheet environment. The current study explores the learning processes that occur when working in a multi-representational spreadsheet environment, aiming to uncover mechanisms that facilitate algebra learning. To achieve our aim, we adopted the commognitive theory (Sfard, 2008)[1].

[1] In the commognitive theory we talk about realizations and not representations. We use that word from now on.

The commognitive theory

The commognitive theory (Sfard, 2008) views mathematics as a discourse, with distinct characteristics. A change in any of these characteristics is evidence for learning. Routines are one of the discourse's characteristics. Routine consists of a sequence of actions performed in response to a prompt. A routine is the combination of task and procedure (Lavie et al., 2019). The task consists of what the person performing the routine perceives as her objective in a specific context, while the procedure consists of the series of actions that she enacts to accomplish that task. A routine can be process-oriented (ritual), that is performed according to social expectations (e.g. the teacher), or product-oriented (explorative), that is performed to achieve an outcome. These two types of routines are on a continuum, and the transition from process-oriented to product-oriented routine is called a de-ritualization process, and it is a learning process.

One characteristic of product-oriented routines is objectification. Objectification is the extent to which the narratives are about abstract mathematical rather than concrete objects (Lavie et al., 2019). The process of objectification involves, among other things, saming (Sfard, 2008). Saming is an act of calling different things by the same name, or associating one name with many realizations (Sfard, 2008). It stands at the heart of the objectification process since mathematical objects are often the result of multiple processes being samed and reified. For example, "three" is a result of saming multiple processes such as counting to three, making sets of three objects of various kinds, and more. These processes are denoted by various realizations (e.g. '3', 'III', 'three'). To objectify "three", young children need to become familiar with the various processes that lead to endorsing the narrative (e.g. "there are three things here"). This process of objectification continues as students are introduced to increasingly sophisticated mathematical discourses. For example, Weingarden et al. (2019) showed the usefulness of classroom discussion that relates to various realizations of an algebraic pattern, and the ways by which such exposure can encourage saming, and through that, increase explorative participation. However, previous studies of saming processes did not involve technological environments.

In the current study we look for evidence for saming between realizations in a spreadsheet environment and examine if and how it can facilitate learning. In the context of pairs of beginning algebra low achieving students, working in a spreadsheet environment on tasks that require saming between realizations, we ask – what mechanisms of de-ritualization can be identified in students' performed procedures? Due to space restriction, we detailed one mechanism that emerged from the work of one pair of students working on one task.

Methods

This study is part of a larger project exploring how spreadsheet-based tasks might aid beginning algebra low achieving students with developing their mathematical discourse. The study involved five pairs of seventh-grade students selected based on their teachers' recommendations as low achieving students. In this case study we focus on Ido and Uri (pseudonyms), who demonstrate in their work a change in the way they connect between realizations. The students participated in ten, one-hour long meetings with the first author, in an out of school setting once every two weeks. During these meetings, they engaged in specially designed spreadsheet activities that aligned with the

seventh-grade mathematics curriculum. The researcher refrained from intervening unless the students were unable to proceed. All sessions were recorded with two cameras (one capturing the screen, the other directed at the students and the computer). They were then transcribed verbatim.

The main task in the activity on which the analysis of this paper focuses (based on Resnick & Tabach, 1999) was to compare weekly allowances of four children given in different realizations: table (Dina), graph (Moshon), symbolic expression (Danny) and verbal (Yoni) (see Figure 1). The students had to build a table in a spreadsheet, one column for each child's allowance, by writing an expression that represents the allowance. For that, the students needed to define a column for the week's number (expectedly column A) and write an expression that makes use of that column. We focus here on the expression the students wrote for Moshon's allowance. They had to translate the graphical realization to a symbolic realization and write an expression such as $5 \cdot A1 + 30$ (A1 is the first cell in column A in the spreadsheet).

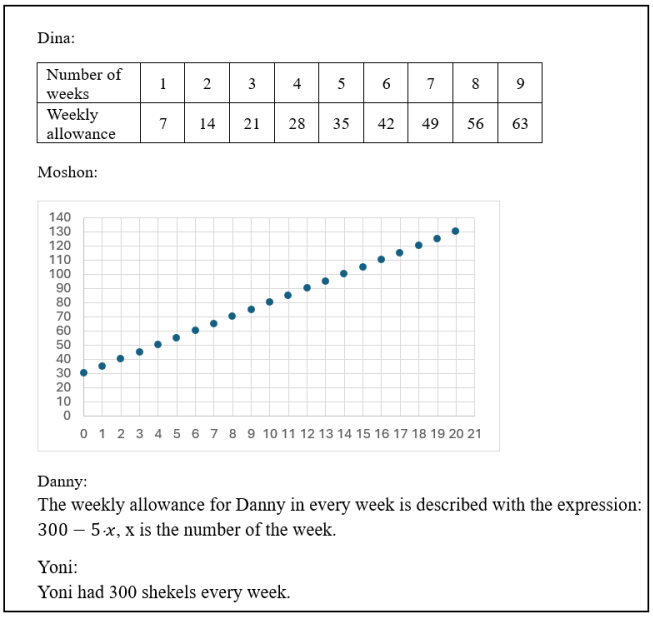

Figure 1: Weekly allowances for Dina, Moshon, Danny and Yoni

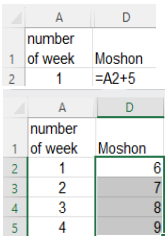
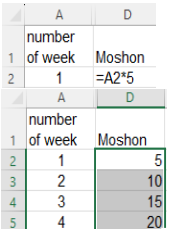


We analysed the data based on the commognitive theory. In what we report below, we examined the routines the students performed and looked for changes in the routines' performance. Specifically, we sought evidence for saming between realizations of Moshon's allowances, by searching for evidence that the students see two realizations as representing the same thing.

Findings

In this section we show growth of the routines the students enacted, when initially Ido and Uri did not same between realizations in the activity and performed the routines ritually, and at the end of the process they samed between the realizations and this is evidence of de-ritualization.

At the beginning of the process, Ido and Uri wrote an expression (symbolic realization) in the spreadsheet for Moshon's allowance, given in a graph. They first created a column (A) for the number of the week, wrote the numbers 1 and 2 in the first two cells of column A and dragged the numbers



until number 20. Then they wrote the expression *A2+5* (the number 1 is written in cell A2) for the first week's allowance. Ido explained the expression: "because every week 5 is added". After dragging the expression down the column, the numbers 6, 7, 8, 9 etc. appeared (see Figure 2). The students saw the numbers and that they did not match the statement that every week Moshon had 5 shekels more, and decided their expression was wrong. Then they tried to fix it. The routine the students enacted for fixing the expression is presented in Episode 1.

Figure 3: Screenshot for Episode 1

Episode 1 – Fixing the expression for Moshon's allowance

174	Ido:	I think we are wrong. One second.
175	Uri:	So multiple 5.
176	Ido:	Why?
177	Uri:	Let's try. I think. *(writes the expression* $A2 * 5$*, see Figure 3)*.
178	Ido:	Like every week he has 5 more.
179	Uri:	Yes *(presses the "enter" key and drags the column, see Figure 3)*.
180	Ido:	So…
181	Uri:	Here *(says when he sees the results of the dragging)*.
182	Ido:	Why?
183	Uri:	Here, 5, 10, 15.
184	Ido:	Oh, yes, I got it.

The routine presented in Episode 1 has ritual aspects: after they rejected their first expression, Uri suggested to correct the expression by multiplying the number of the week by the number 5 [175], probably because Ido mentioned that every week Moshon had 5 shekels more. Uri could not explain why ("Let's try. I think") [177], but Ido repeated his reasoning [178]. Uri agreed, pressed the "enter" key and dragged the column. The numbers 5, 10, 15, etc. appeared in the column. Ido was not sure the numeric realization is correct [182], but when Uri read the numbers [183], Ido accepted that [184]. The students continued with the activity, so we conclude they were pleased with the expression they wrote.

By accepting the A*5 formula as correct, Ido and Uri showed they were not saming the graphical realization for Moshon's allowance (Figure 1) and the numerical realization that was created from dragging the symbolic realization they entered the spreadsheet (the expression A2*5) - since the numbers in the table did not agree with the numbers in the graph. For example, according to the graph, in the first week Moshon had 35 shekels, while the spreadsheet showed he had 5 shekels.

During the next tasks a change happened. The students were requested to "find on the table you created all the weeks in which the allowances of two children are identical". Ido and Uri marked

Moshon and Danny on the table that had 150 shekels in week number 30. Then they were presented with four graphs (see Figure 4), one for each child's allowance, and were asked to match each graph to a child and to mark on the graph the dots of two children having the same allowance in the same week. Ido immediately said: "Let's check week number 30" (he meant in the graph), and they saw that this week Moshon and Danny had different allowances, contrary to what they marked at the table. Ido said: "Maybe we were wrong". This statement leads us to conclude that at this point Ido started saming between the graphical realization and the symbolic/numerical realization and thought they should match. The students then created a new task for themselves – try to understand why the result was not as they expected; this move to focusing on the *product* of their procedure is evidence for a de-ritualization process.

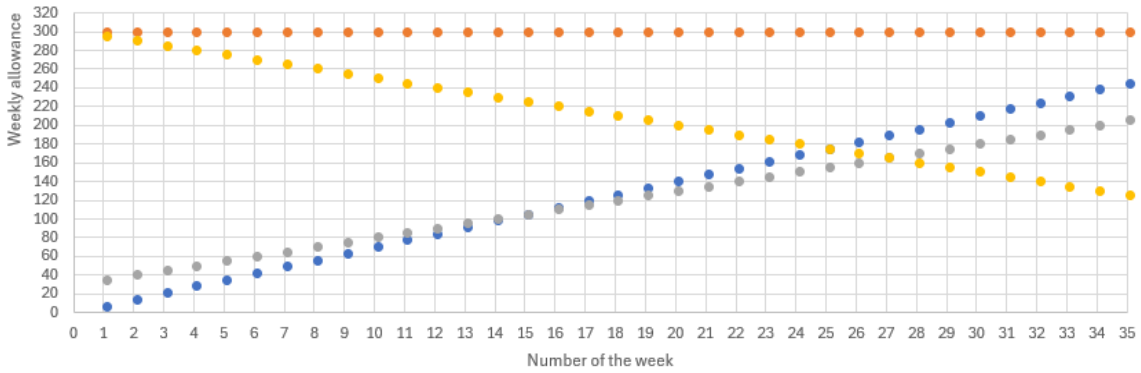

Figure 4: Graphs of allowances

After checking the intersection points in the graph and trying to find them in the spreadsheet table, the students concluded that the expression they entered into the spreadsheet to calculate Moshon's allowance was wrong. Their attempt to fix the expression is presented in Episode 2.

Episode 2 – Correcting the expression for Moshon's allowance

427	Ido:	You said you wanted to start from 35. 35 and…35...
428	Uri:	Plus
429	Ido:	No, let me think. 35 and then every week, 35, write equals 35
430	Uri:	Well…
431	Ido:	35 *(Uri writes* "*=35*"*)*
432	Uri:	Like, plus 5
433	Ido:	No, plus the number of the week times 5. No.
434	Uri:	What? I think we should do like that *(deletes the 35)*
435	Ido:	Plus the number of the weeks,
436	Uri:	I think we should do *(marks the cell A2, the number of the first week)* multiple or plus *(writes the expression A2+35, see Figure 5a, presses the* "*enter*" *key and sees the number 36 in the cell)*. Oh, right, I know why.
…		
439	Ido:	plus 35, plus 35 plus 5.
440	Uri:	multiply 35 *(writes the expression* $A2 * 35$*, see Figure 5b)*.
441	Ido:	no, why? Why?
442:	Uri:	Look *(presses the* "*enter*" *key and they see the number 35 in the cell, Uri starts dragging the column)*.
443	Ido:	Oh, I got you.
444	Uri:	Look *(after he drags the column, see Figure 5c)*.

445 Ido: No, it's not good.
The students write different expressions that lead to an error response from the spreadsheet: "$= 35 + 5 = A2$", "$= A2 = 35 - 1$". *Then the researcher intervenes.*

465 Researcher: How much does he get every week?

466 Ido: 5.

467 Researcher: What does it mean, what should be in the expression?

468 Ido: multiply 5.
The discussion continues and with mediation of the researcher, Ido writes the expression "$35 + 5 * A2$", *they press the* "*enter*" *key and see the number 40 in the first cell. Ido decides to write the number 35 in the first cell and to write an expression only from the second cell.*

484 Ido: Number of the weeks *(writes the expression* "$5 * A3$", *presses the* "*enter*" *key, and they see the number 10 in the cell. Ido deletes the expression). After that they write the expression* "$35 + 5 * A3$" *(see Figure 5d). They observe the number 45 in the cell and change the expression to* "$35 + 5 * A2$" *(see Figure 5e). They observe the number 40 in the cell and drag the column.*

Figure 5: Screenshots for Episode 2; 5a Screenshot in line 436; 5b Screenshot in line 440; 5c Screenshot in line 444; 5d Screenshot in line 484; 5e Screenshot in line 484

In Episode 2 Ido and Uri tried to write a symbolic expression for Moshon's allowance: In line 427 they said that the first number should be 35, not like in the previous expression that gave the number 5 in the first cell. They cancelled the expression "$A2 + 35$" (cell A2 contained the number 1) because it gave 36 and not 35 [436]. This is evidence for saming between the realizations of the graph and the symbolic expression of Moshon's allowance. They wrote the expression "A2*35" [440], that gave the number 35 in the first cell. When Uri saw that number, he started dragging the column, meaning he was pleased with this number. But when they saw the result of the dragging (the numbers 70, 105, 140, etc.), Ido said "it's not good" [445]. This is another evidence for the saming they made – each number should be bigger by 5 from the previous number. In all those attempts to write the symbolic expression, they samed between the symbolic realization and the graphical realization – they wanted the expression to create the number 35 in the first cell of the column [427], and every number after that to be bigger by 5 (they said "plus 5" twice [432, 439]), similarly to the graph. They disqualified every expression they wrote that did not match one of those conditions. After 8 procedures they succeeded in writing the correct expression. The iterative corrections were all due to the saming they made between the graphical and numerical realizations. These quick iterations were made possible by the spreadsheet realizing the algebraic formula quickly and efficiently, enabling the students to concentrate on the product of the formula (or algebraic realization) rather than on calculations of the numerical values.

Discussion

We examined the work of a pair of seventh-grade students, Ido and Uri, while handling activity in a spreadsheet environment that involves different realizations. We showed a change in the way the students enacted their routines. Initially they worked ritually with no saming between the realizations of Moshon's allowances that were involved in the activity. They translate graphical realization into wrong symbolic realization and did not see the gap between these realizations. But as they continued working with the spreadsheet, they developed saming between graphical and numerical realizations of Moshon's allowances, and as a result, identified their wrong expression. In the process of changing the expression (the symbolic realization), they tried writing many expressions, comparing each one of them to the graphical realization. This means they performed the routine exploratively. This movement, from ritual routine to explorative routine, is a de-ritualization process.

We suggest that saming between realizations is one mechanism by which a spreadsheet can help students enter algebraic discourse. Working in a spreadsheet environment encourages the development of saming between realizations due to several factors. The task, which is in the focus of this analysis, required the students to interpret a few different realizations and to move from one to the other. Also, working in a spreadsheet makes it is easy to create numerical values, by dragging an expression. Beginning algebra students feel it is more convenient to work with numbers rather than symbolic expressions. Another reason is that when changing a symbolic expression, the spreadsheet automatically changes the related numerical values (makes all the computations). In that, it gives the students the opportunity to easily same between three different realizations: the algebraic, the numerical and the graphical. Saming is a challenging process that takes time to develop (Sfard, 2008). It seems that the possibility the spreadsheet allows, to move easily from symbolic realization to numerical realization, encourages developing the saming process.

This paper demonstrates the effectiveness of the commognitive theory in analyzing and identifying learning process in a technological environment. The de-ritualization process' characteristics were examined also in other studies (e.g. Nachlieli & Tabach, 2022), but they were not examined in a technological environment. Here we showed that one characteristic – saming, which is part of the objectification characteristic – is relevant also for a de-ritualization process that takes place in technological environment.

Baccaglini-Frank (2021) showed that technological environment can foster explorative participation in mathematical discourse. In this study we go one step further in understanding the contribution of the technology, in this case – spreadsheet, for learning, by suggesting one mechanism by which this may happen – saming of different realizations. More research is needed on other de-ritualization's characteristics, looking for more such mechanisms.

Abstract

This research investigates the emergence and manifestation of analogies between algebraic and graphical models in the context of solving systems of equations. Drawing on Fischbein's theory of analogical reasoning, which underscores the significance of graphical representations in understanding functions, the study examines students' performance using both models. Through tasks specifically designed to require the use of both algebraic and graphical models, the study highlights when and how students establish connections between these methods, revealing that many struggle with transitioning between them. Findings suggest that while necessity can trigger the use of analogies, mastery of both models and the development of strong mental images of graphs are crucial for facilitating these connections. The paper concludes by discussing the educational implications, proposing that the ability to link different models is a teachable skill that can improve mathematical problem-solving.

Keywords: Analogical Models, System of Equations, Graphs, Solution, Mental Image.

Introduction

This paper presents partial findings from an ongoing study investigating how students construct mathematical knowledge through analogies, guided by Fischbein's (1987) theoretical framework of analogical models. Fischbein defines an intra-mathematical analogy (of the second kind) as an analogy between a symbolic (algebraic) model and an intuitive (often graphical) model. A key example is the graphical representation of functions based on the fundamental isomorphism between numbers and figures.

Mathematics educators emphasize the significance of mastering multiple representations in algebra, particularly the ability to navigate both algebraic and graphical models. However, research shows that students often struggle to connect these forms of representation when solving equations. Despite awareness of this issue, many students find it challenging to transition between algebraic and graphical models.

This study investigates the moments when students form analogies between algebraic and graphical models while solving a system of equations, focusing on the knowledge and tendencies that support this cognitive shift. We aim to reveal how these analogies between models manifest and determine if specific prerequisites are needed for their emergence, providing valuable insights for educators and researchers in mathematics education. In this context, "emergence" refers to the initial, internal formation of connections between the models within students' cognitive processes—an intangible, invisible event. Conversely, "manifestation" is the observable application of these analogies, evident as students employ these mental connections in their problem-solving methods.

Theoretical Background

The importance of multiple representations in algebraic thinking has been well-documented in mathematics education, with research showing that proficiency in advanced mathematics depends on students' ability to navigate various semantic representations (Duval, 2017; Heinze, 2009). While solving equations involves both algebraic and graphical models, many students struggle to establish connections between them (Friedlander & Tabach, 2001; Star & Newton, 2009; Bieda & Nathan, 2009). Knuth (2000) noted that students often have only a superficial mastery of algebraic-graphical connections, particularly when solving routine problems. Similarly, Testa and Catena (2022) observed that high school students found algebraic representations more challenging to interpret than other forms.

We hypothesize that these difficulties arise from personal reflections of representations in students' minds—cognitive models—so these difficulties have a cognitive nature. To explore this, we turn to analogical reasoning in mathematics. Polya (1954) demonstrated the value of analogies in mathematical thinking, highlighting their accessibility to both experts and novices. Fischbein (1987) stressed the importance of educating students to recognize similarities, identify isomorphisms, and describe common structures in mathematics. He wrote, "much more attention should be given to educating students sensibility for similarities, the ability to identify isomorphisms and describe common structures." (1987, p 210). Hofstadter and Sander (2013) further reinforce the view of analogy as a core mechanism of thought.

Our study builds on Fischbein's theory of intuitive models, which suggests that students use intuitive representations to make abstract ideas more understandable. Following Fischbein, we describe a model (system B) as analogical to another (system A) if they share a certain isomorphism, allowing solutions in A to be reflected in B and vice versa. Fischbein posits that the transformation from symbolic to intuitive representations facilitates productive thinking. The nature of these intuitive models is sensorial; objects within them can be perceived and manipulated much like concrete reality. This enables them to serve as platforms for generating hypotheses. The results of mental operations performed within these models can then be reflected in the original symbolic models, enhancing understanding through a dynamic isomorphic relationship. Fischbein particularly highlights the graphic representation of functions as a significant type of intra-mathematical analogy due to its isomorphism between numbers and figures.

This study aims to examine the emergence and manifestation of analogies between algebraic and graphical models during students' problem-solving processes, specifically in the context of solving a system of equations. Our objective is to identify when and how students naturally form these analogies and the subsequent impact on their problem-solving strategies. This is an observational inquiry, not a pedagogical intervention.

Research questions

1. How does the analogy between the algebraic and graphical models manifest in students' problem-solving processes when solving systems of equations?
2. What conditions foster the emergence of analogies between algebraic and graphical models?

Method

Task design

The task (Figure 1) was designed to facilitate students' formation of analogies between algebraic and graphical models. It features two systems of equations: the first is solvable using both models. In contrast, the second necessitates graphical reasoning, as it cannot be resolved through standard algebraic methods alone and must incorporate the graphical model for resolution.

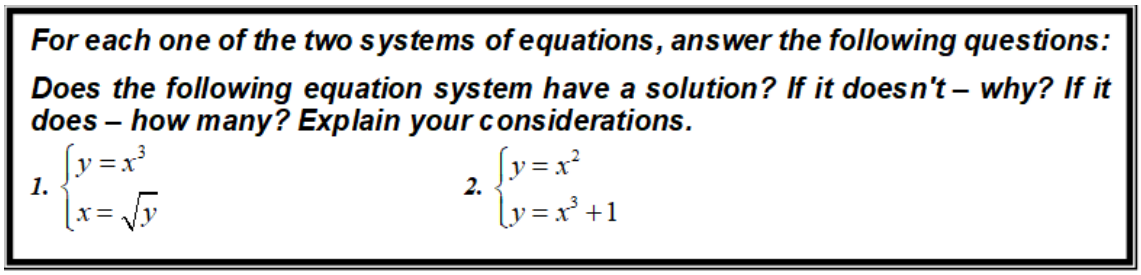

Figure 1. The task

Research population

Twelve pairs of student volunteers participated in the study, encompassing secondary school students from both regular and advanced mathematics levels and first-year engineering students. According to the Israeli mathematics curriculum, all participants were versed in the relevant mathematical concepts for this study.

Research description

The study was organized as a two-hour clinical interview (for each pair) in laboratory conditions. The students' work was videoed and transcribed to analyze their learning process. The interviews were conducted as semi-structured interviews. The interviewer was instructed to minimize interference in the interviewees' discussions. Instead, the interviewer was to use structured, pre-designed hints to facilitate the emergence of analogies between representations should the students require assistance. Examples of these hints are detailed in the findings section.

Data analysis

We define the "emergence" of an analogy between models as an internal cognitive event where students form connections between different models, inferred from observable actions such as explicitly referencing or applying a term from one model while solving a problem with another. Fischbein highlights the intrinsic properties of these models, noting, "An intuitive model is, by its very nature, of a sensorial kind. It may be perceived, represented, or manipulated like any other concrete reality" (p. 121). In addition, Fischbein states, "Using a model means thinking productively in terms of the model. A mental model is a reasoning device. It inspires solving strategies, suggests solutions, and often confirms the coherence and meaningfulness of solutions obtained by means of the original" (p. 124). These quotes elucidate the various manifestations of productive thinking, which include students' use of sensorial language and gestures, their application of the model to generate hypotheses, and their leveraging of insights from the graphical model to draw conclusions in the algebraic model.

Findings and Analysis

In our study of 12 student pairs, an analogy between the algebraic and graphical models emerged in six pairs. Interestingly, this analogy did not surface in interviews with regular-level students nor in two pairs of advanced-level mathematics students. These students initially approached the problem algebraically; upon encountering difficulties, they concluded that a solution was non-existent. Even when hints were provided—urging a shift to alternative methods—they persisted with algebraic strategies without success. It was not until the interviewer explicitly suggested the use of the graphical model that they considered this approach, though they failed to see its relevance or to apply it. Conversely, for the other six pairs, the analogy emerged first and was then actively used to form a link between the algebraic and graphical models.

The following sections explore how the analogy between models uniquely manifested among three pairs of students. We will focus in-depth on two pairs, analyzing interview excerpts to uncover different aspects of the analogy's impact. For one pair, we will demonstrate how the interviewer's hints catalyzed the emergence of the analogy. For another, we will illustrate how the analogy's manifestation contributed to solving the system of equations, addressing our first research question. Additionally, the third pair briefly demonstrates another instance of the analogy's emergence. Further exploration of what specifically triggered the analogy for each pair will lead us to identify potential prerequisites for its emergence, thus answering the second research question.

Individual Cases

When analyzing the emergence of analogies, we treat the student pair as a unit, regardless of who introduced the analogy. We observed that once one student suggested the analogy, their partner cooperated even if it wasn't their original idea.

Sam and Talya, first-year engineering students, attempted various algebraic methods to solve the system of equations during their problem-solving session but could not find a solution, leading them to conclude that no solution existed. The interviewer then questioned their reasoning.

Sam:	We didn't find a solution through algebraic methods.
Interviewer:	You didn't find a solution, algebraically, you're saying now, yes?
Talya:	Correct.
Interviewer:	Algebraically?

The interviewer repeatedly emphasized "algebraically," hinting at other possible methods for finding a solution. Despite this, Talya and Sam missed these cues. The interviewer then used a pre-prepared hint and explicitly suggested considering alternative representations.

Interviewer:	Consider the equations $y = x^2$ and $y = x^3$. Could there be another representation for these equations?

Talya and Sam's fixation on algebraic methods limited their exploration of alternatives

Talya:	With t, usually like... (substituting an expression with a new variable- t)
Sam:	...no, but it doesn't work here.

The interviewer continued to guide them with an example of a linear equation, which could inspire a connection to graphical representations:

Interviewer: For instance, if the equation is y=2x, how can it be represented other than as an algebraic expression?

Talya: x equals half of y?

Interviewer: True, That's still algebraic. Is there a different tool we could use?

Finally, the analogy between the linear function and its graphical representation emerged for Sam, who gestured with his arm elevated in a straight line to illustrate.

Sam: Could it be a graph? Like graphing y = 2x as a function.

Following their new insight, they proceeded to draw the graphs.

Talya's and Sam's eventual success in solving the system underscores their proficiency in algebraic manipulations and familiarity with graph functions. Despite this, they required numerous hints before the analogy between the models became clear. The turning point appeared to be the equation y=2x, which Sam recognized as a linear function. This equation evoked a mental image of a straight line rising across a coordinate system—an image Sam revisited when the interviewer asked to consider a different form of representation. It seems that they lacked such a mental image of the functions $y=x^2$ or $y=x^3$, as the analogy didn't arise when the interviewer suggested another representation for them. Perhaps their mental images for $y=x^2$ and $y=x^3$ were not vivid enough to spontaneously trigger the analogy between the models.

Ron and Effy, advanced-level high school students, encountered a similar challenge: not reaching an algebraic solution. After unsuccessful algebraic attempts, they reached the equation $x^2 = -\frac{1}{x-1}$.

Ron: …I got $x^2 = -\frac{1}{x-1}$, so the function x^2 is a parabola…

Effy: It's as if we have two functions…

Ron: Oh, but we can also look at these: x^2 and $x^3 + 1$

Ron visualized x^2 as a parabola—a concept he could immediately and easily graph. He hesitated with the graph of the other function, acknowledging his lesser familiarity but confident he could delineate it if needed. Once he articulated his visualization of the parabola, the connection between the models became clear, enabling him to extend this approach to the original functions, x^2, and x^3+1, which he found simpler to graph. For Ron and Effy, the analogy emerged after they exhausted their algebraic skills but without any prompting from the interviewer.

Yoni and Nir, first-year engineering students, immediately related the problem to typical questions about the intersection of a straight-line y=k with a function, noting that identifying the existence of intersection points didn't necessarily require finding their exact locations. From the outset, the analogy between the algebraic and graphical models was apparent, exemplifying the benefits of using both models constructively. Yoni preferred the graphical approach, solving the first system of equations graphically despite the availability of algebraic solutions. Upon confronting the second system, both Yoni and Nir found algebraic methods inadequate and shifted to the graphical model. Their work exemplifies how they kept both models active in their awareness, using the graphical model to think productively across models. Here are some examples illustrating their approach:

Yoni and Nir identified two intersection points for the first system at (0,0) and (1,1). Yoni then sketched the graphs of x^2 and x^3+1, noting no intersections in the first quadrant. Nir probed further into the range x>1:

Nir: Who says they won't meet later when $x>1$?

Yoni: Will they meet later? Excellent question. x^3 increases faster than x^2, so they aren‘t likely to meet. This means that if at this point it is above it, from now on, they won't meet, x^3 flees away.

Yoni describes the relationships between the graphs using everyday language, employing terms such as 'meet,' 'flee away,' and 'one function is above the other.' This choice of words indicates his sensorial use of the graphical model. This behavior aligns with Fischbein's description of an intuitive model, which he characterizes as "of a sensorial kind, which can be perceived, represented, or manipulated like any other concrete reality." (Fischbein, 1987, p. 121)

Nir then considered the range $x<0$, where an intersection point was evident, implicating a solution:

Nir: On the left-hand side,

Yoni: There is one intersection point.

Nir: How can you find it?

Yoni: I don't need to find it. The question is if there is a solution, not what the solution is, so we conclude that there is one solution in the second quadrant.

Nir and Yoni agreed that identifying an intersection point in the graphical model, even without precise coordinates, suggests a solution in the algebraic model. This observation supports Fischbein’s second claim about the contribution of analogies to productive thinking: "(b) By providing an intuitively accessible structure, mental operations which would be difficult in relation to the original system are facilitated. The products of these mental operations can then be interpreted and evaluated in terms of the original system" (Fischbein, 1987, p. 142)

Nir then evaluated the interval $0<x<1$, using numeric analysis to assess solution feasibility:

Nir: Between 0 and 1, every number is a fraction; squaring it keeps it less than one. So x^3+1 is more than one, indicating no intersection in this range.

Nir's algebraic considerations led him to conclude that no intersection points existed between the graphs within the domain of $0<x<1$ in the graphical model, confirming the absence of solutions to the system of equations in the algebraic model for this range. This type of analytic thinking was a consistent feature throughout their problem-solving process. Their approach involved simultaneous considerations of graphical and algebraic elements; for instance, Yoni observed that x^3 increases faster than x^2 for $x>1$—an algebraic observation, which he coupled with the graphical statement 'it is above it.' Furthermore, even without precise coordinates, their confidence in the existence of an algebraic solution was evident upon identifying an intersection point in the second quadrant.

The solution process of Nir and Yoni exemplifies how they constructively used the analogy between the models, in line with Fischbein's description: "Analogies contribute in the following ways: (a) As a heuristic means of generating hypotheses." (Fischbein, 1987, p. 142) They effectively utilized the graphical model to hypothesize about potential solutions. This model enabled them to focus on specific ranges, facilitating a segmental analysis of intersections that would not have emerged solely from algebraic reasoning. This strategic use of both models underscores the productive application of analogies in enhancing mathematical understanding and problem-solving capabilities.

Discussion and Conclusions

As outlined in the methods section, our study involved two tasks: the first could use algebraic or graphical methods, and the second resisted algebraic solutions. We hypothesized that the limitations of algebraic methods in the second task would catalyze the emergence of an analogy between symbolic and graphical models. The results showed a spectrum in the analogy's emergence. For some students, particularly at a regular level, the analogy remained elusive despite hints and explicit instructions. For others, like Sam and Talya, the analogy materialized following interviewer prompting. For Effy and Ron, it appeared only after recognizing the futility of algebraic solutions, without external cues. Conversely, Nir and Yoni preferred the graphical approach from the start, consistently opting for it even when algebraic methods were available. This variability raises key questions: Are students like Nir and Yoni unique in their approach? Is their preference for graphical methods a distinct personal trait, or does it suggest a teachable skill—a robust linkage between models that could be cultivated in other learners?

Conditions for the Emergence of the Analogy

Our findings identify key factors influencing the emergence of the analogy between algebraic and graphical models:

1. Mastery of Skills in Each Model: Proficiency in both algebraic and graphical models is essential. Students lacking graphical skills often failed to utilize the analogy effectively as the graphical model was absent from their toolkit. For example, regular-level students with limited graphing ability struggled to leverage graphs for problem-solving despite direct prompts from the interviewer.

2. **Necessity:** We hypothesized that necessity would catalyze the analogy's emergence, but results varied. Some students, like Ron and Effy, driven by necessity, adopted new strategies beyond algebra, fostering the emergence of the analogy between the algebraic and graphical models. Others stuck to algebraic methods without success, preventing the analogy's emergence. Meanwhile, Nir and Yoni experienced spontaneous analogy emergence without a pressing need for alternative approaches.

3. Mental Imagery: Strong mental images of equations played a significant role. For Sam and Talya, it was the image of a straight line from the linear equation; for Ron and Effy, the parabola from $y=x^2$. Yoni had vivid images of functions like x^2 and x^3. The data indicates an inverse relationship between necessity and mental imagery: stronger mental images reduce the need for necessity in analogy emergence. For instance, Nir and Yoni quickly formed analogies without external prompts, whereas Effy and Ron and Sam and Talya required exhaustive attempts and multiple hints, respectively.

Additional Influences on the Emergence of the Analogy

Beyond primary conditions, we found that students' beliefs about solutions significantly influence the analogy's emergence. For instance, Sam and Talya insist that legitimate solutions must have precise coordinates, which restricts their acceptance of valid non-algebraic solutions.

Sam: But how can we achieve this result algebraically? There must always be an algebraic way to achieve the solution because it is math!

Talya: If I used only algebraic methods, I would conclude that there was no solution.

This belief that algebraic solutions are inherently more legitimate or accurate may deter students from recognizing or accepting solutions that emerge through graphical models, thereby influencing the likelihood and manner in which the analogy between models manifests.

Implications for Teaching

The results show that all engineering and half of the advanced-level high school students encountered the analogy between algebraic and graphical models with varied immediacy. This variability may arise from personal visualization tendencies, which help some effectively utilize the graphical model. The analogy was more prevalent among higher-level students, suggesting it's a skill developable through training, not merely innate talent. Educators should emphasize building strong mental images of functions to promote analogy development, enhancing students' problem-solving capabilities.

The different functions of illustrations in solving word problems

Lorenzo Cosci, lorenzo.cosci@supsi.ch

University of Applied Sciences and Arts of Southern Switzerland (SUPSI);
Università della Svizzera Italiana (USI), Switzerland

Word problems are a topic of great relevance in mathematics education. Research on this topic has developed in several directions, classifying, and investigating the functions, and effects of illustrations on word problem solving, just to name a few. The findings of these studies are somewhat inconsistent concerning the impact of different types of illustrations on problem solving processes. This paper describes a study that investigated the utilization and interpretation of diverse types of illustrations by lower secondary school students during the resolution of word problems. The findings suggest that a range of factors influence students' consideration and interpretation of illustrations, thereby raising questions about the possibility of a priori and univocally classifying the functional role of the illustrations that flank word problems.

Keywords: Word problem, problem solving, functions of illustrations, use of the illustrations.

Introduction

In mathematics education, a word problem is a text that describes a situation familiar to the student and poses a quantitative question, an answer to which can be inferred from the information (usually quantitative) conveyed by the text (Greer et al., 2002). Word problems are an extremely relevant topic, especially for primary and secondary schools, as they allow students to apply mathematics to solve a problem within a context. The interest in this topic is also evident in the importance placed on it by institutions around the world (Eurydice, 2011; OECD, 2017), which consider competence in solving this type of problem as one of the key objectives of mathematics education. International research on this topic has developed in different directions. Some of these strands of research have investigated the effects of different word problem formulations on the solutions of students across various grade levels, focusing on the authenticity of the questions, enriching the narrative context, introducing specific warnings (Dewolf et al., 2017) and placing different types of illustrations alongside the problem (Dewolf et al., 2014; Elia & Philippou, 2004). Research about illustrations is crucial to teaching and learning in general, and specifically in mathematics. The relevance of the topic, specifically in the context of problem solving activities, is highlighted by the PISA 2022 Mathematics Framework (2023). This framework highlights the ability to interpret information presented in graphical form and/or diagrams, as mentioned in its definition of mathematical literacy. Research on illustrations in problem solving activities has focused on classifying their function for the resolution and their effects on students' performance. In particular, a relevant study in the area of illustrations in relation to word problems is that of Elia and Philippou (2004), which introduces a taxonomic model for illustrations in terms of the functions they perform during the problem solving activity, distinguishing them into decorative, representational, informational and organizational illustrations. The authors find an effect on problem-solving activity for all types of pictures except decorative pictures. Subsequent research on this topic, on the other hand, has produced conflicting results, confirming the non-significant effect of decorative illustrations, but also refuting the positive

effect highlighted by Elia and Philippou in 2004 for representational illustrations (Agathangelou et al., 2008; Dewolf et al., 2014; 2017), finding that students tend to ignore this type of illustration (Dewolf et al., 2015) and that informational illustrations also have, in some cases, negative effects on problem-solving activity (Gagatsis & Elia, 2004; Elia et al., 2007). Further research is therefore needed on the role that different types of illustrations can play in problem solving, to clarify which of them are observed, manipulated, or used as a source of information, and under what conditions this occurs. This paper presents the findings of a study investigating the use of the different types of illustrations identified by Elia and Philippou, by sixth, seventh and eighth grade students, during the problem-solving process. This study constituted a part of a larger research project whose aim was to investigate the effect of such illustrations on the problem-solving process.

Theoretical framework

Research on the use of illustrations in educational contexts is part of the broader study of multimodal learning, specifically the combined understanding of different forms of representation, such as text and illustration. Schnotz (2005) outlines an integrative model of text and picture comprehension (ITPC model) and discusses, on the basis of experimental data, the potential of his model to predict the conditions under which the relationship between text and picture supports or hinders learning. The ITCP model predicts that the combination of a text and an image can help students build a mental model and thus improve learning if the two representations are semantically correlated (coherence condition) and if they are presented in close spatial and temporal proximity (contiguity condition). The study by Elia and Philippou (2004) focuses specifically on word problem illustrations, which are intended as pictorial representations of the context of the problem. The authors classify pictures according to their function in relation to the problem-solving task, based on the categorisation formulated by Carney and Levin (2002). *Decorative*, if the illustration is completely unrelated to the context described by the problem; *representational*, if it represents part or all the narrative contexts; *organizational*, if it is structured in such a way as to provide a direction for thinking or working to produce a drawing that supports the solution process; *informational* if it contains relevant information not included in the text of the question. This qualitative study of 8 students found significant effects for representational, informational, and organizational illustrations, and showed that representational illustrations had a positive effect on problem solving for sixth grade students. Elia et al. (2007) investigated the same types of illustrations in solving one-step problems of additive structures by first, second and third grade students. The authors conclude that students essentially overlooked the presence of the decorative image, while they performed poorly on problems involving informational illustrations. Research on the same types of representations for one-step mathematical problems of additive structure was conducted by Agathangelou et al. (2008). Their results show that the presence of decorative and representational pictures did not affect students' performance.

The effect of representational illustrations is also investigated in the studies conducted by Dewolf et al. (2014; 2015; 2017), considering word problems with realistic modelling complexity. The research team investigates the influence of representational illustrations on the production of realistic responses by fifth and sixth grade students to problems that require contextual considerations for solving. The underlying hypothesis is that appropriate representational illustration can provide a rich pictorial description of the problem situation, supporting the construction of a more detailed mental

model of the context, and thus, in conclusion, prevent students from solving the problem by mechanically applying a mathematical operation inferred from data or keywords in the text, but encourage them to consider the context of reality.

The research teams conducted three studies. The first study (Dewolf et al. 2014) examined the effect of illustrations and warnings on the percentage of realistic answers, finding no significant impact.

To investigate why the illustrations did not have a positive effect on the realistic solution of word problems, the authors set up a second study (Dewolf et al. 2015) in which they observed the solvers' eye movements during the task using an eye tracker. The results of this second study show that the students involved ignored the displayed illustrations in almost all cases, although representational illustrations were observed significantly more often than decorative ones. Furthermore, even when students were prompted to look at the illustrations by being shown only the illustration for five seconds before presenting the text of the question, the percentage of realistic answers did not change significantly. The third study (Dewolf et al. 2017) tested the effectiveness of enriched illustrations and explicit warnings, but again, no significant improvement in realistic answers was observed. The three studies, particularly the second, found that illustrations were actually excluded from the students' solving process. The authors hypothesized that students' beliefs about word problems and the nature of illustrations may have hindered their ability to use visual information effectively. They suggest that future research should explore more detailed illustrations.

Our study moves in this direction, by investigating the use of different types of illustrations during the problem-solving process of mathematical word problem. Specifically, the following research question guided the study: To what extent do lower secondary students employ illustrations when solving mathematical word problems? How do lower secondary students utilize different types of illustrations when solving mathematical word problems, in terms of observation, manipulation, and extraction of information?

The following text will discuss how, in some cases, students can pay close attention to illustrations and the information they contain when solving problems, formulating hypotheses about the factors that led to the careful use of illustrations in this case study.

Methods

The study involved 254 students from three school years (sixth, seventh and eighth) in northern Italy. Guided by the working hypothesis that variations in the presentation of the questions could be reflected in the student's answers, five tasks were selected from the database of the national tests of the National Institute for the Evaluation of the Education and Training System (INVALSI), which were considered significant from a content point of view, with a clear reference to the real context and a low rate of correct answers. All problems were illustrated, and at the same time the functional role of the illustrations was classified in the light of the theoretical framework, all illustrations were discussed before approval, but not pre-tested. Different versions have been produced for four of these, distinguished by the type of illustration flanking the word problem. In this article, due to space limitations, only two of the problems involved in the study, problems 4 and 5, will be presented. The problem 4 was presented to 33 sixth graders, in the format shown in Figure 1, with the illustration

placed centrally and immediately below the text. The illustration shows part of the context described by the text, depicting three characters walking through a classroom, and was therefore classified as representational according to Elia and Philippou (2004).

Mario, Renato and Fabio measure the length of their classroom in steps.
Mario counts 26 steps, Renato 30 and Fabio 28. Who has the longest step?

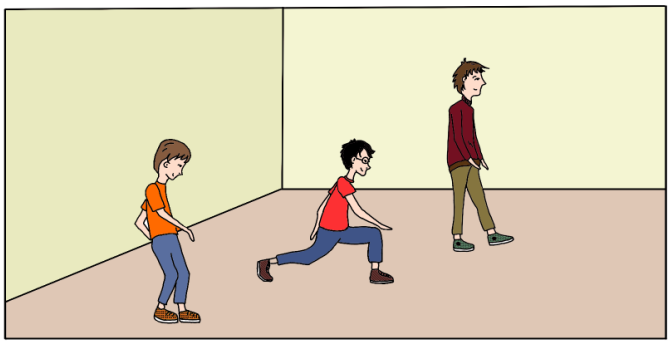

Figure 1: Problem 4

The problem 5 was presented to 79 sixth and seventh graders in three versions, which differed in the type of illustration. Figure 2 shows one of the versions presented to the students. During the stage of problem making the illustration was considered organizational, since it depicts all the pills allowing students to group them by drawing on it, thus supporting the solution procedure.

A medicine is sold in boxes of 28 divisible pills like the one in the picture. Each pill contains 20 mg. Piero's grandmother needs to take 30 mg of this medicine every day for a month. For how many days can Piero's grandmother take her daily dose of the medicine using just one box?
Write down how you found the answer and then report the result

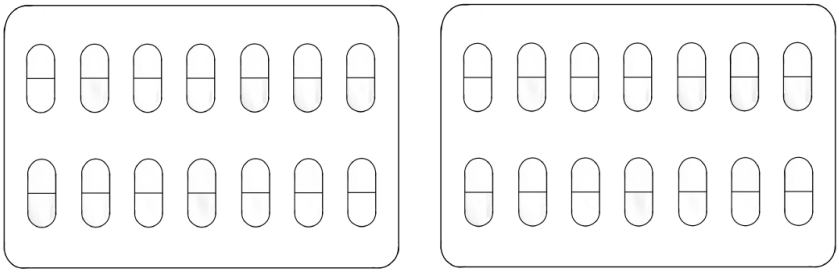

Figure 2: Problem 5

In addition, both problems were accompanied by the instruction: 'Report the result and explain the reasoning you used to answer, specifying whether you used the illustration or not'. This indication was also orally repeated when the problem was presented to the students.

Data consists of students' written productions, audio recordings of class discussions, and individual interviews with students. Students were given a maximum of one hour to solve one problem. The data was qualitatively analysed by searching for any references to the illustrations in the answers, and relating them to the information gathered from the discussions and interviews conducted with the students, with the aim of highlighting and interpreting the phenomena in focus, such as the use of the illustration, the resolution strategies that emerged, and the interaction between these aspects.

Data analysis

The qualitative analysis allows us to observe different uses of the illustrations. In particular, it was observed that the students paid close attention to all the illustrations considered in the study. Moreover, in some cases, students derived additional information from the illustrations and used this information in the solution procedure, even though, in the authors' conception, these pictures should have had other functions, such as helping to understand the context (representational function) or supporting the solution procedure (organizational function).

The qualitative analysis of the data relating to problem 4 shows that 17 out of 33 students (52%) pay attention to the illustration and that of these 11 students draw information from it that is essential for their own reasoning and solution procedure. Specifically, the students derive information from three distinct aspects of the illustration. Firstly, from the order of the characters depicted. In this case, the students associate a name with the characters in the illustration by assuming that the order in which the characters are depicted in the illustration is the same as the order in which the characters are introduced in the text, and then they reason about the illustration to reach an answer to the problem question.

For example, Maurizio writes: "[...] Fabio has a normal stride compared to Renato who does it on purpose to lengthen his foot, so I say Fabio". Maurizio claims to have thought about the illustration and seems to have considered the way in which the characters are depicted in the illustration, in the act of taking unnatural steps. In this type of answer, the numerical data in the text are not mentioned in the resolution and do not seem to have been involved in the reasoning.

Another type of information extracted from the illustration concerns the spatial arrangement of the characters. Some answers seem to relate to the illustration in a different way to the information drawn from it, the detail being taken into account is not the order of the figures but rather their arrangement in space. This is exemplified by the explanations of some students who reported that they had noticed that one character had walked a greater distance than the others. Matilde, for example, answers that it is Fabio who has the longest stride because "it is clear from the drawing that he is also the one who is in front of Renato", denoting that she had paid attention to the aspect of the arrangement of the characters in the illustration. Although it is not clear how she arrived at her answer, she may have first assigned names to the characters using the above strategy to then identify which of them had moved a greater distance.

Finally, other aspects of the illustration that served as sources of information were the height of the characters and the fact that they were depicted in the act of forcing their stride unnaturally. Carolina, for example, concluded that "none of them has the longest stride" because "Renato does it on purpose to make it so wide". During the discussion phases, the height of the characters also came up for consideration, as described by Luca, who recounts some of the confusion felt during his resolution: "I honestly didn't know where to turn, because Mario should be the tallest one, and the one with the fewest steps, so the one with the longest step. But if we look at the drawing, we can see that one boy is putting much more distance into the steps than both Mario (he points to the boy on the right in the illustration, who actually appears to be the tallest) and this other boy (he points to the character on the left)".

What was observed in the administration of this problem is a conspicuous variety and amount of information that was drawn from the illustration during the resolution. It was noted that 11 out of 33 students interpreted the illustration as informational, i.e. an illustration containing information relevant to the solution and not in the problem's text.

Concerning problem 5, 6 out of 45 students gave the answer "9 days", exactly half of the expected answer of "18 days". These students reported that they had looked at the illustration and inferred the number of tablets in a box, having interpreted the illustration as showing two boxes. Alberto, for example, writes: "Piero's grandmother has to take a box of 14 tablets, and if she takes half a tablet + half a tablet, she should finish it in 9 days".

In this case, the quantity of tablets was explicitly stated in the text. However, these students utilized the data extracted from the illustration to solve the problem.

Discussion

These observations call for a re-evaluation of the classification made when designing the task. The illustration of the problem 4, for example, was conceived as representational, taking into account the expected answer, because it represented part of the context described by the text of the problem. Similarly, in problem 5, in addition to the organisational function, an informational role for the illustration is evident, as students interpreted the two blisters shown as two different boxes. Significantly, these students chose to use the illustration rather than the text to get the data for their own reasoning, confirming an informational interpretation of the illustration.

It will also be necessary to reconsider the possibility of investigating the use of certain types of illustrations by students, where the latter attribute a different functional role to the illustrations than that assumed a priori by the researchers through the model used. We, therefore, question whether it is possible to classify illustrations of word problems unambiguously and a priori in terms of their function for solution, ignoring the interpretations given by the solvers themselves. In both above cases discussed, what was observed differs from what was obtained by Dewolf's (2014; 2015; 2017) research group in terms of the attention paid to the illustrations and the use made by students in solving word problems, specifically, our data shows that in some contexts students seem to attribute great importance to illustrations. Furthermore, it was observed that students drew additional information from the illustrations, attributing to them an informational function in Elia and Philippou's (2004) framework, even though the authors' intention was for these illustrations to have a representational and organizational function.

Conclusions

In light of the observed results, it can be posited that, under certain conditions, students may interpret the functional role of an illustration, flanking a word problem, differently from what can be said through Elia and Philippou's model, for example by interpreting the representational illustration as informational and thus extracting information from it that will be involved in the reasoning and solution. An informational interpretation is also accompanied by a certain focus on illustrations. The latter aspect seems to differ from the findings of previous studies on this topic, as the research by Dewolf et al. (2015, 2017). It can be hypothesised that these observations can be interpreted in the

light of conditions relating to the classroom context, the structure of the problem and the illustrations themselves and students' beliefs. In particular, students' interpretations of the function of illustrations could be related to the context in which the problem solving activity takes place.

This context is determined by factors such as the relevance attributed to the illustration, directly or indirectly, by the text of the problem and question, by the structure of the illustration itself, its size, its position in relation to the text, or by the researcher during the delivery and presentation of the problem. For example, the prompt accompanying the problems: "Report the result and explain the reasoning you used to answer it, indicating whether or not you used the illustration" may have drawn the students' attention to the illustration and contributed to the idea that it was fundamental to the solution. In this case, the students may have been looking for information in the illustration that could be used in the reasoning. This observation does not seem to be consistent with the findings of Dewolf et al. (2017), who do not observe a significant effect of warnings on attention to illustrations. It can be hypothesized that this discrepancy in results can be interpreted in light of the contextual aspects discussed in this paragraph, which may have convinced students that observing the illustration can be useful, to the point of interpreting it as informational and thus looking for information useful for the solution.

A second type of factor that can be used to interpret these results relates to the contribution of the illustrations to the narrative context. Specifically, it could be hypothesized that if the relationship between text and illustration is strong, and thus the illustration faithfully and realistically represents the context of the problem text, students may be inclined to pay attention to it. Factors that may influence the representativeness of illustrations include references to them in the problem text itself, the presence of decorative details, whether it is a drawing or a photograph, and whether it is schematic in order to emphasize certain aspects depicted (such as the spatial order of the characters in Figure 1). Finally, factors such as students' beliefs about the role, and importance of an illustration within a problem and more general beliefs about the problem solving task, seem to play a decisive role.

In conclusion, our results show mostly an informational use by students of all the types of illustrations considered, from which data and information not foreseen in the formulation of the questions were drawn and subsequently used in problem solving. This suggests that is not possible to do a univocal and a priori classification of the illustrations accompanying the word problems since contingent and contextual factors could influence the students' interpretation of the function of the illustrations. The factors that seem to influence students' attention to illustrations and interpretations of their functional role seem to be the context in which the problem-solving activity takes place and the relationship between illustration and text in constructing the narrative context. Particularly in cases where the illustration realistically represents the content of the text, students may be led to draw information from it for the solution procedure. The results of this study suggest that further research is needed to investigate the role of the factors proposed here and new factors in determining students' interpretation and use of the illustrations that accompany word problems.

Learning mathematics with body-centred and object-centred movement: Expanding on Bruner's enactive mode of representation

Julia-Marie Hölzer and Rose F. Vogel

Goethe University, Faculty of Computer Science and Mathematics, Frankfurt am Main, Germany; hoelzer@math.uni-frankfurt.de

This paper focuses on considerations for expanding the known modes of representation (according to Bruner) with the mode of movement. Our expansion is based on an examination of the modes of representation described by Bruner – which are widespread in (mathematics) lessons – and their significance for cognitive development and learning processes. In particular, we clarify the difference between internal and external representations. We illustrate the extension of Bruner's model of representation modes through a content-analytical examination of a learning environment, revealing the potential of the movement mode of representation for the mathematical learning process.

Keywords: Elementary school mathematics, mathematics activities, modes of representation, body-centred movement, object-centred movement.

Introduction

Supporting learning processes and thus accompanying the development of students' mathematical skills is a central aspect of teachers' professional competencies. There is a long tradition in mathematics education research of exploring the use of different representations for learning mathematics. Already in the 1960s, Bruner (1967) distinguishes between three modes of representation: iconic representations, enactive representations and representations in words or language (symbolic representation). These representations are significant in cognitive development of learners and are later (in adulthood) used in combination for learning processes. Each mode has its own way of representing cognitive processes and their results (Bruner, 1971). These three modes of representation are often used in everyday school life to justify decisions in the design of mathematics lessons (Bruner, 1974). In this context the paper focuses on extending the enactive mode of representation through body movement. This extension appears to make sense, since Bruner's reception initially seems to refer exclusively to object manipulations/actions with the enactive mode of representation, although Bruner also considers movements in space in the individual modelling of the experienced world.

In the designing of mathematics teaching and learning large motor movements of the whole body with and without material arrangements as well as small motor movements without material (including – among others – gestures) seem to be rather neglected and not explicitly used in school practice. Indeed, although gestures and large motor movements are currently being researched (e.g., Huth, 2021; Radünz & Benölken, 2021), they are still hardly considered in the design of learning environments in the school context.

In this paper, the following overarching research question will be pursued using an example: *How can the modes of representation formulated by Bruner be further differentiated regarding to body*

movement and the movement of objects in space (large motor), and how can the relevance of such an extension be illustrated?

Theoretical Framework

According to Bruner (2009), children develop knowledge in an active and social process. For learning activation, Bruner (1967) recommends offering students different access to learning content for absorption and understanding. In this case, it can be assumed that the term 'representation' refers to external representations. These are "text, pictures, graphs, tables, sound and music" (Schnotz and Kürschner (2008, p. 175) that can be used flexibly by learners. This medial specification is also addressed by Bruner (1971). Internal representations, meanwhile, are also referred to as "mental images" (Goldin & Shteingold, 2001, p. 5), and these "multiple internal representations interact with multiple external representations" (Schnotz & Kürschner, 2008, p. 176).

> Accordingly, there is not a one-to-one relationship between forms of external representations and forms of internal representation. On the one hand, a text as an external descriptive representation results internally both in a descriptive and a depictive representation. On the other hand, a picture or diagram as an external depicture representation results internally both in a depictive and a descriptive representation. (Schnotz & Kürschner, 2008, p. 180)

Overall, the difference between external and internal is less discussed, as Bruner rarely makes the distinction explicitly; this leads to differences in interpretation. However, Bruner's work certainly reveals differences between the internal and external representations. For example, he writes: "But the child's symbolic world does not make a clear separation between internal motives and feelings on the one hand and external reality on the other" (Bruner, 2009, p. 34).

> We cannot, of course, observe anyone's internal representations directly. Rather, we make inferences about students' internal representations on the basis of their interaction with, discourse about, or production of external representations. Skilled teachers do this almost automatically, paying attention to their students' words, written work, use of manipulative materials or use calculators and computers as they try to understand individual conceptions and misconceptions. (Goldin & Shteingold, 2001, pp. 5–6)

These explanations show that a distinction should be made between internal and external representations, because they mean different kinds of representations: internal representations refer to the internal conception of a mathematical content, while external representations refer to the externally visible representation of a mathematical content (for example by manipulating/sorting/arranging blocks).

Further models of modes of representation are being developed in mathematics education research. For example, Lesh's translation model names "five forms of mathematical representation" (Johnson, 2018, p. 2): "pictures", "manipulatives", "written symbols", "real-life situations", and "verbal symbols" (Johnson, 2018, pp. 2–3). Learners interactively use different mathematical representations to develop mathematical concepts. This requires "representational fluency" (Johnson, 2018, p. 2), which describes the ability to use different representations and to flexibly switch between them. Johnson (2018) also describes the change of representation as a central element in learning.

In this paper, we further differentiate the enactive mode of representation based on Bruner. Bruner (1967) describes situations from everyday life, such as playing tennis, skiing, or cycling; in these cases, it is difficult to verbally describe the exact actions, and images only model partial aspects of the movements. This means that learning processes for these situations can only be represented through actions:

> We know many things for which we have no imagery and no words, and they are very hard to teach to anybody by the use of either words or diagrams and pictures. […] We have come to talk about the first form of representation as enactive […]. Enactive representation is based, it seems, upon learning of responses and forms of habituation. (Bruner, 1967, as cited in Lotz, 2022, p. 20)

Bruner (1971) also considers the tying of a knot to be enactive. One knows the knot through the usual process of tying it, but the representation in words or in a picture never succeeds completely; how the knot is actually tied can only be partially represented. The representation of the knot tying therefore takes place in the medium of the action.

Regarding mathematical learning, Bruner (1974) describes activities, such as investigating quadratic equations by assembling wooden blocks, which can be assigned to the enactive mode of representation. Bruner (1974) also mentions the creation of equations by working on the beam balance as an example of enactive work. According to Bruner, in such situations, enactive constructive work is a useful introduction to a topic.

Looking at the implementation of the enactive mode of representation in school life, it seems that small motor movements with materials are predominant. Here at most, the objects are moved in the plane on the table. In most cases, object manipulation with the hands takes place (here, referred to as small motor object-centred movement). These object manipulations could be compared with Bruner's description of knot tying or building with wooden blocks in connection with equations. Movements of objects in three-dimensional space (here, referred to as large motor object-centred movement) are rarely observed in mathematics lessons. Bruner's research does not describe large motor object-centred movements in relation to mathematical learning.

The skiing movements described by Bruner refer to movements of the body. During skiing, limbs are moved in relation to the trunk, and the trunk is also tilted in different ways in space (here, referred to as small motor body-centred movement). At the same time, skiing also involves spatial movement: the body as a whole is moved through space (here, referred to as large motor body-centred movement). We can infer that Bruner had already considered including the body in the individual modelling of the physical experience, but he did not extent this idea to the mathematical world.

The body-movement-inclusive view of enactivity is supported by embodied cognition theory, which highlights the relevance of body movement for (mathematical) learning and thought processes. According to Tran et al. (2017), learners' actions and how they think are directly interrelated. Both gestures and manipulation of material, as well as body movement, support mathematical learning processes (Tran et al., 2017). Ottmar et al. (2019) distinguish movement between "body-centred", "body-in-action", "object-centred", "object-in action" and "environment centred".

A differentiation of the enactive mode of representation becomes clear here. In the context of mathematical learning, the switch between the different modes of representation is also important (Bruner, 1967). This is not only a vertical change, from one mode of representation to another (for example, a change from the iconic to the symbolic mode of representation), but also a horizontal one (for example, switching from one iconic representation to another iconic representation) (Lotz, 2022).

In summary, the following can be said regarding movement as an enactive representation: a distinction can be made between object-centred movements (material-supported) and body-centred movements. In object-centred movements, objects are manipulated in the plane and in space. In body-centred movements, the body itself is manipulated and moved in space. Both modes of representation (object-centred and body-centred) can involve small motor or large motor movements. With small motor movements, the movement space is small (small movements in the plane); with large motor movements, the movement space expands (large movements in space) (see Table 1).

Table 1: A comparison of object-centred and body-centred movement

Object-centred movement	Body-centred movement
Small motor activities on and with materials: for example, placing symmetrical figures with tiles, also known as action.	Small motor movements with your own body (without moving in space): for example, bending both arms symmetrically at right angles pointing upwards. Here is an overlap with gestures.
Large motor movements on and with materials, and the dimension of movement in space is added: for example, placing symmetrical arrangements with baskets and chairs in the room.	Large motor movements with your own body, and the dimension of movement in space is added: for example, the symmetrical movement of two people with arm movement.

Methods

To better describe the differentiation of the enactive mode of representation, we observe the working of the young learners on symmetry problems. These symmetry problems are presented to the students in a learning environment that enables an open approach to a learning subject and gives learners the space to work independently on a mathematical problem.

This analysis of this exemplary problem-solving process focuses on the following research question: *Which large motor movements were used in the learning environment for the topic of symmetry?*

A team of university students in a seminar for the primary school teaching degree program developed the learning environment on the topic of "mathematical learning from a multimodal perspective with a focus on movement". The environment was tested with primary school children (third graders, about nine years old).

The university students designed learning environments that focused on using the children's own body movements in line with the seminar's overall theme. In the learning environment on the topic of 'symmetry', an empty room and various objects, such as chairs and boxes, are used as the starting

point. Two children are involved in the learning environment. The university students divide the learning environment into different sequences, which are initiated by problems and impulses. The following sequence order is chosen: 1. objects (chairs, baskets, bottles, etc.) are used to create as much chaos as possible in an empty room; 2. the children organize the objects; 3. the room is divided into two fictive rooms, which are designed in the same way with the existing objects (the word symmetry is not explicitly used during the implementation); 4. the wall between the two rooms (i.e., the axis of symmetry) is marked with adhesive tape; 5. the two children enact symmetrical body movements; 6. the children participate in an symmetrically designed racket play.

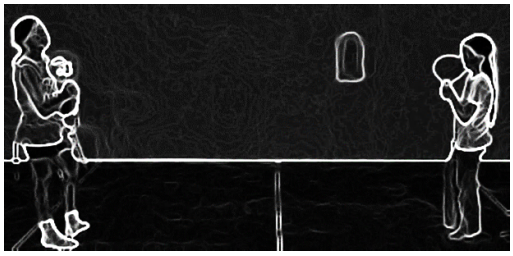

Figure 1: Sequence 6 – Racket play

For the analysis, we use the methods of the qualitative content analysis according to Mayring (2014). The category system was developed according to this study's research aim and consists of main categories and subcategories derived from the types of movement described in the literature (Ottmar et al., 2019) and the authors' expansion of the enactive representation mode (see Table 1). The system was s also expanded inductively by working with the video. The types of movement described in Table 1 serve as main categories that are differentiated into subcategories: object-centred movement – large motor, object-centred movement – small motor, body-centred movement – small motor, body-centred movement – large motor, symbolic mode (spoken language), gesture (deictic), and iconic mode. The movement categories arise from Bruner's differentiated enactive mode. The categories symbolic and iconic also originate from Bruner´s theory about modes of representation. The ‘Gestures’ category has also been included to categorise deictic gestures in particular. Gestures, which are described as movements of the limbs, partly show small motor movement. Gestures are divided into iconic, metaphorical, deictic, and beat gestures (McNeill, 1992). Consequently, gestures can also have an iconic character, as they can symbolise or visualise something. In this case, they were categorised as iconic. As soon as a movement of the limbs was not connected to language and the movement alone carried meaning, it was categorised as a movement category. The coding unit comprises 10 seconds. One code is assigned per time unit.

Analysis

The coding was carried out separately for each person (G1 – girl 1, G2 – girl 2): a code bar was created for each child (see Figures 2 and 3).

In the first step of the analysis, the code bars are described in terms of their modes. Sequence 1–4: Here, the large motor, object-centred movement is mainly expressed by the two learners distributing the large objects (symmetrically) in the room. Sequence 5: Here, both small and large motor body-centred movement is expressed – small motor, because individual body parts are placed

symmetrically in relation to each other, and large motor, by moving one's own body symmetrically in relation to another person. Sequence 6: Both body-centred and object-centred movements occur here. These tend to be large motor movements, as the children move around the room when passing the ball and use the racket to handle an object.

Two parts with frequent code changes are selected for presentation of results: sequences 4 and 6. These sequences indicate a lively change of representation and possibly the potential for intensive learning processes. Sequence 4 shows that objects are moved around the room, and positions are sought in accordance to find a symmetrical objects-arrangement in the room. The code bar shows (see Figure 2) that in the subsequent observation of the object constellation (iconic mode), linguistic negotiations take place, which in turn lead to a continuation of the arrangement of the object constellation. This alternation between large motor object movements and linguistic negotiation processes suggests that large motor object movements require a still image as an intermediate stop for orientation. On the contrary when objects are moved on the table, such an orientation or verification can be carried out permanently. At the same time, still images (taking distance from the objects-arrangement and view it from the outside) encourage descriptions of object constellations to a greater extent. The movement of objects in space (large motor object-centred movement) requires more spatial orientation (in relation to objects and people) than small motor object-centred movements.

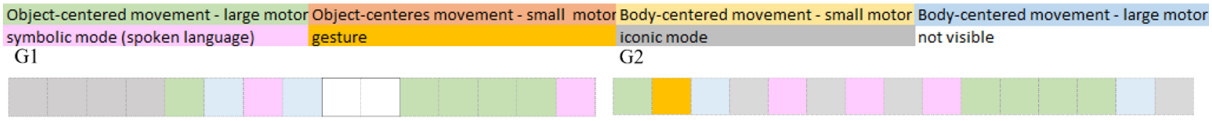

Figure 2: Sequence 4 – Attaching an adhesive tape as an axis of symmetry

The code bar for the sequence 6 shows an intensive alternation between large and small motor object-centred movements and large and small motor body-centred movements, as well as longer speech sequences. This is partly due to the game and partly due to the task of making symmetrical movements during the game. These symmetrical movements are countered by the individual preference in games to strike objects with either the right or left hand. Learners can experience the change in axial symmetry orientation in a special way through the inconsistency between the task assignments and their individual hand preferences during movement. The linguistic phases enable an exchange about this inconsistency and can stimulate processes through the change of representation.

Figure 3: Sequence 6 – Racket play

Conclusion

The theoretical analysis of Bruner's modes of representation shows the importance of the distinction between internal and external representations. The external perspective on representations provides information on how learning opportunities can be presented and learning processes can be supported, while the internal perspective on representations focuses on individual learning processes and the development of mathematical concepts. This connection can be reconstructed in the multimodal expressions of the learners (see sequence 6).

Furthermore, the analysis of the example reported here shows that selected mathematical topics can be implemented in learning environments involving large motor movements. These movements can initiate cognitive activation and a cognitive irritation in the learners, which can lead to a differentiation of mathematical concepts. This becomes clear in sequence 6, where the constraints of axial symmetry conflict with individual preferences. This irritation causes a bodily experience of the properties of axial symmetry. In this context, it can be presumed that the immediacy of mathematical experience through the integration of the body enables different approaches to mathematical concepts than those involving small motor movements with objects (horizontal change within the enactive mode – big and small one), which can only be experienced at a distance through observation.

We can also advance the hypothesis that the physical expression can show mathematical concepts that cannot initially be expressed by learners in language. This has already been showed in the range of gestures (McNeill, 1992). In our example, the property of non-orientation is physically experienced as something that is not right, i.e., does not correspond to the individual movement with the racket. In this situation, a mathematical interpretation and the resulting mathematical property of axial symmetry are not explicitly stated, i.e., they are not expressed in words.

In this context, body-centred movements are frequently accompanied by speech, as is evident in the analysed learning environment. This shows that the fleeting body-centred movements – large and small like gestures (Huth, 2021) – are often paired with an intensive verbalization of the experience, enabling a communicative continuation. On the other hand, the joint discussion requires a argumentation that makes individual experiences accessible to others. In summary, considering the Bruner's enactive mode as merely ‘actions’ is insufficient, because mathematics can also be experienced in other physical ways.

The project MoMaMat (Moving Makes Maths) aims to investigate this assumption (Hölzer & Vogel, in press). In particular, we intend to pursued the following research question: What knowledge (concepts) of the learners can be reconstructed in the large motor movements compared to small motor movements?

Visual feedback in example-eliciting tasks: from artifact to instrument

Amal Kadan-Tabaja

Haifa University, Faculty of Education, Haifa, Israel; math33444@gmail.com

This study examines how the use of visual feedback is integrated into example-eliciting tasks that requires students to reflect on them, transform from an artifact to an instrument on their learning process. By analyzing the interactions of middle school students (ages 12-13) with these tasks and feedback, we track their progression from procedural use to deeper conceptual understanding of comparing fractions. Episodes involving students Ali, Noa, and Ameer demonstrate how visual feedback supports their self-reflection processes and enhances comprehension of mathematical relationships. The findings underscore the need for designing learning environments where visual feedback fosters conceptual insight and generalization.

Keywords: Fractions, visual representation, artifact, instrument.

Introduction and theoretical background

Visual representation is crucial in mathematics education as it serves as a bridge between abstract concepts and concrete understanding. A significant advantage of a visual representation is that it supports cognitive processes which are essential for effective problem solving in mathematics and lead to deeper conceptual understanding. Additionally, these artifacts foster self-reflection, enabling learners to identify and correct misconceptions more effectively (Taylor et al., 2021).

Based on Olsher and Lavie (2021), task design is crucial for assessing generalization processes. Their research emphasized that well-constructed tasks should incorporate visual representations to support and enhance the generalization process. Visual representations such as diagrams and graphs help learners abstract and apply mathematical concepts beyond specific instances, facilitating a deeper understanding of the underlying principles. By engaging with tasks that integrate visual representations, users can develop more robust strategies for recognizing mathematical patterns and relationships. The study highlights that tasks designed with these visual elements not only aid in problem solving but also encourage students to generalize their knowledge across different contexts, ultimately enhancing their ability to transfer mathematical ideas to novel situations. Visual representations become particularly powerful when they are integrated to formative assessment processes. When visual feedback is used in tasks in which students generate examples, it can transform from a simple artifact into a dynamic instrument that enhances learning.

According to Rabardel, instrumental genesis involves learners' reflection on and adaptation of their use of artifacts. Artifacts are defined as "anything which human beings create by the transformation of nature and of themselves' (Wartofsky, 1979, p. 14) and are incorporated in human activity in order to support problem-solving. As students refine their use of artifacts, their cognitive processes are also enhanced. This relationship underscores how adapting artifacts fosters deeper learning and artifact proficiency, which Rabardel (2002) defines as an instrument. An instrument is 'a composite entity made up of an artifact component (an artifact, a fraction of an artifact or a set of artifacts) and a scheme component (one or more utilization schemes, often linked to more general action schemes'

(p. 86)." In other words, although artifacts are objects themselves, instruments are broader constructions that encompass both these objects and the ways they are used.

Rezat (2021) examined how automated feedback, initially a mere artifact in the form of digital responses and hints provided by textbooks, evolves into a critical instrument for fostering conceptual development in primary students. The study highlights that, while automated feedback itself is an artifact—essentially a technological feature designed to offer immediate responses—it becomes an instrument when integrated into the learning process. This transformation occurs as students interact with the feedback, using it not only to correct errors but also to deepen their understanding of mathematical concepts. By analyzing how students engage with and use this feedback, Rezat demonstrated that automated responses can support conceptual development when they are effectively incorporated into instructional strategies. Thus, automated feedback, originally a passive artifact, has become an active component of the learning environment, aiding students in applying and generalizing mathematical principles more effectively.

Despite the recognized importance of visual representations, there is a notable gap in how these representations are used as feedback in example-eliciting tasks (EETs) on assessment platforms. Although existing research has focused on the design and implementation of visual artifacts, there has been limited exploration of how these artifacts function as feedback instruments that can influence students' problem-solving strategies. Specifically, there is a need to understand how visual representations, used as feedback in EETs transform from mere artifacts to integral instruments that drive learning and engagement in formative assessment platforms.

This study addresses this gap by investigating how visual feedback in EETs can evolve from simple artifacts to crucial instruments within the learning process. It explores how middle school students engage with visual feedback during tasks to compare fractions, and examines how this engagement affects their problem-solving process and overall mathematical understanding.

Our research question was: How does visual feedback in example-eliciting tasks for comparing fractions transition from an artifact to an instrument?

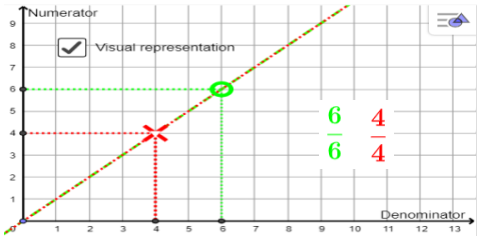
Methodology

Participants and data collection. To answer this research question, we designed activities that contained EETs when students were asked to construct fractions with specific requirements using an interactive diagram (ID). Seventy-five students participated in the overarching project. In this study, we focused on three episodes of three students, aged 12-13 years from Israeli middle school, while working individually on two tasks and asked them to think aloud. The interviewer's role was to help them with technical issues and repeatedly ask them to explain what they did and why. Before the experiment, students participated in a preparatory session that included five tasks completed in 30 minutes, during which they experimented with the platform, the ID, and the types of questions asked to become familiar with them. Data were collected by videotaping students' work on their activities. Students were selected based on their parents' agreement to participate in the study.

Data analysis. This study applies Rabardel's (2002) Instrumental Genesis Theory, which explains how learners transform external tools into cognitive instruments for mathematical understanding, to

analyze students' interactions with visual representation feedback. Following the framework of Baccaglini-Frank et al. (2024). The analysis examines students' transition through three phases: Initial Engagement (Artifact Use), where they manipulate the tool procedurally without deep reflection; the Instrumentation Phase, where they begin shaping the tool to support reasoning; and the Final Instrumented Scheme, where they internalize the tool as a conceptual instrument for problem-solving. Data were analyzed through video recordings, screen captures, and student reflection.

The tasks in this study asked the students to construct fractions by dragging points on the Cartesian coordinate system (the left side of Figure 1) and to self-reflect (the right side of Figure 2) on given statements that are mathematical characteristics. These characteristics are predefined mathematical properties of the fractions that the student chose to satisfy the requirements of the tasks (e.g., the fraction is less than one) and the relationship between the properties of this fraction and the properties of another fraction (e.g., both fractions have the same denominator). The student was asked to construct examples that had as few characteristics as possible while still meeting the requirements of the tasks.



Construction part	**Reflection part**
	☑ 1. The fractions that you chose are equivalent
	☑ 2. The visual representation ray crosses all points at the same time
	☑ 3. You chose a fraction that is less than one
	☑ 4. The fraction is an expansion or reduction of the green fraction
	☑ 5. You added the same integer to both the numerator and the denominator of the fraction to create an equivalent fraction

Figure 1. Construction and self-reflection parts of task 1

In the interactive diagram (ID) (Figure. 1), which is used in this study, the fractions are represented in the Cartesian coordinate system by a point whose vertical coordinate is the numerator and whose horizontal coordinate is the denominator (Arnon et al., 2001). All the equivalent fractions are represented by a straight ray passing through the origin, which appears automatically when the fractions are equivalent. The origin and points on the vertical axis do not represent any fractions. Points that exist on a ray with a greater slope represent a greater fraction (Figure 1).

The first task (Kadan-Tabaja & Yerushalmy, 2025), "Choose two equivalent fractions by dragging the X (red) and O (green) points. To the right of the ID are five statements that can help characterize the two fractions that you have created. Check for each characteristic present in the example before submission. *Try to submit two fractions in a way that your submission should comply with as few statements as possible.* Submit three such examples, as different as possible from each other." In this task, we focused on statement 2, which is related to visual representation. Applet for illustration: https://www.geogebra.org/m/fmfvcdjr.

The second task (Kadan-Tabaja & Yerushalmy, 2024) (Figure 2), "Choose two fractions, the O (green) one greater than the X (red) one, which applies *as few statements as possible* from the given

set of statements. Mark the statements from the set of statements that exist in your example and answer the task requirements." In this task, the ID automatically presented a fraction that was greater, and visual representations were reflected for each tagged statement as a construction in the ID. Statement 6 should be included in every example that satisfies these requirements. In this task, the ID automatically identifies the fraction that is greater. Applet for illustration: https://www.geogebra.org/m/xypss2f6.

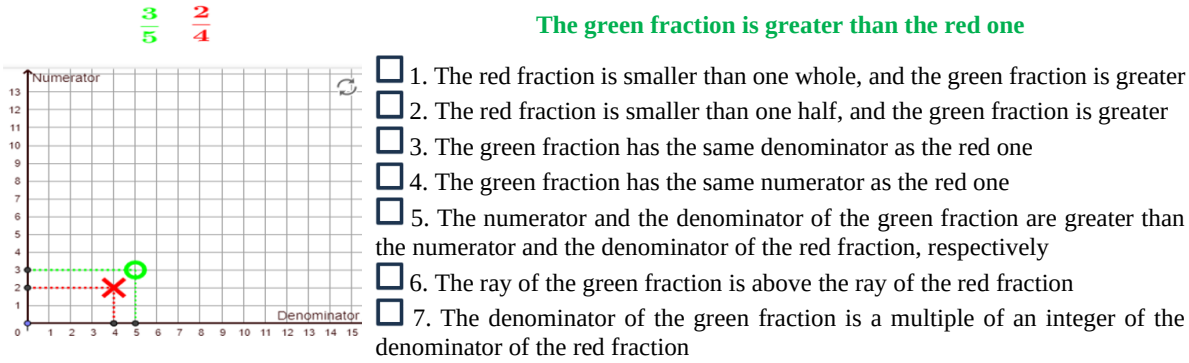


Figure 2. The interactive diagram of Task 2

Results

This paper presents an analysis of the three episodes of Ali, Noa, and Ameer. These cases were selected because they demonstrated the typical use of feedback as an instrument when working with visual representations in EETs.

Episode 1: Ali's discovery of the relation between the ray and the equivalence fractions

Ali worked on an equivalent fraction task using an ID. This task required him to construct three examples of equivalent fractions as different as possible. Initially, Ali applied the expanding method by multiplying both the numerator and denominator by the same integer (e.g., $\frac{2x2}{5x2} = \frac{4}{10}$) to generate equivalent fractions. He then dragged points on the ID to visually represent these fractions (e.g., $\frac{2}{5} = \frac{4}{10}$). At this stage, Ali treated the visual representation as an artifact using a diagram to check correctness rather than exploring the deeper mathematical relationships involved.

As he activated the ray representation to verify its presence in his example, he noticed that two points representing equivalent fractions always formed a straight ray. While reflecting on his example through the given statements, he attempted to create equivalent fractions where they answered the requirement of the task with as few characteristics as possible. In other words, he tried to have equivalent fractions in which this characteristic was not present, but failed. This repeated failure prompted deeper reflection, leading him to recognize that any two equivalent fractions must lie on the same ray. This realization marked his shift from procedural engagement to conceptual reasoning.

Ali internalized visual feedback, realizing that any fraction along the same ray was equivalent to the given fraction. Testing this insight, he chose $\frac{1}{4}$ and moved to another point along the same ray, confirming that fractions such as $\frac{4}{16}$ and $\frac{6}{24}$ were also equivalent. By the end of the task, Ali no longer

relied solely on numerical calculations but instead used visual representation as an instrument to identify and generate equivalent fractions.

His concluding statement, "I can move the point anywhere along this ray, and it will always give me fractions that are equivalent to the chosen fraction," demonstrates his conceptual understanding. This episode exemplifies the students' final instrumented scheme, demonstrating how visual feedback facilitates the transition from artifact-based interaction to generalizable mathematical insight.

Episode: Noa's discovery of slope and fraction value

Noa worked on the comparing fractions task using ID. She used "the same denominator" method to construct fractions, ensuring that when the numerator was greater, the fraction was also greater (e.g., $\frac{4}{5}>\frac{3}{5}$).

At the beginning of the episode, Noa interacted with visual representations of fractions and their corresponding rays, treating them as artifacts—a tool for verifying correctness, rather than exploring deeper mathematical relationships. While experimenting with tagging statements with as few characteristics as possible, she adjusted the points on the interactive diagram without a structured method. However, when she tagged statement 6, she observed that the ray representing the greater fraction was consistently positioned above the ray of the smaller fraction.

Noa began engaging in instrumentalization, shaping the tool to match her cognitive processes. She systematically placed points on rays with different slopes and compared the corresponding fractions such as of $\frac{3}{5}$ and $\frac{4}{5}$. This process led her to a fundamental insight: "The higher the slope of the ray, the greater the fraction." This marks a shift from procedural manipulation to conceptual understanding of fraction comparison using slopes.

By the end of the task, Noa confidently predicted the fraction values based on ray steepness: "If the ray is steeper, the fraction is greater." This transformation indicates that she had moved from an artifact-based interaction to an instrumented scheme, where she internalized visual representation as a conceptual tool. Her concluding statement, "I can tell which fraction is greater just by looking at the slope of the ray," exemplifies her development of a generalizable mathematical strategy.

Episode: Ameer's use of visual representation as an artifact-to-instrument shift

Ameer was assigned the task of constructing a fraction greater than another, while tagging a set of provided statements with as few characteristics as possible (Task 2). Initially, he manipulated the interactive diagram without a clear strategy, merely confirming fraction comparisons. His use of the tool was procedural, activating and deactivating statements and dragging points without systematically analyzing their effects. At this stage, visual representation serves as an artifact rather than an instrument for deeper understanding.

As Ameer continued, visual representation transitioned from simple verification to active reasoning. He tagged all statements activating visual representations, and then carefully dragged points to find counterexamples for the given characteristics. He began recognizing critical fraction properties such as the fact that the ray of the greater fraction was always positioned above the ray of the smaller fraction. He also realized that the denominator and numerator values alone do not determine the fraction magnitude, marking a key conceptual breakthrough.

Ameer refined his strategy by systematically eliminating incorrect fraction possibilities and leveraging visual feedback to construct mathematical generalizations. He realized that he could systematically find counterexamples and construct fractions that satisfied the task conditions by focusing on the slope of the rays. He pointed to the black area on the diagram (Figure 3) and explained, "The greater fractions should be in this area because the ray that crosses the O point is above the one that crosses the X point."

His final realization—that fraction comparisons can be determined by analyzing the ray position—demonstrated his shift to an instrumented scheme. His ability to generalize across multiple scenarios shows that he uses visual representations as a cognitive tool, rather than just a procedural aid.

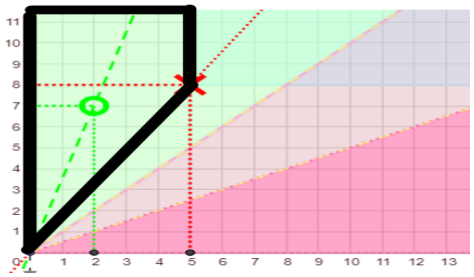

Figure 3: One possibility of the example that meets the requirement of Task 2

Table 1 summarizes the three episodes, illustrating how Ali, Noa, and Ameer transitioned from artifact-based interaction to instrumented understanding through visual feedback in Example-Eliciting Tasks (EETs).

Table 1: Summary of the three episodes

Student	Initial Engagement (Artifact Use)	Instrumentation Phase	Final Instrumented Scheme
Ali	Uses expansion method without recognizing ray significance	Notices that equivalent fractions always form a single ray	Uses rays as an instrument to generalize fraction equivalence
Noa	Uses ray steepness as a verification tool	Notices pattern between fraction values and slopes	Generalizes that steeper rays indicate greater fractions
Ameer	Tests conditions by activating/deactivating statements	Eliminates incorrect fraction properties using visual feedback	Uses systematic reasoning to construct valid fraction comparisons

Discussion

The episodes presented in this study illustrate how students transition from using visual representations as artifacts to employing them as instruments for deeper mathematical understanding. The interactive diagrams (IDs) provided not only support for procedural engagement but also guide learners toward conceptual reflection and generalization, demonstrating the critical role of feedback in promoting cognitive processes.

Our findings align with broader literature that underscores the essential role of visual representations and dynamic interactions in learning environments. Olsher and Lavie (2021) explored how dragging

in dynamic settings revealed user intentions and cognitive processes. For example, Ali initially used an ID to verify the equivalent fractions. He recognized that equivalent fractions align on the same ray through dragging points and received visual feedback. This transformation of visual representation from an artifact to an instrument allowed him to generalize his understanding of equivalence, reflecting Yerushalmy's (2005) assertion that interactive artifacts facilitate the comprehension of complex concepts by making them more manipulable.

In Noa's episode, her interaction with the ID led to an understanding of the relationship between the ray slope and fraction values. Initially focused on checking correctness, Noa's reflection on visual feedback revealed that a steeper slope indicates a greater fraction. This shift from procedural use to conceptual insight exemplifies the cognitive advances described by Arzarello et al. (2002), where dragging supports conjecture development by dynamically testing the geometric properties. Noa's ability to generalize the relationship between slope and fraction value demonstrates the educational potential of dragging, as noted by Leung and Lee (2013), in refining problem-solving strategies and uncovering geometric relationships.

Ameer's episode further illustrates this transition from artifact to instrument. Initially, Ameer used visual feedback to systematically test different fractions. As he engaged more deeply, he recognized the correlation between the slope of the ray and the fraction value, leading to a more generalized understanding of fraction relationships. This progression echoes Baccaglini-Frank and Mariotti's (2010) description of dragging as a means of conjecture making in which continuous movement aids in forming and verifying hypotheses. Ameer's refined strategy of eliminating incorrect options and narrowing choices highlights how visual feedback evolved into an instrument for logical reasoning and problem-solving.

The cognitive benefits observed in these episodes are supported by Robutti (2010) and Koedinger and Corbett (2006), who emphasized the role of visual representations in enhancing cognitive processes. The EETs in this study align with this goal by integrating visual representations designed to promote conceptual insight (Olsher & Lavie, 2021).

Furthermore, the findings of this study align with those of Baccaglini-Frank et al. (2024), who examined the transition from tools to instruments in mathematical learning environments. This study demonstrated how students develop instrumented schemes by integrating visual feedback with their conceptual understanding, reinforcing the notion that dynamic tools facilitate deeper mathematical insights.

In conclusion, this study demonstrates how dynamic visual representations, particularly when paired with dragging in EETs, facilitate a shift from procedural to conceptual understanding. The automatic visual feedback provided by IDs plays a key role in fostering generalization, allowing students to internalize mathematical concepts more effectively. This shift from artifact to instrument underscores the importance of designing learning environments that support not only interaction with mathematical objects but also reveal the cognitive processes underlying problem-solving strategies. As illustrated by the episodes involving Ali, Noa, and Ameer, these interactive artifacts can effectively guide students toward deeper mathematical insights and enhance their overall learning processes.

Note: This study and the associated writing are part of the author's Ph.D. research, titled *Automated analysis of students' interaction with elements of an assessment platform: A metacognitive perspective on comparing fractions*, conducted at the University of Haifa under the supervision of Prof. Michal Yerushalmy.

Representational affordances of addition in the app Rechenfeld: Pitfall or potential? An object-integrating perspective on interaction

Nina Köhne

Bielefeld University, Institute for didactics in mathematics; nina.koehne@uni-bielefeld.de

In the past years, virtual manipulatives have moved into focus in teaching mathematics. Their programmability offers new possibilities in representing mathematical objects, but the affordances of a virtual manipulative might run the risk of turning into pitfalls. The paper aims to investigate and better understand the processes by which an affordance effects the development of an interaction and thus the resulting learning process. To reconstruct the interactional process of an exemplary sequence where a first-grade student is confronted with the affordances of the virtual manipulative in presenting an addition term, an object-integrating interaction analysis is used. The analysis reconstructs how a potential pitfall for the students' understanding of addition emerges.

Keywords: Manipulative materials, interaction process analysis, mathematical concepts, tablet computers, elementary school students.

Introduction

Manipulatives are widely used for teaching mathematics. In this paper, I adopt the definition of virtual manipulatives proposed by Moyer-Packenham and Bolyard (2016):

> an interactive, technology-enabled visual representation of a dynamic mathematical object, including all of the programmable features that allow it to be manipulated, that presents opportunities for constructing mathematical knowledge. (Moyer-Packenham & Bolyard, 2016, p. 13)

The programmer of a virtual manipulative usually wants to transport a certain mathematical idea by intentionally designing action possibilities and restrictions (Larkin et al., 2018). Such action possibilities and their relation to the agent (in this papers case, the child) are constitutive to the concept of affordance as used in this (Bulamaqui & Dong, 2014). Constraints, limitations or restrictions are regarded as affordances of a virtual manipulative, too (Tucker, 2016). If the virtual manipulative is used as intended, the representational affordances can contribute to the learners' construction of an internal representation of a mathematical object that is close to what the programmer had in mind. Tucker (2016) states that although the same affordance is accessed, the outcomes can vary among students. Thus, affordances may affect the construction of varied internal representations that not necessarily follow the programmer's idea of the mathematical object.

Affordances in terms of limitations of actions are usually meant "to restrict the students' externalizing actions to support the internalization of specific properties of the objects in consideration" (Ladel & Kortenkamp, 2013, p. 3). For example, in a study by Manches et al. (2010), students' strategies on partitioning were compared in a physical environment and in a digital environment where in the latter, restrictions to the possible actions were an integral part. Due to the restrictions, children used much more compensation strategies, whereas children in the physical condition used commutative strategies (Manches et al., 2010). The results showed that changing the action a child could perform

led to “a significant difference in how children identified solutions” (Manches et al., 2010, p. 638). Soury-Lavergne (2016) described how the limitation of actions on a digital tool, the e-pascaline, can convey a more appropriate image representation of the mathematical object than its analogue counterpart. Despite these positive experiences, we have to take a careful look at how the representational affordances are understood by the children using the virtual manipulative. That is because “virtual manipulatives always contain and reflect the experience and the knowledge of the programmer or designer” (Ladel & Kortenkamp, 2016, p. 28), but that does not certainly imply that children develop the intended ideas. Considering this, we need a better understanding of how precisely an affordance influences the mathematical learning process or – during that process – might turn into a pitfall.

The regarded data derived from a study that takes a closer look at the interaction of a child, a teacher and a virtual manipulative. The focus of the study is to examine the interactional roles of these participants especially in moments where confusion is interactionally displayed, regarding how mathematical meaning is negotiated in the interactional process. Special to this study is the perspective on the virtual manipulative not as a material, but as a participant in the interaction. In this article, we will take a look at an exemplary scene of a student interacting with a virtual manipulative and its intended affordances. The scene serves as an example of a course of interaction between a student and a virtual manipulative where a moment of discontent was indicated by the student. Since this interactional phenomenon occurred similarly in several of the conducted interviews, it requested closer examination.

Rechenfeld (Urff, 2024) is a tool to foster understanding of the operations of addition and subtraction from first to third grade. It allows many possible actions, but due to this papers’ focus, only those relevant to the analysis will be introduced. As the mathematical object, which refers to the “concept, content or mathematical process […] targeted by the app” (Larkin et al., 2018, p. 68) in the regarded sequence is addition up to twenty, the surface’s settings are defined accordingly. By touch-gestures tapping the corresponding area, the child can make the virtual manipulative place red (left hand side, representing the summand) or blue (right hand side, representing the addend) counters in a 20-frame. It is possible to either place one, five, or ten counters at the same time. Whilst the counters are being placed, the place value of the corresponding number in the addition term that is represented below the field changes linked simultaneously.

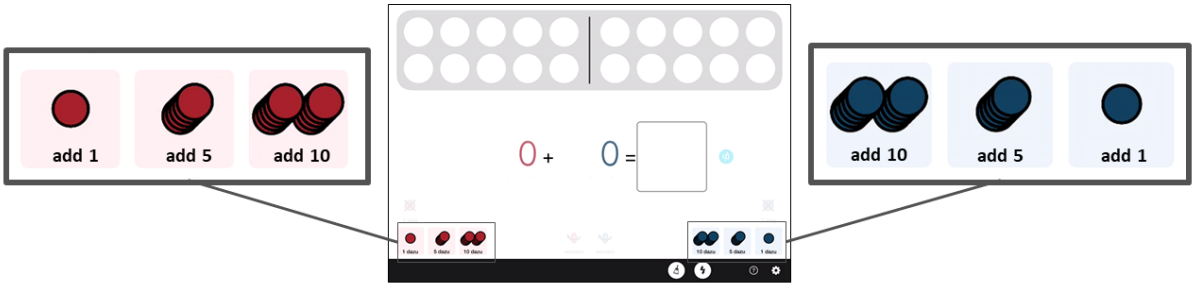

Figure 1: Screenshot of the virtual manipulative Rechenfeld

As the summand corresponds to the quantity of red and the addend to the quantity of blue counters, Rechenfeld only understands addition represented by two quantities of different colours as an

addition. This affordance is intended by the programmer: the virtual manipulative is programmed to only show the requested symbolic addition term if it's generated through the corresponding tapping of blue *and* red counters. This issue is going to be the topic of the analysed sequence.

Theoretical Framework

The exemplary sequence will be regarded from an interactionist perspective on learning (Schütte et al., 2019). This is a constructivist perspective aiming to describe how learning takes place in interaction. Deriving from symbolic interactionism, the collective negotiation of meaning is seen as constitutive part of the learning process (Schütte et al., 2019). Following the thematic development of the interaction, one can gain information about how the individual notion of the mathematical object – which is the mathematical idea in question, e.g., addition – is being constructed by the actors during the interaction. The mathematical object itself does not contain meaning, but the meaning has to be given to it by the individuals. "According to the interactionist perspective, individual processes of interpretation are developed, transformed and stabilised in the exchange with other individuals" (Schütte et al., 2019, p. 105). Mathematical learning – in contrast to the use or reproduction of existing knowledge – from an interactionist perspective takes place during the ongoing negotiation of meaning in an interaction (Schütte et al., 2019).

Because in this paper the virtual manipulative plays a central role in the process of negotiation of mathematical meaning, it is of interest to examine the role of the virtual manipulative in the interaction in close detail. Latour (2005) offers a sociologic perspective on objects (by object, Latour here refers to e.g., the virtual manipulative, not to the mathematical object as described above) by stating that "objects too have agency" (Latour, 2005, p. 63) and can actively participate in an ongoing interaction by offering for example (new) thematical contributions to a process or by taking over parts of an argument (Fetzer, 2013). Fetzer (2013) incorporates this idea to "follow the actor" – the object-actor – by focusing on its actions and roles in the interaction process. Therefore, Fetzer combines Latour's sociology of objects with the interactional theory. Thus, the virtual manipulative is no longer only talked about and used for argumentation, but it is regarded as participant in the interaction. Through its representational affordances, the virtual manipulative (partly) transports the programmer's construction of meaning of the mathematical object.

Methods

The regarded sequence derived from an interview study in which an interviewer conducted semi-structured clinical interviews. During the 30-minute interview, the first-graders worked with the virtual manipulative *Rechenfeld* (Urff, 2024) on a tablet device. The children were asked to solve addition tasks (e.g., 5+1, 2+6, 10+5) using the virtual manipulative and to explain their actions and thoughts.

The theory presented above implies the methodological approach of the interaction analysis, which is used to analyse an exemplary sequence. The aim of the interaction analysis is to investigate how and at what moments the virtual manipulative's (restrictive) representational affordances come into play and how children react and interact with them. Thereby, I want to investigate how an affordance can affect the interactional process of negotiating mathematical meaning.

The interaction analysis is combined with the object-integrating perspective (Fetzer, 2013) to closely follow the actors through the interaction process. The turn-by-turn interaction analysis is a micro-sociological, sequence-analytical method that stems from the tradition of interpretative social research (Schütte et al., 2019). Turns can be actions of the student, the interviewer, or the virtual manipulative – or two of them taking a combined turn. Every single action is interpreted as a turn to previous actions with the analyst generating as many alternative interpretations as possible. The interpretations are reviewed during the following interaction with the final reconstruction being presented in the results section. The object-integrating interaction analysis (Fetzer, 2013; Fetzer & Bräuer, 2023) based on Latour (2005) regards not only humans, but also objects as actors (Fetzer & Tiedemann, 2018):

> An object's opportunity to become an active participant in the course of action is strongly connected to human-actors' interpretations and perceptions. It is only in moments of networking, that their acting becomes observable. When inter-acting with other actors, objects traces render perceivable. Accordingly, the basic idea of analysis is to grasp the acting of objects indirectly. (Fetzer, 2013, p. 7)

To investigate the object's action, specifically the turns following on an object's turn are relevant. The response of the student to the object's actions provides information about how the object participates in the interaction process (Fetzer, 2013).

Results

The following transcript is translated from German to English. Actions are transcribed in italics. Figure 1 and Figure 2 illustrate the virtual manipulative's turns.

Interviewer:	How would you calculate 5+1 with it?
Tablet:	[Figure 1]
Student + Tablet:	So without dots? *Points with one hand over the 20-frame [Figure 1].*
Interviewer:	No, with dots.
Student + Tablet:	Then I have to write the task down there. *Taps add 5 blue [Figure 1].*
Tablet:	*5 blue counters slide from the top into the 20-frame. The addend changes to 5.*
Student + Tablet:	*Looks at the surface [Figure 2a]. Taps add 1 blue.*
Tablet:	*One blue counter slides into the 20-frame [Figure 2b]. The addend changes to 6 [Figure 2c].*
Student + Tablet:	*Looks at the surface [Figure 2c].* Aaaah bother! Bumms. I did it wrong. Wait- *Taps the broom.*

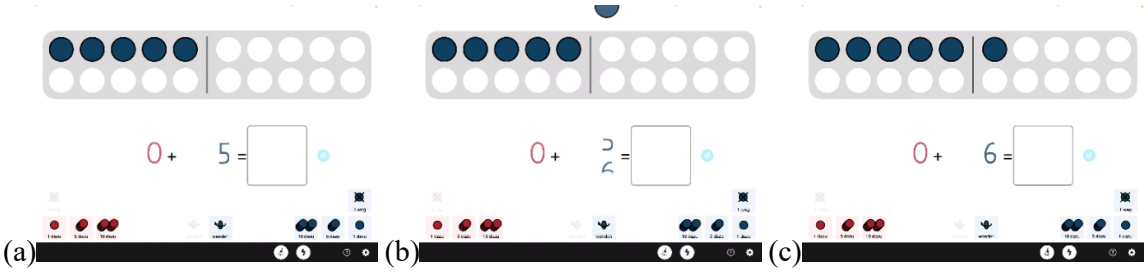

Figure 2: Three screenshots (a), (b), (c) of Rechenfeld

The presented scene took place right after an explorative period in which the student discovered the functions of the different touch areas. The student was asked to "calculate 5+1 with it", by which the

interviewer referred to the virtual manipulative presented on the tablet screen. The virtual manipulative offered the surface (Figure 1) including the affordances the student had discovered so far: tapping on the touch-areas results in the virtual manipulative placing a certain number of counters in the 20-frame and changing summand and addend accordingly. The student reacted to the prior turns by asking “So, without dots?”, pointing over the 20-frame. The interviewer answered that she wanted her to use the “dots”, picking up the wording used by the student. By that, she likely moved the students focus onto the virtual manipulative’s iconic representation. The student then assumed that she had to perform the task “there”. Right afterwards, she starts tapping the add-5-blue area, so she begins to work on the first step of the task. The tablet, as programmed, places 5 blue counters in the 20-frame as an iconic offer and changes the addend of the term from 0 to 5 as a symbolic offer. The student looks at the surface and proceeds with another action. That indicates that she is satisfied with the offer(s) she got from the tablet. Now it would be interesting to know if she checked for the offered iconic representation of the counters in the 20-field, for the offered symbolic representation or for both. It can be assumed that she looks at the iconic representation out of two reasons. Firstly, she was requested to do so. Secondly, the symbolic representation – if regarded and negotiated – could already have provided her with an indication that the virtual manipulative was not going to represent her input in the manner she had anticipated: not the summand altered – as she might have expected –, but the addend did. She continues by tapping the add 1 blue area, presumably to perform the addend. The virtual manipulative answers by sliding one blue counter into the 20-frame, where then, in total, six blue counters are presented as an iconic offer. At the same time, the addend of the symbolic term changes from 5 to 6 and thereby offers a change to the symbolic term that can be negotiated. It is possible that offer containing the animation of the counter sliding into the 20-frame still satisfied the child (as well as the total amount of 6 counters, assuming the student had already solved the task). Also, the six counters presented may be regarded as appropriate. As the animation and the total amount may align with the child’s expectations, it is unlikely that they would cause her irritation. Therefore, it can be inferred that her negotiation of the symbolic term is the source of her discontent. The student looks at the surface, followed by an articulation of dissatisfaction: “Aaaah bother! Bumms” and a verbalization of acknowledgement of herself having done something wrong. By “wait”, she presumably wants to stop the interviewer from interfering. As she moves on to the next action, she already has an idea of how to proceed, which she probably got from the virtual manipulative’s offer.

Discussion: potential and pitfall?

Following the interaction, it is obvious that despite the virtual manipulative’s different offers (enactive: animation of counters, iconic: counters in 20-field, symbolic: addition term), the student’s attention is directed towards a particular form, in this case, the iconic one. Turn by turn, the virtual manipulative reveals its affordances (e. g. counters are placed in the 20-field by tapping, the different units of the additional term are informed by the amount of counters, the addend is informed by the amount of blue counters, placing further blue counters increases numerical value of the addend corresponding to the amount of counters placed, no change occurs to the summands numerical value if no red counter is placed) in presenting an addition term, but it takes the student until the last turn to realize them. The role of the virtual manipulative that can be reconstructed in the interactional

process changes significantly due to how the child reads its offers. Indeed, as long as the child seems to be focused on the iconic representation, the virtual manipulative's role is to offer an iconic representation. This offer suits the child's expectations enough, so the interactional process continues until the point where the virtual manipulative's symbolic offer (addition term) is considered by the child and the interaction is disrupted. This emphasises that the manipulative's offers only change the interaction when they do not correspond to the student's expectations. The student does not seem to read the symbolic term as an offer to interpret but rather as a correction to her own actions. This becomes evident when the student instantly seems to abandon the previous interpretation (placing five counters first and one counter afterwards corresponds to the term 5+1) as soon as she regards the symbolic term (0+6). There is no evidence that a discursive negotiation process took place, instead, the virtual manipulative's offer is accepted as right while her own process is exposed as wrong in contrast. Accordingly, the student directly assumes that she was the one who made a mistake. This may be attributed to experiences that convey the notion that digital devices are invariably accurate. Another possible explanation might be coming from previous experiences implying that digital devices cannot be corrected by the user. This hinders the student from questioning the virtual manipulative's offers – what can make certain affordances of virtual manipulatives even more powerful.

Of interest is that the virtual manipulative's affordances give rise to the assumption that there is only one single "correct" way to present an addition term: using red counters for the first and blue counters for the addend. Through its offers, the virtual manipulative gives the child clues to its intended affordance. Following the interaction, the student in the end might not only have understood how to use the virtual manipulative properly to solve the given task, but the interaction might also have a narrowing influence on her (former) construct of addition. Solving the task, the student shows a concept of addition that contains the notion that the total of identical units represents one summand, no matter if they appear simultaneously or one after the other. When she regarded the virtual manipulatives offer, her solution process was no longer negotiated as 5+1, it was considered "wrong" for representing 5+1. The conflicting experience made in the sequence can have an influence on her construct of addition. Whether or not that experience is relevant for the student depends on various factors, one of which is the stability of her previous experiences.

In this example, we can see that the virtual manipulative has the potential to disrupt the current interactional process. The meaning of addition seems defined in a sufficiently aligned way by all participants for the first eight turns. When the virtual manipulative's offer does not suit the student's construction anymore, the student starts to attune her construction of meaning to an extent that happens to satisfy all participants of the interaction. Because such processes of negotiating or attuning of meaning from an interactional perspective are "constituent of learning processes" (Schütte et al., 2019, p. 103), it becomes inevitable to consider that the virtual manipulative not only disrupted the current interactional process, but also the student's construction of the mathematical object in question. By trying to negotiate a meaning that is suitable to the virtual manipulative's intended affordances as well as the student's ideas, as the virtual manipulative cannot adjust its offers, the student needed to adjust her notion to the offer. To maintain a functioning interaction afterwards, the student needs to align her actions to the affordances of the virtual manipulative – from now on,

representing an addition term by using red and blue counters instead of only blue ones – and thus, she might also adjust her notions: notion is being modified during the processes of negotiation of mathematical meaning in the interaction (Schütte et al., 2019).

Concluding remarks

Affordances, as we learned before, might hold the potential to guide student's ways of doing math. However, if left unaddressed, they may also lead to an unreflective acceptance of an intended affordance as part of a notion of a mathematical object, applicable in a broader range of contexts. In that, the affordance effecting the present interaction might also influence further situations: if the child activates this subjective domain of experience, containing their modified notion of addition, and therefore struggles to mathematically make sense of a new mathematical situation, the learning process might be disrupted.

This example provides insight into the importance of regarding the role of the virtual manipulative in the interaction, especially how its affordances come to bear during the interaction of offers from the virtual manipulative and how they are interpreted by the other participants. In order to take a closer look at the probably emerging pitfall, the object-integrating interaction analysis was conducted. By retracing the interaction of the subject and the virtual manipulative, including especially the intended affordances that the virtual manipulative consists of, it becomes visible how intended affordances can guide and narrow students' actions, meaning making processes and thus, can influence the student's learning of mathematics.

As "differences in actions resulting from the representational medium may lead to differences in the ideas fostered" (Manches et al., 2010, p. 624), we have to start following those actions and how they seem to be perceived by the child. Teachers have to be aware of virtual manipulatives' representational affordances – with their possibly structuring and/or restricting properties – and their potential pitfalls' influences on learning processes and take them into account when teaching.

Interpretation and representation of fractions in problem solving

Chloé Lemrich[1,2], Marie-Line Gardes[1] and Emmanuel Sander[2]

[1]Lausanne University of Teacher Education, Switzerland; chloe.lemrich@hepl.ch,
[2]University of Geneva, Switzerland

This exploratory study investigates the dominant conceptions of fractions in problem-solving contexts using various interpretations and representations of fractions. For this purpose, we proposed six problems for pre-service teachers and students to solve. We examine the strategies and the representational registers that they use to solve these problems. The results show that pre-service teachers tend to use solving strategies that align closely with the anticipated interpretation of the problem, while students tend to rely more on the part-whole strategies. We demonstrate that several conceptions coexist, but the part-whole interpretation is the dominant conception among participants. Students mainly use symbolic representations.

Keywords: Fractions, dominant conception, problem solving, representation, mathematics education.

Introduction and conceptual framework

Teaching and learning fractions are considered one of the most challenging areas of primary school mathematics. Several studies have suggested that one of the main factors contributing to this complexity is that understanding fractions requires grasping multiple interpretations and representations (Behr et al., 1983; Charalambous & Pitta-Pantazi, 2007). Behr et al. (1983) identified five interpretations of fractions. The part-whole interpretation expresses the relationship between a whole divided into equal parts and one or more of those parts. The measure interpretation expresses the measure of a quantity in terms of a unit of measurement. The operator interpretation operates on a set in a multiplicative way (increasing, decreasing). The quotient interpretation expresses the result of a division. The ratio interpretation expresses the relationship between two quantities of the same or different nature. Authors suggest that these interpretations can be associated with operations (for example, addition related to measure), equivalence (related to ratio), and problem-solving. If some students do not recognise or understand a particular interpretation, they may have difficulty in solving specific problems (Charalambous & Pitta-Pantazi, 2007). Furthermore, fractions can be represented with a variety of signs depending on the context, such as words, numbers, or geometric shapes. These signs are not the mathematical object itself; rather, they are representations of mathematical objects, facilitating its accessibility (Duval, 2006). Based on the research of Duval (2006), four types of representation registers are identified: the symbolic, the verbal, the visual, and the number line. The symbolic register includes symbolic notation and writing (e.g., $\frac{1}{2}$, which in the symbolic register can also be 5/10 (fractional writing), 0.5 (decimal writing), or $1 \div 2$ (divisional writing), or 50%). The verbal register uses natural language (e.g., “half”, “one out of two”). The visual register includes drawings and figures (e.g., a disc is divided into two equal parts, and one part is taken). The number line register is a point on the number line (e.g., for ½, the point exactly between 0 and 1).

In the field of mathematics education, the concept of *conception* emerged from empirical work highlighting the stability of student errors that hinder learning and focusing on an individual's

construction of concepts. Brousseau (1987) points out that a conception is an instance of the student's knowledge in a situation, identified by a dual approach: an epistemological analysis of the concept and a study of the individual's knowledge of the concept. He gives examples of conceptions of fractions (measure and ratio) and shows that they can coexist. In cognitive and developmental psychology, a conception is a set of principles and mental representations that guide the interpretation of concepts and individual behaviour. Conceptions allow for the prediction of individual behaviours. They are qualified as intuitive when they are based on prior knowledge and persist after learning at school (Fischbein et al., 1985; Gvozdic & Sander, 2018). Teachers remain influenced by their conceptions and may interpret students' errors in this way (e.g., for conceptions of division, Tirosh & Graeber, 1991).

The current study

Research shows that some conceptions resist instruction and continue to influence individuals, even after the concept has been formally taught in school (for a review, see Gvozdic and Sander, 2018). Studies suggest that people rely on these conceptions to build their knowledge (Brousseau, 1987), which is particularly relevant in the understanding of fractions (Lemrich et al., 2023). Conceptions provide a means of predicting and explaining errors, particularly those related to the whole numbers bias (Ni & Zhou, 2005). In this study, the individuals' conceptions are characterised by the mobilisation of interpretations that can be related to problem-solving strategies (Charalambous & Pitta-Pantazi, 2007). We refine some of our results by also considering representations, which facilitate the accessibility of an aspect of the mathematical object (Duval, 2006).

At CERME13, in TWG24 (Lemrich et al., 2023), our aim was to identify the intuitive conceptions of pre-service teachers using an open-ended questionnaire. We showed that the intuitive conceptions of pre-service teachers were the part-whole interpretation. We have also assumed that the quotient interpretation is a conception most likely related to teaching fractions. Overall the symbolic and visual registers were the most used. In this research, we are interested in extending these initial results by exploring dominant conceptions in problem solving and contrasting pre-service teachers' and students' conceptions. Research has already examined the success of teachers and students when they are asked to solve fraction problems linked to a specific interpretation (e.g., Charalambous & Pitta-Pantazi, 2007; Lamon, 2006). However, to our knowledge, no study has ever shown, by analysing solving strategies, that a fractions problem may indeed be tied to a specific interpretation and that some solving strategies are dominant in several contexts. Firstly, we aim to confirm the link between a problem and a specific interpretation. For that purpose, we identify a priori a specific interpretation for each problem and then compare it with actual solving problems strategies of participants. We assume that adults, who are more experienced than students, should use the most expert and direct solving strategies that are close to the identified interpretation. Secondly, we want to find out whether there is a dominant conception from which problem-solving strategies are derived. Building on previous research (Charalambous & Pitta-Pantazi, 2007; Lemrich et al., 2023), we hypothesise that although some adults may use part-whole strategies in some contexts, students are more likely to mobilise them systematically to solve problems, as well as symbolic and visual (circular) registers.

Methods

We collected data from 206 pre-service teachers and 69 sixth graders (average age 11) during the 2023-2024 academic year. The pre-service teachers were in university training to obtain tenure in the French-speaking part of Switzerland for either primary (103) or secondary (103) schools. Sixth graders were studying fractions for the second year.

We created a questionnaire consisting of six problems to be solved (see Figure 1). Each problem was selected based on its proximity to one of the fraction interpretations, as suggested by previous works (e.g., Charalambous & Pitta-Pantazi, 2007; Lamon, 2006). For each problem, we chose fractions that were sufficiently familiar to students, allowing them to represent them in different ways. We also varied the contexts. For the interpretation of quotients, we chose to present the same problem twice, changing the size of the fraction and using one proper and one improper fraction. In the given material, all fractions are written in the form $\frac{a}{b}$.

Part-whole	Andrea celebrates his/her birthday, his/her cake is cut in 12 parts, Andrea eats 5 of them. What fraction of the cake was eaten?
Measure	I'm taking part in a bike race. Each stage represents 1/4 of the race. How many stages must I complete to reach 3/4 of the race?
Operator	There are 120 children in the school playground, and 3/4 of them are playing ball. How many children are playing ball?
Quotient	There are 5 people and 6 chocolate bars. Each person receives the same quantity of chocolate. How much will each person get? And the same problem with 8 people and 3 chocolate bars.
Ratio	A chocolate drink is made by mixing chocolate and milk. Alix's drink has 2 parts chocolate to 3 parts milk. Charlie's drink has 1 part chocolate to 2 parts milk. Who has the most chocolatey drink?

Figure 1: Problems proposed to participants linked to interpretation

For each problem, we defined a priori solving strategies close to each interpretation (between two and four, see for example Figure 2). To determine which strategy is closest to which interpretation, we referred to research (e.g., Behr et al., 1983; Charalambous & Pitta-Pantazi, 2007). Part-whole strategies involve dividing a whole into a certain number of parts and taking a specific quantity. Measure strategies involve considering the size of a part as a subunit and repeating it a certain number of times. Quotient strategies involve dividing the number of units by a given number. Operator strategies involve applying a fraction to a continuous or discrete whole. Ratio strategies involve determining the relationship between two distinct quantities.

For the *part-whole* problem, we defined 3 a priori solving strategies.	
Part-whole	The cake is cut into 12 slices, so I take 5 slices to make 5/12.
Measure	The cake is cut into 12 pieces, each piece is 1/12. 5 slices have been eaten, which means 5×1/12=5/12.
Quotient	I do 5 divided by 12, which means 5/12.
For the *operator* problem, we defined 4 a priori solving strategies.	
Part-whole	I split the 120 children into 4 groups. That's 30 kids per group. And there are 3 groups of children playing ball, making 90 children.
Measure	3/4 is 3×1/4, 1/4 of 120 is 120/4=30, 3/4 is therefore 3×30=90
Quotient	I do 3/4 × 120=90
Operator	I divide 3 by 4 and multiply by 120, which means (3÷4)×120=90.

Figure 2: Example of solving strategies linked to interpretation proposed to participants

To collect data, pre-service teachers received problem-solving tasks in the form of multiple-choice questions. For each problem, they first solved the problem and gave the answer, then chose the solving strategy (see Figure 2) that was closest to their own. This step was necessary to check that they were answering the problems correctly and to understand the strategies used. Given the simplicity of the problems, we opted for multiple-choice questions, assuming that they would provide an answer without detailing their strategy. The students solved the problems using a pen and a paper questionnaire. They were explicitly asked to document their strategy, which gave access to the representations and strategies used to characterise the conceptions.

With the aim of avoiding that the order of the problems would influence the results, the problems were proposed in four different orders, taking care not to pair the two quotient problems too close together. For each problem type and for each participant, we first checked whether the problems were solved correctly (correct, incorrect, no answer). If the answer was correct, we evaluated the strategy used. For the pre-service teachers, because of the multiple-choice format, the information was in a spreadsheet. For the students, we used MaxQDA software to code the responses and then extracted the data into a spreadsheet. As they did not respond to a multiple-choice test, we had to evaluate correctness and score the strategies they used. These strategies were sometimes the same as those found in the a priori analysis, so they were coded using the same indicators (i.e. strategies related to interpretation) as the pre-service teachers. Students sometimes left no trace of their solving strategy. In these cases we coded their answer in the category without justification. Occasionally, students used strategies that we had not considered in our a priori analysis. For example, some students solved the 3/8 quotient problem by adding an arbitrary (but relevant) number of squares to each bar. They managed to solve the problem by distributing the squares to each individual tree. These strategies were coded in the category other.

To analyse the representation registers mobilised by the students for each strategy, we used four registers: the symbolic, the verbal, the visual and the number line registers. For each problem, we coded the registers used among the correct answers. We did not include incorrect answers in our coding process because the remnants left by the students were not consistently usable (partially crossed out or erased writing, incomplete drawings or writing, etc.). We did not have access to the representations for the pre-service teachers through the multiple-choice questions.

Results

To identify the most successful problems, we first looked at those that were solved correctly (see Table 1, the percentages therefore reflect the correct answers). Among the pre-service teachers, the most successful problems are part-whole (91%), measure (95%) and operator (92%). The same sucess rates hold for students, although they are slightly less successful on the operator problem (37%). Participants are less successful overall on quotient and ratio problems. Their success rate is close to 70% for pre-service teachers and 30% for students.

To confirm whether a problem could be associated with a particular interpretation, we categorised the strategies used by the pre-service teacher (see Table 2). For all the problems (except for the operator), the pre-service teachers tended to use the strategies closest to the type of problem proposed (see Table 2, grey cells). However, for each problem, a few pre-service teachers also used part-whole

as a solving strategy. Other procedures closely related to other interpretations were also used, but to a much lesser extent.

Table 1: Percentage of correct answers by problem type and participants group

	Part-whole	Measure	Operator	Quotient 6/5	Quotient 3/8	Ratio
Pre-service teachers (206)	91%	95%	92%	75%	73%	71%
6th Grade students (69)	61%	67%	37%	31%	26%	26%

Table 2: Percentage of response strategies mobilised, for each problem, for the pre-service teachers (206), among correct answers

	Strategies close to					Other procedures
	part-whole	measure	operator	quotient	ratio	
Part-whole	73%	18%		9%		
Measure	45%	55%				
Operator	41%	24%	30%	3%		
Quotient 6/5	5%	13%		83%		
Quotient 3/8	9%			91%		
Ratio	20%				68%	12%

In order to determine which conceptions were most frequently used by the students for each problem type (see Table 3), we categorised the strategies used by the students. For all problems (except ratio), students used the part-whole strategy more often than any other possible strategy, which they hardly used at all (see Table 3, grey cells).

Table 3: Percentage of response strategies mobilised, for each problem, for the 6th grade students (69) among correct answers

	Strategies close to					Other procedures	Without justification
	part-whole	measure	operator	quotient	ratio		
Part-whole	52%						48%
Measure	24%	9%				2%	65%
Operator	73%	8%		4%			15%
Quotient 6/5	50%	5%		45%			
Quotient 3/8	39%			22%		28%	11%
Ratio	28%				28%	6%	39%

To examine the representation registers used by the students for each solving strategy, we used four registers: the symbolic, the verbal, the visual and the number line registers. Symbolic register is the most used of all the strategy. In the case of the part-whole strategy, 60% of the students used at least one symbolic register, 31% used the visual register, 8% used the verbal register and only one student used the number line. For the quotient strategy, most students (94%) use symbolic register and the remaining 6% use verbal register. For the measure strategy, 83% of the students use the symbolic register and 17% use the verbal register. For the ratio strategy, 63% of the students use the symbolic register and 38% the verbal register. The operator strategy is never used by the students.

Discussion

Our first aim was to confirm the link between a problem and a specific interpretation based on the solving strategies used. Our results show that pre-service teachers were more likely to use solving strategies that were closest to the type of problem proposed. This confirms that the proposed problems are aligned with the expected interpretation. Therefore, it confirms that the participants interpreted some problems more closely to some interpretations than others, without ignoring the fact that they can be solved in several ways, using several interpretations. Our second aim was to find out whether there is a dominant conception from which problem-solving strategies are derived. Although most pre-service teachers use the solving strategy close to the interpretation identified, some of them used the part-whole solving strategy, indicating that this interpretation is widespread, despite the possibility of using more expert and direct strategies. On the contrary, students make more use of the part-whole strategy for all problems, compared to the other strategies, which they hardly use at all. Ratio and quotient strategies are not yet part of the curriculum, but students should already have encountered the operator and measure strategies. These results show that the use of solving strategies derived from the part-whole interpretation is the most common for both pre-service teachers and students, used in all situations. This interpretation manifests itself in different situations, it persists for most participants, hence the dominant aspect. Consequently, we characterise the use of the part-whole interpretation as a dominant conception. To check whether this knowledge is acquired outside the classroom and whether it is also an intuitive conception, it would be necessary to interview students who have not yet been taught fractions. This study is currently in progress.

To refine our findings and enhance the characterisation of the conception, we aimed to identify the representations used to guide the students problem-solving processes. The results suggest that regardless of the strategy used, they tend to rely more on the symbolic register than on the visual register. We assume that the students, unused to solving problems with fractions, thought that they had to approach these problems in the same way as with whole numbers, using operations and the symbolic register. The representations available to them are then fractional and decimal writing, which they have just discovered in their curriculum (introduced in 5th grade in the Swiss curriculum). We hypothesised that the visual register would be mobilised in students' answers for all strategies. However, this hypothesis was not verified. We assume that some representations are more spontaneous than others, but their use is strongly influenced by the context of solving problems and that further studies (including adults) are needed to verify these results.

For this reason, and in view of the results of previous study (Charalambous & Pitta-Pantazi, 2007; Lemrich et al., 2023), we qualify the dominant conception of fractions as part-whole interpretation with symbolic or visual representation. Indeed, while the dominant conception is associated with the part-whole interpretation, the other conceptions associated with other interpretations should not be overlooked in teaching with an aim to promote a deeper mastery of the concept of fraction. According to Brousseau (1987), the different conceptions must coexist and be articulated to form the conceptual field of the mathematical concept. This highlights the complexity and richness of mathematical understanding. For a comprehensive understanding of the representation used, it would be interesting to review all the tasks of the previous study (Lemrich et al., 2023) on the use of representational registers, with the aim of integrating its findings with the present study. To this end, in a forthcoming study, we will combine the two questionnaires in order to obtain a better characterisation of conceptions through spontaneous responses and problem solving, with adults and students who have or have not had previous instruction. In this way, the intuitive aspect of the conceptions can be examined.

While the results of this study provide valuable insights into dominant conceptions of fractions in problem-solving contexts, it is important to acknowledge a few limitations that may affect the generalisation and interpretation of the results. Firstly, the problems proposed in the questionnaire are not of the same nature. For the operator and measure the fraction is given and the participants must operate with it. The other problems (part-whole, ratio and quotient) consist of finding the fractions involved. This might explain why the operator and measure problems are almost as successful as the part-whole problem for pre-service teachers. In addition, the choice of numbers also makes it easier to solve the problem using alternative (e.g. for the quotient, adding an arbitrary but relevant number of pizza slices) or erroneous (e.g. for the ratio, referring only to the quantity of chocolate and not taking the quantity of milk into account) strategies to the one derived from the hypothesised interpretation, which may explain the greater success with these problems. Secondly, the difference in the method of data collection between the two groups of participants may influence the comparison. Although the participants solved the same problems, the teachers used a multiple-choice format while the students worked on paper and pencil. The criteria for defining the students' strategies were based on those proposed to the teachers, which were based on an a priori analysis of possible solutions. We considered the changes necessary in order to access the strategies used by the pre-service teachers, but any change of format might imply a bias in the comparison of the groups and affect our results.

Conclusion

For each problems, this study has shown that for adults, with the exception of the operator, the solving strategies employed were indeed consistent with the intended interpretation. The results also highlighted the prominence of the part-whole interpretation, from which the most common solving strategy for solving these problems is derived. Some of the problems proposed were close to the part-whole interpretation, others were further distant. Given this and the persistent use of this strategy over time, this suggests that the dominant conception of fractions is the part-whole one. Other ones, which could be described as secondary, coexist and need to be mastered, but are not the most spontaneously mobilised. A question then arises: what are the most promising ways of intervening in the classroom?

Given the strong anchoring of conceptions in various contexts, building on them seems inevitable. Therefore, students need to be guided on how to evolve from one interpretation to another in order to avoid an overemphasis on the part-whole strategy and to enhance the capacity to adaptively switch from an interpretation to another when such a switch makes a strategy more adequate than another (Scheibling-Sève et al., 2022). This work will be carried out in a pilot study in a primary school.

From multiple discourses to algebraic discourse

Giulia Lisarelli[1], Bernardo Nannini[2] and Samuele Antonini[2]

[1]University of Pisa, Italy; giulia.lisarelli@unipi.it

[2]University of Florence, Italy

This study is framed within a commognitive perspective and is based on the theoretical stance that subsuming is a key discursive process for relating different representations, providing an alternative way of learning compared to memorizing meaningless procedures. We designed activities in digital learning environments to promote this subsuming process in the context of school algebra. We analyze the story of Aldo and Giulio, two high school students, showing how this process can feature and how algebraic discourse can emerge as a possible subsuming discourse.

Keywords: Algebraic discourse, commognition, digital learning environments, equations.

Introduction and theoretical background

A large body of research into school algebra has highlighted several key challenges and strategies for improving teaching and learning. Classical studies in mathematics education show that students frequently rely on memorized procedures and this results in well documented problematics as a procedural view of the equal sign or difficulties with the letter-symbolic form of equations (e.g., Carpenter et al., 2005; Kieran, 2022). In a different perspective, Kieran and Drijvers (2006), along with Nachlieli and Tabach (2012), emphasize the importance of learners coming to consider different mathematical representations as being the "same" object. An implication for task design is to use multiple representations to make algebraic objects such as variables, expressions, and equations more meaningful to students. In this study, we draw on these two strands of research that we see as related, since a way to give meaning to the memorized procedures might be to associate the involved objects with multiple representations and relationships among them. Within the broader project this study is situated in (DynaMat), multiple dynamic explorative objects (DEOs) are designed for representing the relationships between two algebraic expressions of the same variable. The students participating in the project are involved in sequences of activities requiring for an explorative participation with these DEOs. We embrace the commognitive lens (Sfard, 2008) for analyzing students' interactions with the DEOs, and, through this analysis gaining insights into their learning of school algebra. This theory has proven effective in studying communication processes at different school levels (e.g., see, the special issue by Cooper and Kontorovich, 2021).

The processes of saming and subsuming in the Theory of Commognition

According to the Theory of Commognition, mathematical objects are discursive objects and this leads to mathematical communication involving continuous transitions from *signifiers* to other entities that are called *realizations*. In particular, "signifiers are words or symbols that function as nouns in utterances of discourse participants whereas the term realization of a signifier S refers to a perceptually accessible object that may be operated upon in the attempt to produce or substantiate narratives about S" (Sfard, 2008, p. 154). For example, the word 'equation' can have the role of signifier in a discourse and its possible realization can be a symbolic writing as $6+x=2x+1$ or a graph

of two intersecting lines. A peculiarity of mathematical signifiers is that each of them has several possible realizations such that every *endorsed narrative* - i.e. every narrative labeled as true by the community of discursants (Sfard, 2008, p. 134) - about a signifier can be translated into an endorsed narrative about one of its realizations. In these terms, the learning process may be expressed as the creation of new signifiers by collapsing different realizations into one, that may give rise to the creation of new mathematical objects. An important role in this complex process is played by the discursive act of *saming* which is described by Sfard (2008, p.170) as "assigning [the signifier] to a number of things that, so far, have not been considered as in any way 'the same' but are mutually replaceable in a certain closed set of narratives". An example of saming can be seen when an algebraic expression, e.g. $6+x=2x+1$, and a scale in balance are considered as realization of the 'same object' and they are all-in-one addressed by the word 'equation' (Weingarden et al., 2024).

Commognition describes the development of mathematical discourse as a recursive expansion in which new discourses integrate previous ones, either by merging familiar discourses or by creating a meta-discourse that encompasses older ones. More specifically, Sfard (2008) defines *subsuming* the process through which existing discourses are incorporated into newly developed discourses and it is possible to distinguish between two situations. The first one occurs when a discourse is subsumed by its meta-discourse. For example, arithmetic discourse was subsumed centuries ago by the algebraic one, which in commognition is seen as "metaarithmetic, or more precisely, as the unification of arithmetic with its own metadiscourse" (Sfard, 2008, p. 120), that is the mathematical discourse on arithmetical relations and processes (Caspi & Sfard, 2012). The second occurs when two discourses are subsumed by a discourse containing an isomorphic reflection of these two discourses. For example, the discourse on algebraic expressions and the discourse on graphs were both subsumed, during the age of Descartes, by the discourse on functions in which an algebraic expression is an isomorphic reflection of a graph. The echoing of historical processes in students' individualization of mathematics discourses was described in a study by Caspi and Sfard (2012), which found that students' formal algebraic discourse was built on the foundations of their informal meta-arithmetic discourse. In the next section we describe how this theoretical lens informed our study and offered insights into students' integration of separate discourses into a cohesive mathematical understanding.

Discourse about balancing mobiles and discourse about moving arrows

Within the DynaMat project we developed DEOs as realizations of mathematical equations and inequalities, both designed in the software GeoGebra. We realized the relationships between two expressions of the same variable in terms of changing weights of the two sides of a mobile and of reciprocal movements of moving arrows (examples are described in Lisarelli et al., 2024; Weingarden et al., 2024). We have discussed in the previous section how different branches of discourse can be seen as subsuming each other. In our study, we initially supported students' development of a discourse about balancing mobiles and of a discourse about moving arrows by engaging them in activities involving separately the two different realizations. Then, one heuristic we used was to design task situations that cannot be fully addressed in just one of these discourses. For instance, we designed a DEO in which a mobile and some moving arrows are simultaneously embedded and connected (Figure 1).

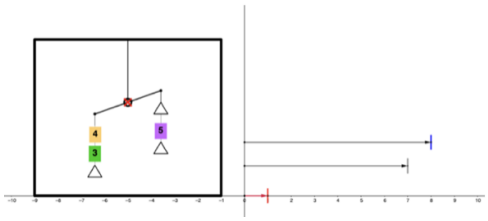

Figure 1: Screenshot of the DEO embedding a balancing mobile and moving arrows

The value of the white triangles in the mobile corresponds to the length of the red arrow below on the right of the screen. The mobile hangs to the side in which the total value of the weights is bigger or, in the case both sides have the same value, it stays balanced. On the right there are three arrows. Two of them, ending respectively with a blue and grey tick mark, correspond to the sides of the mobile, since their length is the same of the value of each side of the mobile. Finally, the length of the red arrow on the numbered line, ending with a red tick mark, as said, defines the value of the white triangles on the mobile (and consequently, also the values of the two sides of the mobile and the lengths of the other two arrows). The red tick mark can be dragged along its line, changing the length of the red arrow. In response to this dragging all the other objects of the DEO move accordingly: the slope of the mobile changes in function of the new weights and the arrows change their length to their new corresponding value. The task situation requires students to drag the red tick mark and describe what happens in the DEO.

Our hypothesis was that students, interacting with this DEO, may produce a broader, subsuming discourse to describe simultaneously all the objects in the DEO and their relationships. Algebraic discourse offers a possible form of subsuming discourse, allowing to express almost everything that can be said in the discourse about the mobile and in the discourse about the arrows, with their own signifiers (Figure 2 shows an adaptation of the diagram in Sfard, 2008, p.175). We observe that the protagonists of this subsuming discourse are expected to be the products of a saming process. For instance, the reciprocal positions of two arrows and of the two sides of a mobile as in Figure 1 can be seen as 'the same relationship', that can be expressed by the inequality '$7+x>2x+5$'.

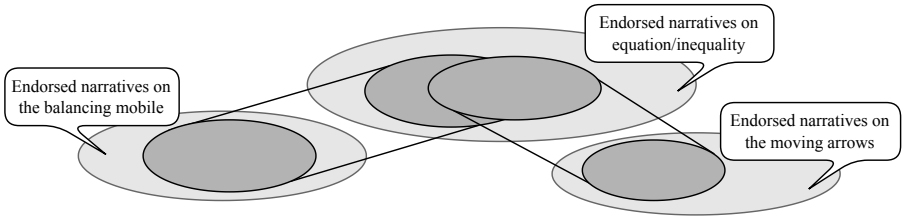

Figure 2: Algebraic discourse subsumes discourses about balancing mobiles and moving arrows

Research objective

In this study we aim to investigate to what extent the discourse developed by students in their interaction with a DEO in which both a mobile and arrows are embedded, subsumes the discourse about the balancing mobile and the discourse about the moving arrows.

Methods

Data collection occurred in an out-of-school learning center with 13 10th grade low achieving students (according to themselves and their teachers), volunteering from different Italian high schools. Participants attended five 2-hours sessions, during which DEOs-based activities were proposed by a researcher, tutoring during the sessions. Data were collected in the form of video recordings, students' written productions, and screen recordings of the tablets.

This paper focuses on Aldo and Giulio's activities after having worked with us with DEOs involving separately mobiles or moving arrows. During the last two sessions, they were given explorative activities aimed at fostering a discourse subsuming the previously constructed discourses about the balancing mobile and the moving arrows. The tutor's questions to students seek to promote saming between the different realizations in the DEO (e.g., "What does this arrow/this side of the mobile correspond to?"). We analyzed data from these two sessions, looking for the possible presence of a subsuming discourse. According to what discussed previously, we operationalized this objective by focusing on the realizations involved and on instances of saming narratives in students' discourse.

The story of Aldo and Giulio

During a preliminary individual interview, both Aldo and Giulio showed difficulties in dealing with algebraic expressions. Giulio, for instance, when asked to say if there are solutions for the equation *13-a=13+11* said, without writing anything, "To find them [the solutions], one must bring all the integer numbers to one side and the unknown to the other, so it would be thirteen plus thirteen minus eleven equals minus *a*... and it would be fifteen but in this case there are no solutions, I think it is impossible […] because fifteen cannot result in minus *a*". Aldo, instead, when asked the same question for the equation *3+a=a+3,* said "it says that three plus *a* equals *a* plus three, that is the two sums are equals […] I don't think it has solutions […] because if *a* goes to the left it becomes *a* squared and so the three goes to the right and becomes minus three and so that ones on the right simplify end so there is no number. So *a* squared equals zero, which has no sense." Both Aldo and Giulio's discourses seem focused on performing procedures and neither of them relates the outcome of these procedures with the signifier "solution of an equation". We do not know how linear equations were specifically addressed in school by their teacher; however, given the common practices in Italy at this level, the two students were certainly exposed to procedures for solving linear equations. Then they participated together in our activities. We report on two episodes where they are the protagonists. For each episode, after describing the task situation, we analyze a short excerpt of the transcript.

Episode 1

During the 4th session, Aldo and Giulio were given, for the first time, the DEO above described in which a mobile and some moving arrows are simultaneously embedded (Figure 1). The task situation was: "What do you notice in this file? Drag the red tick mark and describe what happens".

The following excerpt starts after the students have explored the DEO for approximately one minute.

1	Aldo:	So, that if the triangle is two the mobile stays balanced
2	Tutor:	How can you say if the triangle is two?
3	Aldo:	Eh because we moved *x* onto two and both the arrows are on the nine
4	Tutor:	Ok. And these two arrows?

5	Aldo:	Yes, I mean they meet only at two
6	Tutor	They meet at two, ok
7	Aldo:	But if the triangle is bigger than two, the right arrow will be always bigger
8	Giulio:	Yes
9	Tutor:	Wait, the right arrow
10	Aldo:	The arrow below
11	Giulio:	I mean the arrow below represents the right side of the mobile
12	Tutor:	Ok
13	Aldo:	While if it is less than two the arrow above or the left side of the mobile will be always bigger
14	Tutor:	Ok so explain to me better … the relationships, I don't know, because you already told me something
15	Aldo:	So, if *x* equals two the mobile stays balanced
16	Tutor:	What is *x*?
17	Giulio:	*x* is the triangle
[…]		
21	Aldo:	If a triangle is worth two the mobile stays balanced while if the triangle is bigger than two, two *x* plus five is bigger than seven *x*.
22	Tutor:	Ok, and here *[points to the arrows]* what happens?"
23	Aldo	Ehm the right side so five plus two *x* will be bigger… than seven plus *x*, if *x* is bigger than two. While if *x* is less than two, seven [plus] *x* will be always bigger than two *x* plus five"

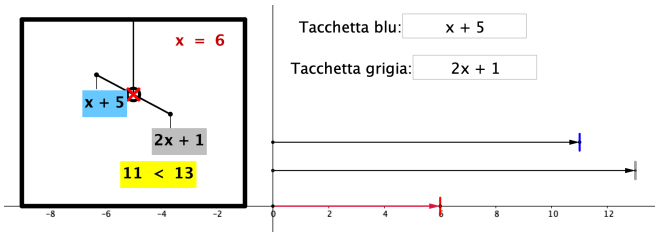
At the tutor's request of synthesizing what they found, they write: "If $\Delta=2$ the mobile is balanced and the two arrows will be on the same position, while if $\Delta>2$, $2x+5>7+x$, while if $\Delta<2$, $7+x>2x+5$".

Giulio and Aldo's discourse is characterized by a series of interesting elements. First of all, we can see a rich intertwining of narratives referring to the mobile (e.g., [1]; [15]), to the arrows (e.g., [3]; [5]; [10]) or to both, blending together terms of the two objects (e.g., [7]; [11]; [13]). Aldo's utterance "if the triangle is bigger than two, the right arrow will be always bigger" [7] well exemplifies this blending: the triangle is an object of the mobile but, here it is linked with the arrow's behavior. Moreover, Aldo talks about "the right arrow" and when asked by the tutor he explains that "I mean the arrow below represents the right side of the mobile" [11]. This can be considered as a meta-discourse because it is a narrative referring the relations about words used in narratives about mobile and words used in narratives about arrows. Moreover, with the "right arrow" he has condensed into the same expression both the "below arrow" and the "right side of the mobile". A second interesting element is that this discursive intertwining is also marked by several saming narratives. Some of them are explicit, such as "the arrow below represents the right side of the mobile" [11], others implicit in the students' discourse, as "if the triangle is two…because we moved *x* onto two" [1-3] where the object whose value is two is, in the same narrative, the triangle and the red arrow. Another saming between the triangle and the red arrow features in students' discourse through the use of the term *x*. It is introduced autonomously by the students to refer both to the red arrow ("we moved *x* onto two", [3]) and to the triangle ("*x* is the triangle" [17]). In other words, the term *x* allows the students to refer to the 'same object' that the triangle and the red arrow realize. Finally, as we can see in the last part of the excerpt, the students exploit the result of their saming processes to describe in a condensed way the DEO's behavior. In turns [21] and [23] their discourse is about the relationships between two algebraic expressions of the variable *x* and it could refer, simultaneously, to the mobile and to the arrows. In other terms, these narratives form a discourse which subsumes the two previous discourses. Evidence of this subsuming discourse is also shown in the written inscription they produced at the

end, in which separate descriptions of what happens to the mobile and the arrows are provided for the equality, but then, only symbolic notation with x and Δ is employed for the other cases.

Episode 2

During the 5th session, Aldo and Giulio were given a DEO similar to the previous one, with the difference that the two sides of the mobile are realized by algebraic expressions, depending on x, within blue and grey boxes (Figure 3). These ones can be defined by means of an input field on the top right of the screen. The same expressions also define the length of the two arrows on the right. As in the DEO of the previous episode, all the objects move accordingly when the red tick mark is dragged. The task situation was: "Insert expressions so that: One tick mark indicates 'x+5'; The other tick mark indicates '$2x$+1'. What do you think will happen when dragging the red tick mark?"



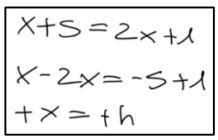


Figure 3: Screenshot of the DEO involved in episode 2

The following excerpt starts after the students have inserted in the input fields the two given expressions and before they could drag the red arrow to interact with the DEO.

1	Giulio:	To find out the point where they are balanced, we could find the x … and we could solve it like an equation *[writes 'x+5=2x+1']*
[The tutor asks Giulio to explain what he meant]		
4	Giulio:	I mean, to find out x that would be the value for which the tick marks meet and so the mobile stays balanced we could make an equation
5	Tutor:	Ok. How do you write this equation?
6	Giulio:	x plus five equals two x plus one, that would be when the mobile is balanced
7	Giulio:	*[solves the equation, see Figure to the right]* So x would be four
8	Tutor:	Ok, please repeat me, we wrote an equation, why Aldo?
9	Aldo	Because, I mean, we wrote this equation as if these two numbers, that is, if these two…if these two parts were balanced and then we did, I mean, we found how much an x is worth
10	Tutor	Ok, how much an x is worth…
11	Aldo	I mean, how much the unknown is worth, that is, this is x, I mean, this x is the one that makes both of them balanced, it makes the mobile balanced

Giulio focuses immediately his prediction on the equality between the two expressions. He writes and solves an equation to determine the value of x, which he uses for expressing "the value for which the tick marks meet and so the mobile stays balanced" ([4]). Here we have an instance of saming that is made explicit by the term "so". Moreover, this approach, relying on the use of algebraic discourse, reflects the student's attempt to integrate the discourse about the mobile and the one about the arrows. Similar to the previous episode, the algebraic discourse, now in the form of an equation, subsumes the other discourses. In turn [9], Aldo articulates his narrative about equations and the procedure of solving equation. He explains that we write the equation as if the system was balanced, and then find

the value of *x* that satisfies this specific state, that he addresses with the term "unknown" ([11]). The students' discourse about the equation, on the one hand encompasses the different algebraic expressions as realizations of DEO's objects, and the equality as a realization of the balancing and alignment states. Moreover, it also includes a saming between the number '4' in the inscription for the last step of the resolution procedure ('*x*=4') and the value of the unknown for which balance is assured, offering in this way a realization for the object 'solution of an equation'.

Discussion and conclusions

The story of Aldo and Giulio offered an example of how well-designed DEOs can foster students' participation in algebraic discourse. This general result confirms other studies claiming on how working exploratively with multiple realizations of algebraic signifiers can be an effective entry point into algebraic discourse for students in respect to the memorization of procedures which often are only treated as symbols on the paper without realizations (e.g., Baccaglini-Frank, 2021). More specifically, this study highlighted how our activities, designed to offer simultaneously multiple realizations, as the mobile and the arrows, can promote students' development of an algebraic discourse subsuming multiple discourse. The conducted analysis on the realizations addressed in the students' discourse and on their saming narratives allowed us to highlight something more, which is *how* this algebraic discourse could feature during the activity. It emerged that Aldo and Giulio's discourse was characterized by a rich intertwining of different narratives, some of them referring to one realization (the mobile or the arrows) and some others referring simultaneously to them both. In this latter case, it happened that students blended terms referring to the mobile with terms referring to the arrows (e.g., "the right arrow" of episode 1), they translated narratives about the mobile into narratives about the arrows, or they produce meta-discourse on the relations about mobile and arrows (e.g., [11] of episode 1). This intertwining characterized students' saming processes. For instance, Aldo and Giulio started referring to the triangle and the red arrow, or one side of the mobile and one arrow, as being the same thing. Note how the saming did not only include objects (referred by nouns and symbols), but also the operations involved (referred by verbs). Indeed, moving the red arrow corresponded to giving a weight to the triangle, and this action would have its counterpart in algebraic discourse in assigning a value to *x.* As a result of these saming processes, algebraic objects appeared in students' discourse (e.g., *x*) providing the protagonists for a subsuming discourse. Moreover, as we saw in the episode 2, the emergence of an algebraic discourse as a form of subsuming allowed students to give meaning to the outcome of the memorized procedure for solving equations. In the analysis we observed that a saming occurred between the number 4 in the inscription '*x*=4' and the value of the "unknown" for which the mobile would stay balanced (and the arrows would be aligned). In this way, the DEO offered also realizations for the object "solution of an equation", that in Aldo's and Giulio's initial interview was just the end of the procedure.

In conclusion, the story of Aldo and Giulio offers valuable insights for both research and educational practice. Specifically, it contributes to the literature on challenges related to the letter-symbolic representation of equations and inequalities (e.g., Carpenter et al., 2005; Kieran, 2022). It underscores the importance of designing didactical approaches aimed at fostering students' learning to talk about multiple DEOs as realizing the same signifier. In this way, it offers thought-provoking perspectives for educators, who often focus their efforts on procedural approaches to solving equations. Shifting

the emphasis toward fostering familiarity with multiple realizations and the connections between these and memorized procedures could open new doors for students into algebraic discourse.

Conceptions of converting units of measurement of length and mass: Two case studies

Tanja Lobnig[1,2]

[1]University College of Teacher Education Carinthia, Klagenfurt, Austria;
tanja.lobnig@ph-kaernten.ac.at

[2]University of Klagenfurt, Klagenfurt, Austria

The present study deals with students' conceptions of conversion of units of measurement. The study examines the existing literature and focuses on two cases of fourth-grade students in Austrian primary schools: the approaches of David, who employs a procedural method for the majority of the time, and Luca, who uses the conception of refining and coarsening units to explain unit conversions. This study is part of an ongoing dissertation project, which is designed as an exploratory study and uses semi-structured one-to-one interviews. The findings confirm that the conceptions outlined in the literature are observable in students' approaches to unit conversion.

Keywords: Conversion of units of measurement, units of length and mass, basic ideas, conceptions, internal representations.

Introduction and theoretical background

Measures is one of the four formulated mathematical areas of competence outlined in the Austrian primary school curriculum "Lehrpläne der Volksschule und der Sonderschulen" (2024) and is regarded as one of the most challenging topics in primary school mathematics (Nührenbörger, 2002). Some studies (e.g., Programme for International Student Assessment) also deal with students' and teachers' individual conceptions of measures in general (e.g., Hagena, 2019) as well as with mathematical competences for measures which also include the topic of converting units of measurement. The conversion of units of measurement is a particular challenge for students (e.g., Lassnitzer & Gaidoschik, 2019). And yet, an understanding of unit conversion is an important basis for solving application tasks in STEM subjects.

A way to conceptualise understanding of a mathematical concept is inferring and describing the internal representations that students develop (Goldin & Shteingold, 2001). These internal representations, also referred to as mental representations (e.g., Kosslyn, 1980) or conceptions (e.g., Piaget, 1954), take various forms, including verbal/syntactic, imagistic, formal notational, strategic and heuristic representations (Goldin & Shteingold, 2001). Since these mental representations cannot be observed directly, they must be inferred by interpreting students' externally expressed and produced representations (Goldin & Shteingold, 2001). However, these external representations may not perfectly align with the internal conceptions of a person (Mainali, 2021). It is important to note that conceptions can be either consciously or unconsciously effective (vom Hofe & Roth, 2023), and since only conscious processes are accessible for verbalization (Jääskeläinen, 2010), it may be difficult for students to articulate them (Goldin & Shteingold, 2001). The term "representations" is often intended to include both external formats and internal cognitive structures (Mainali, 2021). In

this paper, “mental representations” are referred to as “conceptions”, while “external representations” are simply termed “representations”.

Research on students’ conceptions has a long tradition in several countries, which has led to the development of different notions to describe conceptions. For example, Tall and Vinner (1981) developed the theoretical constructs of *concept image* and *concept definition*, where a concept image includes all cognitive structures associated with a given concept. This includes all mental representations, as well as related properties and processes. In German-speaking mathematics education, the term conception is primarily used within the theoretical construct of *basic ideas* (in German: *Grundvorstellungen*). In their work, vom Hofe and Blum distinguish two main types of conceptions: individual conceptions, which provide information about student’s “individual images and explanatory models” (vom Hofe & Blum, 2016, p. 232), and adequate mathematical conceptions called “basic ideas”, which enable students to achieve “adequate conceptual understanding” (vom Hofe & Blum, 2016, p. 231). These basic ideas interpret a context or its mathematical core in typical applications or diagrammatic representations. An example from primary school mathematics is the addition of natural numbers. Several different basic ideas can be associated with this operation, each corresponding to a different application. For instance, in one situation, an initial amount is increased by a further amount resulting in a new total, as when a child has €3 and is given €4 more (vom Hofe & Roth, 2023). In another, two separate amounts are considered together without any change and the question is how much they have in total, for example, when one child has €3 and another has €4 (vom Hofe & Roth, 2023). Each of these typical applications highlights a particular way of interpreting addition. Developing such basic ideas becomes a goal of teaching and learning mathematics. The first step is to consider which basic ideas are useful for teaching certain content or procedures, followed by the development of suitable learning contexts that activate the learners' prior knowledge and lead them to the new content (vom Hofe & Roth, 2023). In this way, learners can grasp the learning context, build up basic ideas and, after appropriate practice and application phases, understand the term or procedure (vom Hofe & Roth, 2023). In short, “basic ideas […] describe relationships between mathematical structures, individual-psychological processes, and subject-related contexts” (vom Hofe & Blum, 2016, p. 231).

For the conversion of units of measurement, there are only a few suggestions for conceptions or basic ideas. For example, Franke and Ruwisch (2010) describe the conversion of units of measurement as refining and coarsening units of measurement. In the metric system, units of measurement can be refined or coarsened simply by multiplying and dividing by a power of ten. To help children understand the relationships between the units of measurement, Franke and Ruwisch (2019) recommend demonstrating these relationships with concrete objects. To exemplify this, they describe the refining a unit of measurement using a one-meter strip of paper that can be divided into centimetres. To demonstrate the coarsening of a unit, they suggest, as an example, walking one kilometre and marking each meter with chalk.

Gaidoschik (2024) writes that if you know the relations between the units, unit conversion can become a kind of algorithm that you have to follow. For example, for metric units of measurement, it is only necessary to shift digits within the metric place value table. Moreover, he states that such an algorithm for unit conversion is easy to understand if you have an adequate basic idea of how to

convert. Gaidoschik (2024) suggests the idea of "measuring the same size twice" as a basic idea for the conversion of units of measurement, finally represented as an equation. In this case, the left side of the equation represents the result of a measurement in the first unit, while the right side represents the result of a second measurement in the second unit. He exemplifies this with the task 5000 cm = ___ m. The conception that to the left of the equals sign is the result of measuring a length in centimetres, and to the right is the result of measuring the same length in meters, would be helpful in solving this task.

Both Franke and Ruwisch's as well as Gaidoschik's suggestions describe possible adequate conceptions for converting units of measurement into smaller or larger units. However, the theories to conceptions mentioned above not only consider adequate conceptions, but also emphasize the importance of considering learner's individual conceptions.

Research question

This paper focus on whether the two theory-based suggestions for adequate conceptions "refining and coarsening" and "measuring twice" are recognizable in unit conversions of students. In more detail, the study reported on in this paper intend to address the following research question: Which of the two theory-based conceptions for unit conversion "refining and coarsening" and "measuring twice" can be identified in the unit conversion approaches for length and mass of two fourth-grade students?

My research focuses on the measures of length and mass due to their common metric structure. Of the six relevant measurement domains in the primary school curriculum in Austria, time is not structured metrically, area is a derived quantity, money requires consideration of decimal notation, and capacity includes only the two units l and ml that are relevant at the primary level. Consequently, for the investigation of unit conversion, the metric-based measurement domains of length and mass offer an appropriate basis.

Methods

The two cases presented are part of an ongoing doctoral project, in which I study the conceptions that children demonstrate when converting units of measurement length and mass. The research is designed as an exploratory study, as this topic has not yet been sufficiently investigated in German- and English-speaking countries. Children's conceptions are collected using an identical set of tasks in semi-structured (Roulston & Choi, 2018) one-to-one interviews. An interview guide is used in the interviews. It was piloted with 15 third-grade students in January and February 2024 to identify the setting (individual, pair or group interview), types of tasks, questions and wording that best support children in expressing their conceptions of unit conversion. To date, 34 primary school children in the fourth grade from six different classes in three different schools in Austria have been interviewed by me. Fourth grade was selected as the target group because, by the end of third grade, students in Austria are typically introduced to all relevant units of length and mass covered in primary school curriculum. The interviews took place in May and June 2024. The plan is to conduct further interviews in the 2024/25 school year. The cases are selected using the theoretical sampling method (Schreier, 2018). Case selection is ended as soon as no new insights can be gained from the interviews

and data saturation is reached (Schwandt, 2007), meaning that the same conceptions are repeatedly observed without offering additional perspectives.

During the semi-structured one-to-one interviews, each lasting about half an hour, students are encouraged to think aloud to identify their underlying conceptions. Before the interview begins, students are informed that the interview is not a test, that there are no right or wrong answers, and that sharing their thoughts through speaking, writing, drawing, or acting is helpful. The interviewer uses gentle prompts (e.g., "What are you thinking now?") and positive reinforcement to support students' efforts to express their thoughts. Paper and pencils are provided for notetaking, drawing, and calculations. One task also provides materials as measuring devices, e.g. measuring tapes of different length, rulers, a beam scale and a digital scale with various weights. This allows students to express their conceptions in spoken words, enactively, iconically, or symbolically. The interviewer listens carefully and asks non-suggestive questions, such as: How do you know that? How do you imagine it? What do you think about…? and Why…? to explore the student' conceptions and understanding of unit conversion. It should be noted that, since only conscious processes can be verbalized (Jääskeläinen, 2010), identifying children's conceptions is challenging, as they often struggle to articulate them. As a result, interviews often provide only fragmented explanations, making it difficult to formulate definitive conclusions about students' conceptions of unit conversion.

At the beginning, the interview tasks for primary school children are very open to ensure minimal influence on the children. For instance, they are simply asked: "What do you understand by converting units of measurement?". As the interview progresses, the tasks become successively more specific. The following are examples of such tasks:

- Solving specific conversion tasks, such as: The interviewer shows the card "7000 cm" and asks how many meters that is.
- Providing explanations for younger children: The interviewer asks how the student would explain to a younger child what converting means.
- Answering questions like "Is it true that 9 mm is the same as 9 000 meters?".

The aim of these tasks is to give children lots of opportunities to formulate their thoughts and to talk about their conceptions of the topic. At the end of the interviews, stimulus materials such as scales and measuring tapes are provided to give children further reasons to talk and act.

The data collected through the interviews consists of verbal statements as well as notes, drawings, and activities with measuring devices. To capture both verbal expressions and non-verbal actions, the interviews are videotaped. The resulting data are then transcribed (in the case of spoken language), interpreted, analysed, coded, and thematically categorized using qualitative content analysis according to Kuckartz (2019). In the context of this study, as a first step, the interviews are coded with two theory-based categories for conceptions of unit conversion: "refining and coarsening" and "measuring twice".

These two students were selected because in some parts of the interview the two adequate conceptions for unit conversion proposed in the literature, "refining and coarsening" and "measuring twice", were recognizable.

Case 1: David

The interviewer tries to find out about David's conceptions about converting units of measurement.

In the first phase of the interview:

Interviewer: What do you understand by converting?
David: […] I always just imagine the table, for both measurements.

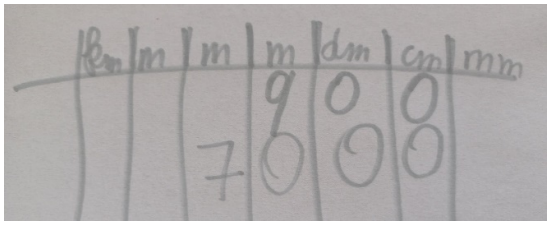

Figure 1: metric place value table for conversion

For most of the interview, David uses the metric place value table as his primary tool for converting units of measurement. On rare occasions, he converts smaller units to larger units by simply deleting zeros. It seems that David understands unit conversion as a memorized procedure in which he fills in numbers in the table, moving either from left to right or right to left and filling in zeros, depending on the task. For example:

David: I actually always have the table in my head and then I imagine it in front of me and then I just fill in the numbers.

Later:

Interviewer: […] If I say convert 7,000 centimetres into meters. How many meters is that?
David: Zero, zero, zero, seven. [David enters the number 0 in the columns cm, dm, m (right column) and the number 7 at m (middle column).]
Interviewer: How do you know? How did you decide where to start writing?
David: At the centimetres. […] Or because you enter in meters first. So, if you enter the meters, you start in kilometres – meters, where the number is and then go to the back. If I also have a number to convert to the front, I go from the back to the front.

Or later with another example:

David: I simply entered the 800 next to the meters in the "How many centimetres are 800 meters?" and then just dragged the zeros backward to the centimetres.

As already mentioned, most of the time he uses a fixed plan, like an algorithm for converting units of measurement without formulating any other conceptions. Once there was an approach to the idea of "refining and coarsening" referring to the gram as a "part" of a kilogram:

Interviewer: Exactly, but how do you explain the gram, for example?
David: The gram? I, the gram is the least, so, underneath. You can just say a part.

Similarly, an approach to the conception "measuring twice" was recognizable one time:

David: If you had a measure, you would probably have to say, because if there were only grams: Please 60,000 grams of concrete bags or something. That's why it's easier with the units of measurement, just 600, 600, 60 kilograms of concrete, something like that.

In summary, David seems to successfully solve conversion tasks by using the same procedure most of the time, by filling in numbers in a metric place value conversion table, either mentally or on paper. His conception of unit conversion seems to be an algorithm, expressed by filling in numbers in the metric place value table. On two occasions, he mentions the conceptions for unit conversion "refining and coarsening" as well as "measuring twice" as described in the literature.

Case 2: Luca

Most of the time, Luca converts units by multiplying and dividing by a conversion factor:

Luca: How many kilometres are 30, 300,000, 300,000 meters? [The task 300,000 : 1,000 was solved before by long division. His result was 300.] I did 300,000. […] 300,000 divided by 100.
Interviewer: I see. You divided that now?
Luca: Divided by 1,000.

His explanations of unit conversions correspond to the conception of "refining and coarsening", especially the conception of "refining" units. He formulates it as "fitting" smaller units into larger ones. For example:

Luca: Converting is something like how many centimetres fit into one meter, for example.

About a minute later:

Interviewer: Okay. And how do you imagine it when you say you can fit 100 centimetres into one meter? How do you imagine that exactly?
Luca: Yes, I think, uh, uh, I think in such a way that I actually see a meter in front of me. And then I would mark the centimetres like this.

By referring to the concrete activity of marking smaller units within larger ones, his conception of unit conversion as "refining" units is emphasized.

When asked what exactly he understands by converting units of measurement, he explains it by describing how a kilogram on a beam scale weighs the same as 1,000 grams:

Luca: 1,000 grams just fit into one kilogram.
Interviewer: Okay. So, 1,000 grams and one kilogram.
Luca: Yes.
Interviewer: How do you imagine that again? [...]
Luca: I often imagine it with weights. One gram weight. One kilo weight. And yes, this is then, this is easier for me then when I…, I take 1,000 one-gram weights and then I take a kilo weight, on a scale or something.

Later in the interview, with a beam scale and weights of one kilogram, one dekagram, and one gram on the table, he actually shows what he explained earlier:

Luca: So, I have a scale [Luca takes the kilogram weight in his hand] and now, that's [Luca takes the gram weight in his hand] one gram. If I put a kilogram in there [Luca puts the kilogram weight in a bowl of the beam scale] [...] If I now put 1,000 of the little things, [Luca puts the gram-weight in the other bowl] then it's the same weight. We don't have 1,000 there now.

This explanation does not correspond to any of the theoretical conceptions discussed above. It does not involve refining or coarsening a unit, because the weight of a kilogram is not divided into smaller parts, nor does it involve measuring an object twice. Perhaps it can be interpreted as an extreme case

of the conception “measuring twice”, in which the weight of a kilogram can be considered as an object that is measured twice, once with a kilogram and once with 1,000 grams, or defined as a separate category.

In summary, Luca seems to have in mind the conception of “refining and coarsening” units when talking about unit conversion or solving conversion tasks. Also, his choice of presenting his way of solving these tasks by multiplying and dividing the measure by the conversion factor underlines his conception about unit conversion. In addition, he (mentally) refines concrete objects or uses measuring devices as a representation for unit conversion.

Conclusion

The conceptions “measuring twice” proposed by Gaidoschik (2024) and “refining and coarsening” proposed by Franke and Ruwisch (2020) are intended as instructional recommendations for teachers aiming to support students’ understanding of unit conversion. The cases of Luca and David show that some fourth-grade students in Austria have already developed such conceptions and are able to apply them effectively. David’s approach to unit conversion appears to be predominantly a memorized procedure, but the conception of “refining and coarsening” as well as the conception “measuring twice” were recognizable only one time each during the interview. In contrast, Luca seems to consequently use the conception of “refining and coarsening” units when converting units of measurement, which he expresses in various parts of the interview. The presence of these theoretically grounded conceptions in students’ successful strategies suggests that they have practical value for classroom teaching. However, the diversity of students’ conceptions also highlights the need for further research to identify and categorize additional conceptions beyond those described in this paper. The cases of David and Luca demonstrated that this is a challenge.

This study examines Audiofunctions (AF), a multimodal interactive digital artifact designed to represent graphs of real-valued functions of a real variable. AF displays function graphs and uses sonification to represent the coordinates of a moving point as the independent variable changes. The paper discusses key theoretical considerations underlying the design of AF, related to a covariational perspective on functions and function graphs. Using a commognitive perspective, it analyses the case of an adult blind user, an expert in mathematics, in interaction with AF. The study investigates the narratives she produces, the function realizations involved other than the auditory one, and how they are related to the function characteristics, providing insights into the potential impact of AF.

Keywords: Function graphs, multimodality, inclusion, covariation, visual impairments.

Introduction

The notion of inclusive education, aimed at providing high-quality education for all students, regardless of disabilities, gained attention in last decades (e.g., Ainscow, 1997). Nevertheless, ensuring the right to education for all faces persistent challenges, such as improving accessibility of materials and content. Despite advancement of assistive technologies, while accessible formats such as haptic or audio options are available for digital textual content (e.g., braille display – a device translating text written on screen in Braille characters accessible to user by touch – or screen readers), there is still research going on to find a general solution for accessible graphs and formulas (e.g., Shahira & Lijiya, 2021). Moreover, a lack of educational research on use of these tools remains, even if some studies showed that using sonification for teaching-learning spatial concepts seems promising (e.g., Damsma, 2024). This paper focuses on the issue of ensuring sustainable accessibility for function, a fundamental concept in scientific education. In functions teaching-learning, interpreting information embodied in function graphs or, conversely, using available information about an assigned function to graph it, is a crucial competence (e.g., Baccaglini-Frank et al., 2023). Access to function graphs' information is essential for understanding functional relationship between dependent and independent variables, but function graphs pose accessibility challenges due to their graphical nature. In this context, Laboratory "S. Polin" of the University of Turin is developing since 2014, and now with the Erasmus+ project "Sonairgraphs", a software solution called *Audiofunctions* (AF), publicly available since 2019 as a web-based application designed to generate accessible single-variable function graphs through use of sound (https://audiofunctions.netlify.app/). In these graphs, at visual level, the cartesian function graph is displayed, with a bullet point moving on it depending on the position of its coordinates; at auditory level, a sound is produced whose characteristics depend on the position of the bullet point on screen (e.g., move mouse pointer wearing headphones to hear *f(x)=sinx*, linked at: https://linkshort.accesee.it/sinx). Therefore, sonification in AF allows visually impaired students to access functions by "discovering" gradually their behaviour through sound.

Next to accessibility issue, literature underscores learning difficulties encountered by students, with or without impairments, in making sense of function graphs. Antonini et al. (2019) emphasise that in literature students show fewer difficulties when they deal with "numerical evaluation or prescribed algebraic manipulation, but they tend to encounter difficulties in analysing or even describing a function's behaviour by looking at its Cartesian graph" (p. 2). Function graphs are often perceived by students as static representations "in which the variations, and the relation between variations – *covariation* – related to functional dependency remain hidden" (Antonini et al., 2019, p. 2, our emphasis). In this paper, we address the ability to envision the relationship between simultaneous variation of values of independent and dependent variables. Prior research (e.g., Thompson & Carlson, 2017) highlighted that covariational perspective on quantities dependence was characteristic of first conceptualisations of function in mathematics' history, even if it was subsequently abandoned. However, Thompson and Carlson (2017) argue that "continuous variation and covariation seem to be epistemologically necessary for students and teachers to develop robust conceptions of functions" (p. 35). In other words, familiarising students with function graphs alone does not guarantee covariational reasoning skills' development, essential for understanding function concept. While ensuring access to this content for all students is critical, it may not be sufficient to foster meaningful learning. It could be worth studying whether AF can be exploited not only as a tool for ensuring accessibility, but as a tool to support development of covariational reasoning for *all students*, since its sonification offers a dynamic but temporally sequential mode of access to function graphs (see Audiofunctions' design paragraph). For sighted students, this dynamic representation contrasts with the static, comprehensive, visual graph. Sound dynamism is replicated at visual level through bullet point's movement, allowing to see the visual graph as a dynamic time-related evolving trajectory. This would make AF suitable for designing inclusive learning activities.

Theoretical Framework

We take a *commognitive* perspective (Sfard, 2008) consistent with previous studies on interaction with digital artefacts investigating development of meaningful narratives in the context of functions and variables (e.g., Baccaglini-Frank, 2021; Antonini et al., 2019). In this perspective, the term "discourse" is intended as a form of communication characterized by specific features, among which we find specialised vocabulary (e.g., terms used to name mathematical objects, as "function") and unique *visual mediators* (such as numerals, symbols, or graphs). Constructing mathematical objects involves a *saming* process, i.e. naming seemingly unrelated things that are seen as equivalent in certain contexts (e.g., "linear function" can refer to *"3x"*, a straight line, or a table of paired couples of numbers). These things become different *realizations* of the same mathematical object. A mathematical object is thus to be understood as a purely discursive object that, in a given discourse, is constituted by the set of its realisations. We emphasize here that realizations of mathematical objects are defined by Sfard without specifying their perceptual nature (Maffia et al., 2023), hence potentially including also auditory mediators. "[Mathematical] discourses are made distinct […] by the form and outcomes of their processes, that is, the *routines* and *endorsed narratives* that they produce" (Sfard, 2008, p. 161). In mathematical discourse, experts "interpret most task-situations as requiring a (re)formulation and endorsement of a particular type of mathematical narrative" (Sfard, 2020, p. 96). "*Narrative* is any sequence of utterances framed as a description of objects, of relations between objects, or of processes with or by objects, that is subject to *endorsement* or rejection with

the help of discourse-specific substantiation procedures" (Sfard, 2008, p. 134). Baccaglini-Frank et al. (2023) discuss how experts talk about function behaviour starting from its graph, emphasizing their exploitation of a covariational perspective that enables them to make sense of the function beyond what they "just" perceive with sight. Different realizations of the same signifier in a discourse are related precisely thanks to discourse rules allowing the translation of endorsed narratives about a realisation into ones about the other. AF offers multiple realizations of the same function, involving visual mediators (algebraic expression, Cartesian graph) and an auditory mediator (sonification). The latter, covariational and dynamic, provides a unique representation for visually impaired users, who can integrate it with other, more common but usually non-dynamic, representations (e.g., tactile ones). In this paper, we want to focus on how a blind expert recognise AF' sonification as a realization of function. Then, we address the following research questions: What other realizations of the function are present in the expert's discourse dealing with AF? How does she translate her endorsed narrative on function into new narrative on sonification?

Audiofunctions' design

The first version of AF, *Audiofunctions.web*, was thoroughly investigated in technical aspects, usability, and accessibility (see Ahmetovic et al., 2019). Its sonification technique maps function related information to sound features: if we name $P=(x, f(x))$ the moving point, sonification conveys the current position of x mapping the range on x-axis from left to right with auditory *panning* (i.e. an x visually closer to the left graph bound is heard more by the left ear), and the value of $f(x)$ mapping the range on y-axis with sound *pitch* (the perceived sound frequency). Pitch is central to sonification, the human auditory system is sensitive to its variations (Dubus & Bresin, 2013). In this way, exploring function from left to right, users can "hear" the displayed portion of graph as the covariation of sound panning and pitch. Originally emerging as a tablet application, the prototype of Audiofunctions.web (Bernareggi, et al., 2016) underwent evaluation by comparing the interaction experience of blind users with respect to their accustomed use of tactile drawings.

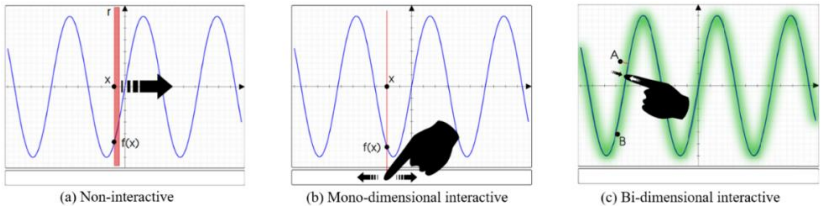

Figure 1. Function exploration modes (Bernareggi et al., 2016, p. 8)

Users freely engaged with three available interaction modes (see Figure 1a,b,c respectively): *non-interactive mode*, where pressing "b" key the software sonifies automatically the entire function, varying x from left graph bound to right one; *mono-dimensional interactive mode*, where, in a dynamic exploration, sonification is reproduced as users move with keyboard arrows or slide the pointer along a horizontal line; *bi-dimensional interactive mode*, where spatial relationships can be grasped by difference in volume since that the highest volume occurs on function line. Bernareggi et al. (2016) indicate Audiofunctions.web as more efficient in terms of response time compared to tactile methods. This highlights the software as a valuable tool for enhancing information accessibility. AF is the latest version developed to specifically facilitate its educational implementation. Among other enhancements, AF implements two distinct types of sonification: *continuous sonification* with clarinet and sine wave timbres, and *discrete sonification* with guitar timbre. There are two key

differences between them: *pitch density* and *threshold passing*. Pitch density refers to the fact that in discrete sonification a predetermined number of notes is established *a priori*, then the displayed *y*-axis range is partitioned into a corresponding number of subintervals of equal width and each interval is then associated with a guitar musical note. In continuous sonification, instead, the notes are distributed continuously along the displayed *y*-axis range. The threshold passing is a sonification strategy that leverages the lower pitch density in the discrete sonification: instead of sonifying a value on the *y*-axis (as in continuous sonification), it sonifies the threshold passing from one of the subintervals on the *y*-axis to another. The *x*-axis is also discretised into subintervals $[x_1, x_2]$, … , $[x_{n-1}, x_n]$, with each position x_i mapped to the note of the *y*-axis subinterval where $f(x_i)$ falls. However, if x_i and x_j are two subsequent positions sonified by AF with guitar, j is the first index greater than i where the note associated to the subinterval containing $f(x_j)$ differs from that of $f(x_i)$. Therefore, users hear a pause between two successively produced notes, since all the x_t comprised between x_i and x_j do not give place to any sound by AF. AF' design is grounded in explicit educational intentionalities, consistent with principles of a well-designed digital environment (Baccaglini-Frank, 2021). This approach, informed by literature on mathematical content sense-making, is crucial for ensuring that technology not only provides accessibility but also supports users in achieving autonomy and fosters cognitive engagement. AF' design in the continuous sonification mode is inspired by a strand of research by Italian researchers, focusing on the use of digital artifacts, called *dynagraphs*, where two ticks moving along one or two straight lines represent the independent and dependent variable (e.g., Baccaglini-Frank at al., 2023; Antonini & Lisarelli, 2021; Antonini et al., 2019). In many experiments the two ticks have a functional relationship unknown to users, who can act directly only upon the tick representing independent variable, thereby indirectly affecting the movement of the tick representing dependent variable. Baccaglini-Frank et al. (2023) emphasise this asymmetry in dragging ticks, arguing that it supports students' development of a covariational view of variables' functional dependency, that they later recognise in Cartesian function graphs. Antonini and Lisarelli (2021) discuss a task sequence, where Cartesian function graph is generated as trajectory of a point of coordinates $(x, f(x))$, dragging the tick representing *x*. Considering AF in mono-dimensional interactive mode (Figure 1b), AF mirrors aforementioned asymmetry between variables, since users can directly act on the independent variable, changing the moving point position, and thus enabling users to interpret function graph as trajectory of that point. AF differs from dynagraphs in the fact that trajectory is multisensorially rendered maintaining visible the static Cartesian representation.

Methods

To answer our question, we carried out some interviews with adults with visual impairments, experts in scientific disciplines, to collect data about their ways of interacting with AF when exploring different kinds of functions. Since our aim was to portray blind users' point of view, we opted for an exploratory approach and a case study design, similar to previous studies concerning blind solvers (e.g., Maffia et al., 2023; Miragliotta et al., 2023). Despite their familiarity with function concepts, participants were unaccustomed to AF ways to represent functions. In this paper, for reason of space, we examine the case of Miriam (pseudonym), a woman in her thirties who works as a business analyst and graduated with an honour degree in mathematics. She has been blind since birth and does not use speech synthesis but reads Braille. She knew that she was going to experiment a software for representing functions but did not know AF; she was used to their algebraic expression and to their

tactile graph. The interview was conducted through an online remote calling; the interviewer was the first author, who shared through the chat of the videocall platform links related to different functions already setted in AF, provided one-by-one during the conversation. For interacting with her computer, Miriam could use tools as screen reader, keyboard, or braille display. The interview was semi-structured: it involved a first phase where she was introduced to the software, and she was asked to freely explore AF setted with some non-standard functions. This was done to favour a focus on the description of the qualitative characteristics of the function behaviour rather than on an attempt to guess its algebraic formula. In a second phase, then, Miriam was asked to explore: different constant functions (e.g., *y=0* and *y=3);* linear functions with different slopes (e.g., *y=x+3*, $y=\frac{1}{2}(x+3)$, *y=−x+3)*; functions having similar behaviour with respect to some properties (e.g., $y=x^4$, $y=x^2$, that are decreasing for *x<0* and increasing for *x>0,* have a point of minimum for *x=0* and tend to infinity for *x* going to *+infinity* and *-infinity*); functions whose domain is not the whole set of real numbers (e.g., $y=\sqrt{x}$). The displayed *x*-axis and *y*-axis ranges for all the functions were pre-determined and set as follows: *-16<x<16*; *-9<y<9*. The choice of functions with similar behaviour was aimed at understanding aspects of sonification used by Miriam to distinguish similar functions from each other. The interview was recorded and transcribed. Accordingly with previous studies exploiting a commognitive perspective (e.g., Baccaglini-Frank, 2021), Miriams' discourse was analysed by looking for words related to different function realizations (e.g., algebraic, visuo-spatial, etc.) and their characteristics, and for words related to transitions between different kinds of realizations.

Data analysis

Miriam conducted the interview using the braille display to modify sound settings or switch functions, and using keyboard keys to explore function graphs. In Table 1 an excerpt is reported where Miriam explores graphs of the constant functions *f(x)=0*.

Table 1. Miriam considerations on *f(x)=0* graph (available at: https://linkshort.accesee.it/afy0; wearing headphones is recommended, and use "i" key to switch from discrete to continuous sonification and viceversa)

Line	What is said	What is done
1		**Miriam** presses the "b" key, and AF plays a single note with the guitar timbre while the red dot moves from left to right along the entire line [graph of the function *f(x)=0*].
2	**Miriam**: But how? Is it already over?	
3	**Interviewer**: Yes. I mean, it's not true that it's over, but it has a strange "thing" here; you should...	**Miriam**, acting on the settings slide bar, changes the timbre from guitar to clarinet.
4	**Miriam**: ...it's all at the same pitch.	**Miriam** presses the right arrow key several times. AF plays, for each key press and while the red dot moves step by step, the same note previously reproduced.
[...]		
11	**Miriam**: It's all a horizontal function.	
12	**Interviewer**: How did you figure it out?	
13	**Miriam**: The sound was always the same.	

The first interaction mode used by Miriam here is non-interactive, using the "b" key, with guitar timbre; she appears confused by what she hears ([2]), and decides to switch the timbre to the clarinet (continuous sonification). She needed the change in sonification to recognise that the pitch was constant ([4]), together with a change in the interaction mode, from non-interactive to mono-dimensional. Continuous sonification in a mono-dimensional interaction mode probably made her experience a multimodal interaction to analyse the function graph, involving her panning-related and

proprioceptive strategies using arrow keys to orientate herself on the graph along the *x*-axis, and her auditory perception of sound pitch. In fact, it's worth noting that Miriam's discourse passes from a narrative about the constant pitch she hears ([4]) – aspect of the auditory realization of $f(x)=0$ – to a narrative about function through an adjective pertaining to discourse on *spatial* level ("a horizontal function" in [11]). When asked why, she states again her perception of constant pitch (narrative about sound in [13]). Miriam's implicit association of the constant sound pitch (one dimensional) with the overall two dimensional shape of the cartesian graph of a class of functions means that she is interpreting pitch as dependent variable and left-right direction as independent variable. Moreover, she juxtaposes an adjective describing the cartesian graph at spatial level ("horizontal") with the signifier "functions", which indicates identification of the function with its graph, that becomes a spatial realization of the function for her. In Table 2 Miriam interacts with non-constant functions.

Table 2. Miriam considerations on the graphs of $f(x)=x+3$, $f(x)=\frac{1}{2}(x+3)$ and $f(x)=-x+3$ (available respectively at: https://linkshort.accesee.it/x3, https://linkshort.accesee.it/12x3, https://linkshort.accesee.it/3x)

Line	What is said	What is done
38	**Miriam**: This one is diagonal! Going upwards. It starts from the bottom and goes up to the top.	The $f(x)=x+3$ graph is displayed. The selected timbre is guitar. **Miriam** presses the "b" key. AF plays a complete scale of notes while the red dot moves from left to right along the line
39	**Interviewer**: Ok. Switch the function again so we can hear the next one, and then you can tell me about the differences.	
[...]		When the $f(x)=\frac{1}{2}(x+3)$ graph is displayed, **Miriam** presses the "b" key. AF plays a complete scale of notes, narrower than the previous one and with longer pauses between the notes, while the red dot moves along the line
44	**Miriam**: It has a lower slope.	
45	**Interviewer**: It has a lower slope. And can you tell me anything else?	**Miriam** plays the function with "b" again. And then she thinks for a while in silence.
46	**Miriam**: No.	
47	**Interviewer**: No. How do you perceive the difference in slope?	
48	**Miriam**: It's a slope that lasts longer. It rises less steeply.	
49	**Interviewer**: Ok. Switch the function again.	When $f(x)=-x+3$ graph is displayed, **Miriam** presses "b" key. AF plays the complete scale of notes sonified for function $f(x)=x+3$ but starting from the higher note to the lower one, while the red dot moves from left to right along the line
50	**Miriam**: It is a descending line. I mean [she seems to correct herself], with a negative slope ("coefficiente angolare" in Italian).	

Despite her return to non-interactive mode with guitar timbre, Miriam keeps speaking about what she hears using words pertaining to discourse on a spatial level (e.g., "diagonal", "upwards", "bottom", "top" in [38]). Miriam uses terms related to vertical dimension to describe sound behaviour ("upwards", "bottom", "top" in her narrative in [38]) but the overall function behaviour is summed in an adjective about two-dimensional space ("diagonal", in [38]). We interpret this as a sign that Miriam is relating pitch with some other variable, maybe time or left-right dimension. Moreover, the dynamic connotation of verbs such as "going upwards", "starts from... and goes up...", "rises", shows that she is associating the dynamic pitch changes with a trajectory on the plane – similarly to endorsed narratives of sighted experts reading static functions graphs (Baccaglini-Frank et al. 2023). In [48] she uses expressions related to time ("lasts longer") and speed ("rises less steeply"), that perhaps refer

to discrete sonification features: the shorter the pause between two successive sonified notes, and the further apart they are on scale, the steeper the function is. When she switches to $f(x)=-x+3$, she introduces the term "slope" ([44]), which pertains again to discourse on a two-dimensional space. In [50] Miriam passes to the formal Italian term for line slope, a shift that we interpret as a way to make her discourse more formal, since she is aware that she is talking to a mathematician. Therefore, we infer that probably here she is implicitly referring, for the first time, to algebraic function realization.

Discussion and conclusions

The interview with Miriam, expert in mathematics, confirms that AF emerges as a valuable tool, providing a comprehensive qualitative overview of functions' behaviour. Miriam seems to implicitly refer to functions realizations she was used to when she was a student: her recurring to words related to two-dimensional space seems to be connected to her knowledge of the cartesian function graphs – developed thanks to the use of tactile graphs. Talking about the function slope, she seems to implicitly refer also to the function algebraic expression. She passes mainly from auditory realization of AF to cartesian graph, in analysed extracts, often linking sonification with the overall two-dimensional shape of function graph, and describing both the sound behavior and the cartesian graph in terms of dynamic variations (e.g., in [38]), a fact that shows Miriam's mastery in covariationally reading the function and interpreting the variation of the sound pitch in dependence on time or on shifts in the left-right dimension. This recalls what is shown by the interviews with experts in Baccaglini-Frank et al. (2023) but in a reverse perspective: sighted experts can read the graph, a static image, as a dynamic trajectory of a moving point. Miriam, otherwise, is able to read a dynamic sound realization of function in AF as a two-dimensional visuo-spatial configuration, "synthesizing" overall sound behaviour. In this perspective, AF seems a potential tool for developing a covariational view of function graphs for students with and without visual impairments, since it allows to work on the connections between a dynamic, covariational function realization and a static synthetic realization. It should be clarified whether and how AF should be used combined with other function realizations, such as tactile graphs, for coordinating auditory mediators with visuo-spatial ones. There is more to understand about how people with visual impairments perceive haptic/auditory information, but Miriam's case suggests that, through AF, users can qualitatively grasp some function features, such as points on the graph where the function is higher compared to other points. Users can compare functions in terms of their growth or decline rates, leveraging the concept of speed of discrete sonification. Combined interaction of discrete and continuous sonification can offer users an initial embodied conceptualisation of derivative, through an auditory completion process when listening to two successive notes. Users can also grasp functions monotony, even if it may not be always easy to distinguish between functions with similar behaviours (about $y=x^4$, Miriam commented "It goes very fast […] at the beginning is at infinity then goes down for a moment and goes up and back to infinity […] But how do I know if it's a V, or if it's like a basin?"). Further studies are needed in this direction.

This paper presents a case study on how individuals with visual impairments interact with mathematical diagrams using NoVABOT, a dialogue-based system developed for the NoVAGraphS project. The study focuses on the experience of a blind participant navigating function diagrams represented as Euler-Venn sets. Through verbal interaction with NoVABOT, the participant explored key characteristics of the diagrams, demonstrating how the system can support the development of diagrammatic reasoning by guiding users through a process of inquiry and reflection. The findings illustrate how NoVABOT enables users with visual impairments to access and interpret graphical information, fostering deeper engagement with mathematical content. This case study highlights the potential of dialogue systems to bridge accessibility gaps in STEM education.

Keywords: Diagrams, functions, inclusion, visual impairments.

Introduction

In recent years, various assistive tools have been adopted by individuals with visual impairments, but these technologies have significant limitations in non-purely textual contexts, and they can restrict user autonomy (Bernareggi et al., 2016). Accessing structured graphical representations, such as tables, graphs and diagrams, presents particular challenges for at least three reasons. First, these images are designed to be perceived through the visual channel (Heller, 2002). Second, common non-visual representations, such as tactile drawings (e.g., Miragliotta et al., 2023), can be cumbersome and require expensive equipment, with overlapping tactile labels potentially reducing readability. Printed drawings lack interactivity, plastic sheets demand manual dexterity, and digital boards, while offering greater interactivity, still require fine motor skills and do not support permanent storage. Sonification approaches provide an alternative but face challenges, including the difficulty of transposing content into sound, the need for extensive training for non-spontaneous metaphoric content-sound association (Manolino et al., 2024), and cognitive demands when interpreting images through audio (Flowers, 2005). Third, creating effective non-visual representations of structured images requires an in-depth understanding of the domain and non-visual exploration techniques.

In the following section, we introduce a chatbot developed by a multidisciplinary team from different Departments (Computer Science, Mathematics, Physics, Social Education, and Economy) of the University of Turin, coordinated by the Research Laboratory for STEM Accessibility "S. Polin", as our proposed voice-based tool for individuals with visual impairments (Oliverio et al., 2024). This chatbot allows users to explore the Euler-Venn representation of mathematical functions through dialogue-driven interactions, enabling them to ask questions and receive responses from the software. Here is the provisional link to the tested prototype: https://delorean.di.unito.it/novagraph.

This paper shares insights from testing the chatbot with a blind participant with no prior experience using the tool. The results prompted several important reflections, particularly regarding mental representations, which were found to differ significantly from those of sighted users.

NoVAGraphS project

NoVAGraphS (Non-Visual Access to Graphical Structures – http://www.integr-abile.unito.it/en/progetto-novagraphs/) is an ongoing project devoted to the development of educational dialogue systems for users with visual impairments that specifically address the treatment of graphical structures. Scientific books frequently contain structured graphical information, such as tables and diagrams, which play a crucial role in conveying complex data and concepts. This project aims to establish standards through best practices and software solutions to enhance the interpretation and comprehension of structured graphical information, branching out into three main goals: (1) the study and the development of algorithms to convert graphical structures in dialogue scripts, which are prototypical dialogue fragments designed to communicate the information conveyed by the graphical structures; (2) the integration of these scripts in educational dialogue systems for users with visual impairments; (3) a comprehensive evaluation of these dialogue systems along different perspectives and disciplines. To fulfil the goals, the developer team designed a new dialogue system called NoVABOT. It is a web-based and accessible text-based dialogue system to which users with visual impairments can have access by using their own speech technologies, such as a screen reader and a keyboard. It is designed to understand and answer questions in Italian, in relation to three different topics: Euler-Venn function diagrams, electrical circuits, and finite state automata (https://delorean.di.unito.it/novagraph/tre_domini). These three topics were chosen as paradigmatic of the three scientific domains involved in the project: mathematics, physics and computer science. In particular, these topics are usually addressed precisely through diagrams: diagrams are both objects of study and tools or vehicles of knowledge. For relevance and conciseness, this contribution focuses on functions as a representative example. In this digital environment, NoVABOT engages in dialogues about functions on finite sets, represented through Euler-Venn diagrams. At this stage, several examples are available, with future plans to allow the software to "read" user-provided diagrams in input, e.g. through a photo. The user interface (see Figure 1) is designed with accessibility for users with visual impairments in mind. It is optimised for screen readers, featuring an input bar and a submit button directly beneath it. Responses to user queries appear below the button, and then a table displays the conversation history. This helps users to track and associate questions with answers. Webpage accessible navigation is simplified using HTML tags. The central feature of the interface will be an accessible and navigable SVG image, although this functionality is still under development. Currently, the image in focus is displayed on-screen but is not accessible (Figure 1).

NoVABOT is designed with a focus on inclusivity, featuring an interface that integrates both graphical and textual elements. This design choice aims to accommodate a diverse range of users with varying needs. For instance, the tool holds potential as a support for students with ADHD, benefiting from its visual aids and some colour-coded highlights of key elements of the function. Furthermore, the NoVABOT interface complies with the Web Content Accessibility Guidelines 2.1, ensuring comprehensive technical accessibility for users with visual impairments. The overall project design aims to enable them to access diagrams, fostering their development of diagrammatic thinking.

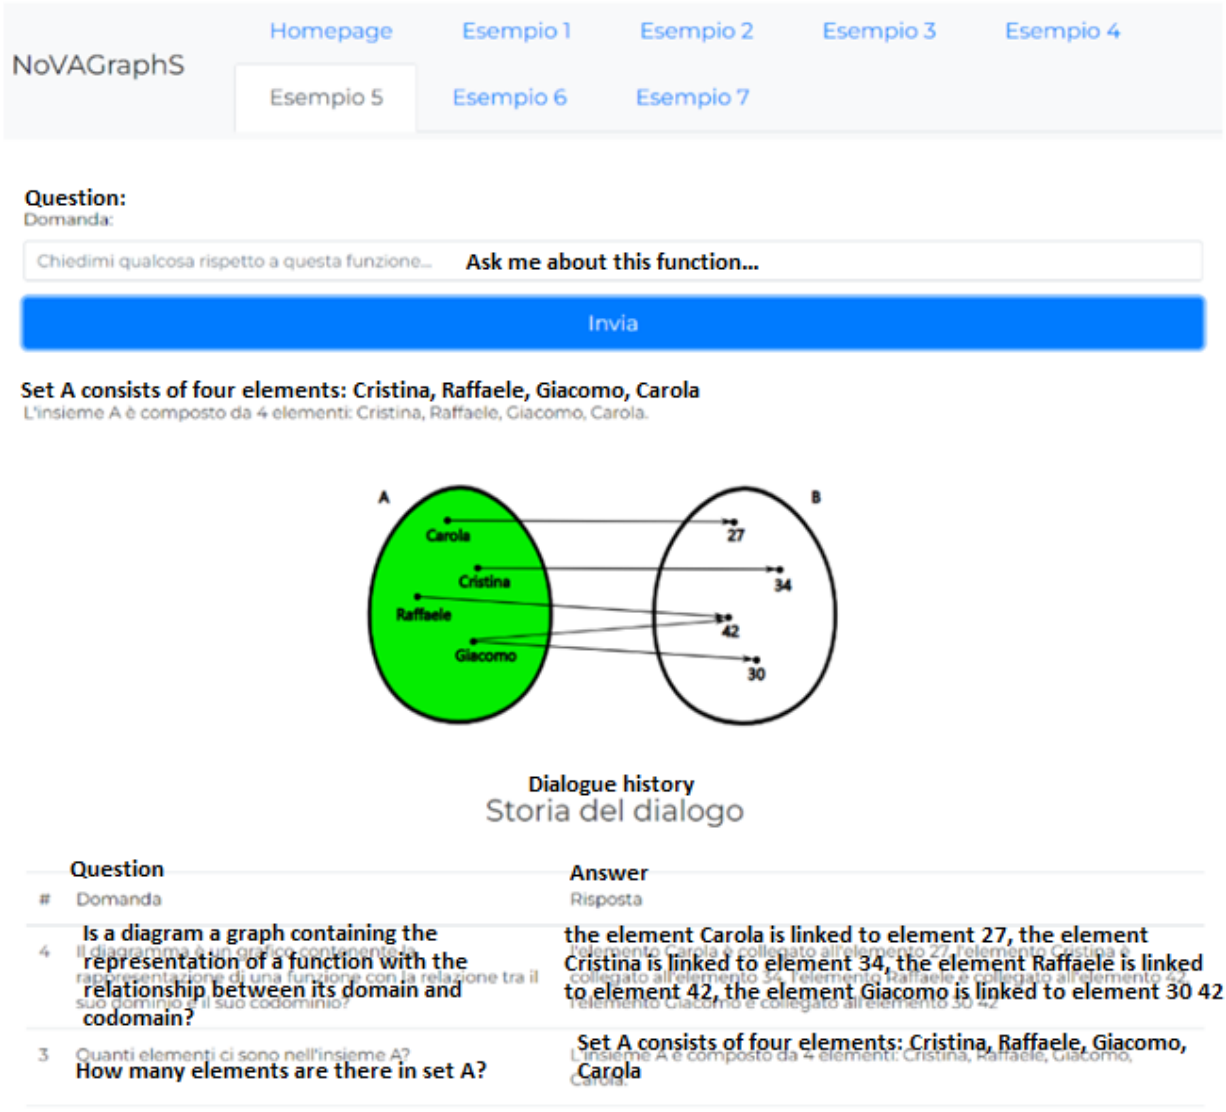

Figure 1. NoVAGraphS interface while exploring an example
[in bold authors' English translation of the texts on the screen, originally in Italian in grey]

Theoretical Framework

Charles Peirce suggests that much of mathematical thought involves observing or visualising results and patterns that emerge from manipulating various types of diagrams (Dörfler, 2005; Peirce, 1965). He defines a diagram as a sign "which is predominantly an icon of relations and is aided to be so by conventions. Indices are also more or less used" (Peirce, 1965, 4.418, 1903). Diagrams' key feature is their iconic nature, as they primarily serve to represent relationships (Bakker & Hoffmann, 2005). For Peirce, diagrammatic reasoning consists of three stages.

- The first stage is to construct diagram(s) using a representation system. This representation is required to show the relationships that are important in a given mathematical object or problem, and it can be done by different means, such as drawn sketches or software.

- The second stage is to experiment with the diagram(s). This experimentation must follow the rules of the specific representational system, so possible actions on a diagram are constrained. The important feature of this stage, as Bakker and Hoffman (2005) point out, is that thinking in general terms is not enough. The ability to observe is essential to act on the diagram.
- The third stage is to observe the results of experimenting and reflect on them.

Considering the concept of diagrammatic reasoning, our broader research aim is to investigate how it manifests in blind mathematics students, or more generally, in individuals with visual impairments when solving mathematical problems. In this paper, we specifically examine how NoVABOT can facilitate the exploration and interaction with diagrams. Consequently, our research question is: How does diagrammatic reasoning manifest in blind students or solvers through the use of NoVABOT?

Methods

We conducted task-based interviews with four blind users, letting them explore NoVABOT. We have used the three stages proposed by Peirce to analyse the process of diagrammatic reasoning of users. Regarding the first stage, "constructing a diagram", in this case, it was we who initially produced a diagram. That is, we prepared and uploaded to NoVABOT six different examples of functions between finite sets represented (graphically) via Euler-Venn diagrams. Given the embryonic nature of this study, we decided to provide the solvers with ready-made diagrams. However, the overall aim of the research project is to also examine, in future studies, the construction process by the users. In NoVABOT there is of course not only the graphical representation. The software implicitly knows the relationships between the different elements. It is therefore able to answer questions posed by users, e.g. about the domain and codomain elements, or the relationships between these elements.
In the first phase of the interviews, we let the users experiment and explore the diagrams in the different examples by asking them to identify characteristics they considered important of the mathematical objects explored. Subsequently, we asked them to reflect on the observed characteristics, to recognise which functions were injective, surjective, bijective, or which were not functions at all. This phase was followed by a meta-reflection moment in which respondents were asked to give feedback on the software and whether and how it can support users with visual impairments in exploring relationships between mathematical objects, where diagrammatic representations are particularly useful in highlighting such relationships, but are inaccessible to them.

In this paper, we present an excerpt from the task-based semi-structured interview, conducted through an online remote calling, with Antonio, a physics graduate who lost his sight six years ago due to a degenerative condition. He regularly uses his personal computer with the aid of speech synthesis. Since our aim is “to portray ‘what it is like’ to be in a particular situation, to catch the close up reality and ‘thick description’ [...] of participants’ lived experiences of [...] a situation” (Cohen et al., 2007, p. 182), to effectively capture the perspective of blind users, we chose an exploratory approach and utilised a case study design. This methodology parallels those used in previous research on expert blind solvers (e.g., Maffia et al., 2023; Miragliotta et al., 2023, Maffia et al., 2025). In particular the last part of the interview, comprising the interviewee’s meta-reflection on his own exploration, turns out to be particularly informative in the case of Antonio, as he is an expert solver of mathematics,

and not blind from birth therefore able to provide interesting comparisons between different forms of mental representation making use of images and not.

To construct diagram(s)

As mentioned, we prepared and uploaded six different examples of functions between finite sets to NoVABOT. Following the work of Martins et al. (2023), who studied 10th-grade students' functional thinking through their understanding of graphical representations of functions, we selected examples that illustrate functions with varying properties. For instance, Example 1 represents a function that is both injective and surjective, and thus bijective; Example 2 depicts a surjective but not injective function. Example 5 presents a relation that is not a function, as one element of the domain has two different images. These examples were carefully chosen to enable users to explore regularities in the relationships between elements and to distinguish the different properties of the explored functions.

Antonio's interview through the Diagrammatic Reasoning stages

To experiment with the diagram

At the beginning of the interview, Antonio is asked to explore NoVAGraphS interface. He observes several examples and chooses to examine Example 5. In this example (visible in Figure 1), as in the others, the diagram is presented alongside an overall description of the situation, which is read via a screen reader. The description states: "In the figure, there are two circles. Each circle contains some elements. Oriented arrows start from elements in the first circle (A) and point to elements in the second circle (B)". This description provides a preliminary overview of the diagram's notable features, as if it was a "first glance" at the diagram. Then, there is the area where the user can write and pose questions to the chatbot. Here is the initial interaction between Antonio and the chatbot.

Antonio: Is the diagram a graph containing a representation of a function with the relationship between its domain and its codomain?
Chatbot: Set B consists of 4 elements: 27,42,34, 30.
Antonio: In set A, how many elements are there?
Chatbot: In the first circle (in the domain) there are four elements: Cristina, Raffaele, Giacomo, Carola.
Antonio: How many arrows are there in the graph?
Chatbot: Forgive me, I didn't understand. Could you try rephrasing the question using keywords such as set, connected to, associated with, or naming some element of the sets?
Antonio: Describe how the elements of the two sets are connected, please.
Chatbot: The sets in our example are two. The first set, set A, called the domain in this case, consists of 4 elements: Cristina, Raffaele, Giacomo, Carola. The second set, set B, known as the codomain, on the other hand, is composed of 4 elements: 27, 42, 34, 30.
Antonio: Describe how the elements are connected.
Chatbot: Element Carola is connected to element 27, element Cristina is connected to element 34, element Raffaele is connected to element 42, element Giacomo is connected to element 30, 42.
Antonio: Giacomo to which element is related?
Chatbot: The element Giacomo of set A is connected to elements 30 and 42 of set B.

At this point, Antonio states that the situation is clear to him. One of the interviewers asks him whether he has therefore understood what is depicted in the diagram, or whether he needs to ask more questions. Antonio replies as follows.

Antonio: So, I have one doubt, though. As it's described, I imagine on one side the set A with the four names – Carola, Cristina, Raffaele, Giacomo, if I'm not mistaken –; on the other side I imagine the four numbers 27, 34, 30 and 42, with Carola connected to 27, Raffaele I think to 34, Cristina I don't remember…to 30 maybe, and Giacomo to 30 and 42. And I picture arrows starting from the names and going like in a direction to… from the set of names, from set A to set B. That is, I picture it in that way. So, the arrows with the arrow pointing from A to B.

Then, he is asked if he can say something more about the representation, considering the information he has gathered.

Antonio: But then, if that is the case, I would say that... I would have said initially that it could be a representation on one side of the names and on the other side of the age of these people. But having already like a two-element link, it's not the age. Which is not a biunivocal relationship, because anyway, it has more elements of the domain...To one element of the domain correspond more elements of the codomain, in the case of Giacomo. Yes, a little bit of this.

In the rest of the interview, Antonio explores additional examples of injective and non-injective, surjective and non-surjective functions. For each example, he is asked to express the properties he notices. For reasons of space, further sections of this interaction are not included here. Instead, we focus on the concluding part of the interview, where Antonio is asked to provide his feedback on the software's functionality and usefulness for a blind person.

To observe the results of experimenting and reflect on them

In response to the interviewer's question, Antonio shares his comments.

Antonio: In my opinion, the interaction with a conversational chatbot – so precisely that one, it has a memory of what has been said – is adequate for this kind of exploration of mathematically complex graphs, because it allows you to ask for information little by little, to mentally reconstructing... Generally, let's say, to mentally construct "the overall", what the whole diagram looks like. In my opinion, it's a good interaction system for the exploration of complex graphs. It's analytical, just like the exploration of the person who has a visual disability can be: analytical, rather than synthetic; later, you do the synthesis yourself, mentally. I'm doing that, though.

[...]

And as I said, for example, I knew before that there were two groups of two sets, connected with elements, and these elements connected with each other. In order to understand, to reconstruct how it was made, I asked at first "what are the elements in the set?", so that I could understand what was in one set, what was in another set, and mentally represent it to myself. Then, the second step, I asked about the connections, so how the elements were connected, in the way to add this information to what I already had in my head.

So I was analytical, in the sense that I proceeded piece by piece: first, the sets, then the elements within the sets, then the connections between the elements, and then mentally I made the synthesis of this information to try to construct by/for myself, precisely, this mental representation. That's it.

Discussion and conclusions

Antonio's reflection serves as a valuable starting point for analysing how he explores the graph and investigating a blind user's diagrammatic reasoning, in dealing with NoVABOT. He begins by examining the various components of the diagram. Knowing that there are two sets, he first seeks to understand their composition. Subsequently, he investigates the relationships between the elements

of these two sets. Observing that an element of set A corresponds to multiple elements of set B, he asks a specific question to confirm this observation. Only at this stage is he able to piece together the overall relationship, recognising that one element in the domain is associated with two elements in the codomain. Although his terminology is not entirely precise, Antonio concludes that the example does not represent a function. An interesting aspect of this deduction is the role played by the example's context. Though not explicitly stated, Antonio infers that the elements in the second set represent ages, and the relationship between the elements in the two sets is "Person is X years old". The fact that "Giacomo is 30 and 42 years old" leads Antonio to deduce that this cannot be a function, as one person cannot have two different ages. It is notable how this insight, which might not be immediately apparent visually, shifts the focus from the "content" of the elements to the presence of a link between domain and codomain elements.

In conclusion, interaction with NoVABOT facilitates targeted exploration. The user can analyse various aspects of the diagram according to their choice, combining the gathered information to understand the fundamental relationships. The software does not offer a generic description but requires the user to engage in analysis by asking specific questions. This process aligns with the intentional activity advocated by Bakker and Hoffmann (2005) in the exploration phase of diagrammatic reasoning. The limitations observed in this excerpt stem from the fact that the dialogue system does not fully capture or maintain the immediacy of the graphical content provided by the Euler-Venn representation of functions. Although NoVABOT does not manage to preserve the immediate visual impact of the diagram, it does sustain the diagrammatic reasoning and, most importantly, ensures user autonomy. Autonomy is a crucial aspect in the context of higher education. As reported for example in Bernareggi et al. (2016) and Piroi et al. (2023), blind students traditionally rely on human intermediaries to access and work with complex diagrams, such as those in focus within the NoVAGraphS project. NoVABOT represents indeed an innovative digital tool for fostering blind users' autonomous exploration of graphical mathematical representations. The benefits of this opportunity for autonomous exploration were highlighted by Antonio and the other participants interviewed in this study.

Further studies are needed to investigate the software usability and inclusive educational potentialities. At this stage of research and software development, some elements remain unstable: determining the extent of knowledge and interaction competence the software should possess to remain responsive without replacing the user's responsibility for knowledge construction; identifying the most appropriate vocabulary for the chatbot – whether it should adopt a neutral, descriptive register (circles, arrows, dots) or a content-related one (domain, image, counter-image); and understanding what can be lost or removed from such representations in order for them to be equally useful but accessible. Addressing these questions may require returning to foundational issues in mathematical epistemology, particularly the conceptual poles around which such representations are structured.

Precedents and explorative participation in mathematical discourse

Federica Poli[1,2] and Elena Macchioni[1]

[1] University of Pisa, Italy;

[2] University of Modena and Reggio Emilia, Italy; federica.poli@unimore.it

The paper examines the case of Carlo, a low-achieving student, who participated in a remedial intervention in which he worked with one- and two-dimensional representations of functions in a digital environment. Using a commognitive lens, we analyze two episodes involving task situations that an expert would recognize as similar, but that Carlo approached differently. Our broad aim is to explore how previously learned mathematics can interfere with remedial interventions, such as the one in focus.

Keywords: Digital environments, remedial intervention, commognition, inclusion, low-achievement.

Introduction

In Europe (OECD, 2023), one in three 15-year-old students struggles with basic mathematical proficiency. For instance, although functions are a cornerstone of mathematics learning, students often find it challenging to analyze or describe their behavior through Cartesian graphs, which are not static images but dynamic representations of relationships between variations (Antonini et al., 2020). Several studies (e.g., Baccaglini-Frank, 2021) highlight the potential of digital environments in supporting mathematics learning, providing immediate feedback, and fostering transitions between different representations of mathematical concepts. Moreover, Nachlieli and Tabach (2012), highlight the significance of learners recognizing different mathematical representations as equivalent. These characteristics also seem optimal in the context of remedial interventions.

The study presented is part of the larger research project, DynaMat, which focuses on designing and implementing remedial interventions for learning algebra and functions within digital environments. It targets 10th-grade students in Italy with a persistent history of low achievement in mathematics (for details: https://www.carme.center/progetto-dynamat/). Here we explore a student recalling prior mathematical experiences during a remedial intervention in a digital environment. Such a phenomenon, which we have not found described widely in the literature, seems rather frequent on others of our case studies within the DynaMat project, making the case under focus prototypical.

Theoretical Framework

We have chosen Commognition (Sfard, 2008) as our theoretical framework because it enables us to describe students' participation in terms of their actual possibilities and forms of participation rather than focusing on their deficits. Commognition indeed provides tools for a fine-grained analysis of students' discourse, emphasizing their gradual and continuous (or interrupted) participation in mathematical discourse. This approach prevents assumptions on what learners "can't do", overcoming the duality between "what the student has in their mind" and "what the student actually says." The goal is to better understand difficulties, moving away from a deficit perspective and instead embracing a participationist approach. In this paper, we will see how the proposed activities enabled a student with a long history of difficulties to engage in explorative participation and with agency

(episode 1). However, this participation can be hindered when previously learned mathematics interferes with the activity that the student is undertaking (episode 2).

In this paper we will use a specific subset of commognitive analytic tools.

Lavie and colleagues (2019) have distinguished between *task situation* (TS) - when someone feels bound to act (in school, the situation typically refers to assignments that teachers give students); and *task* - the student's interpretation of a *given task situation* relying on *precedent*, a situation similar enough to the current one to justify applying the same approach or actions. The process of identifying precedents relies on a preselection within a *precedent search space*, however, only certain elements will be selected as precedents for a specific TS. This selection occurs through *precedent identifiers* - specific features of the current TS that lead a person to recognize a past TS as a precedent. The same TS can lead to different precedent identifiers, resulting in different interpreted tasks for different students. The pair of interpreted task and procedure is called *routine*, which is a pattern of action. Routines will also be our unit of analysis.

A task situation that is recognized as familiar to one student may instead be unfamiliar to another. In this context, we refer to a TS as *familiar* when the student seems to recognize the TS as similar to one they have previously faced . In this case the student has identified a precedent identifier within the TS, allowing them to retrieve a precedent from their mathematical precedent search space. On the other hand, if the TS is *unfamiliar* - not recognized as familiar - the student does not seem to immediately recall any precedent.

In Commognition, a mathematical object is always a discursive object, defined as a *signifier* with all its *realizations* (Sfard, 2008). For instance, a Cartesian graph or an input-output table can be recognized by an expert as different realizations of the same signifier function. Instead, for students entering mathematical discourse on function, these are initially only *visual mediators* of their discourse. This may also be the case for many low-achieving or failing students.

When participation involves merely executing memorized procedures focused on process, it is defined as *ritualistic*. In contrast, *explorative participation* involves constructing meaningful narratives, focused on product. Explorative and ritualistic participation represent the extremes of a continuum, and a student's discourse typically falls somewhere between these extremes. Processes of de-ritualization, such as *substantiability* (the shift of attention from process to product) and *flexibility* (more procedures can be used to solve the same task situation), can help infer if participation is more ritualistic or explorative (Lavie et al, 2019). Moreover, regarding *agency*, students who participate exploratively are more likely to propose new actions or outcomes (Baccaglini-Frank, 2021).

Carlo is a 10th-grade student who joined the DynaMat project. His case captured our interest because of his seemingly different forms of participation in mathematical discourse across TSs on functions during the intervention. Specifically, his participation seemed to differ significantly in two TSs that seemed to be asking quite similar tasks according to the design of the activities (and therefore in the eyes of experts). These TSs are designed to be not immediately recognizable as tasks previously encountered at school and designed to be accessible, even without a specific procedure, therefore

unfamiliar. This paper aims to describe the apparent difference in participation between the two TSs in the light of commognitive constructs outlined in the theoretical framework.

Methods

Carlo participated to the second experimental cycle of DynaMat project between October 2023 and December 2023. All students joined the project voluntarily during the afternoon in the CARME research center. They initially participated in an individual interview, followed by five two-hour activity sessions with digital environments, conducted by a researcher team. The sequence of activities proposed to Carlo involved dynamic representations of functions, known as dynagraphs (Antonini et al., 2020). It begins with a one-dimensional representation of function, as two variables moving along parallel lines (Figure 1a), to promote awareness of covariation. The activities build up to the Cartesian graph by first rotating the line of the dependent variable by 90° relative to the line of the independent variable, so that the variations of the two variables are now perpendicular to each other (Figure 1b). Finally, perpendicular lines are drawn from each variable's position, creating intersections that define each point on the Cartesian graph as the variables change (Figure 1c).

These are the task situations we are going to analyze here:

TS1: The student is given a dynagraph with Cartesian axes and five different Cartesian graphs printed on paper; the tutor asks: "While dragging tick mark A, can you imagine the trajectory of the point (A, B) on the Cartesian plane? Which of the following graphs represents the trajectory of point (A, B)?".

TS2: The student is given a dynagraph with parallel lines, and the tutor asks: "Explore the file and draw below the corresponding graph in the Cartesian plane."

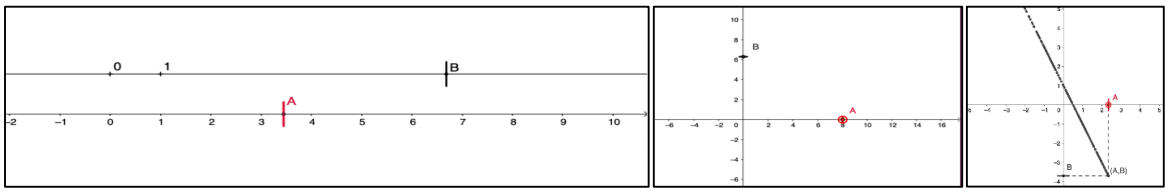

Figure 1: (a) dynagraph with parallel line, (b) dynagraph with Cartesian axes, (c) Cartesian Graph

Both TSs involve dynagraphs, which are usually not introduced in school, and Carlo, in the initial interview, states that he has only studied lines in the Cartesian plane. Moreover, none of the function realizations in these episodes (neither on paper nor in the dynagraph) are lines. For these reasons, we infer that the TSs presented unfamiliar tasks for him. In the TS design process it was essential for the researchers to share the same socio-cultural background as the students.

Both TSs aim to elicit discourse with transitions between multiple realizations of functions. The tutor tried to foster such discourse and she planned to introduce input-output tables. For example she would prompt Carlo by asking: "Could you use tables to write down some pairs of numbers that work?".

Carlo had access to a tablet displaying the dynagraph and to another one for writing or drawing. A tutor would pose the task situations, which could differ from the tasks interpreted by the student. We inferred Carlo's interpreted tasks by observing his procedure.

In the analyses below, both episodes (related to TS1 during session four and TS2 during session five) were transcribed with line numbering starting from 1. Between these two sessions, other activities were carried out.

Data analysis

Episode 1 – Carlo faced with TS1

The tutor reads TS1, which asks to envision the trajectory and identify the corresponding graph, between five different Cartesian graphs printed on paper (TS1). On the other hand, Carlo, after initially interacting with the dynagraph, immediately starts describing it. Thus, the task he interprets is to provide a verbal description of the movement of the tick marks.

3 Carlo: I see that, when I move into negative numbers with A, B rises very, very slowly [moves A to the left towards -∞], while when I lower it, it goes down a little faster [moves A towards zero, approaching from the left].
4 Tutor: Okay, so... when B goes down faster, I didn't understand.
5 Carlo: And then when A... when B goes down more, that is, when A keeps moving towards zero, B goes down faster. Then A, when it goes to 4, on the numbers, as the numbers increase [moves A around 5].

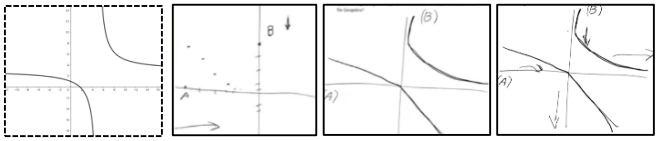

Figure 2: (a) selected Cartesian graph of TS1 ; (b) (c) (d) Carlo faced with TS1

Carlo spontaneously returns to the task situation (showing substantiability) and picks up the graphs chosen to answer the request [Figure 2a]. Now, is interpreted task seems to coincide with TS1.

19 Carlo: This [tracing the graph on the paper with a finger] is the movement of the dot, maybe of the intersection... like, okay, so if like, I don't know, A is here and goes this way, B is here and goes this way [draws the axes, inserts A and B, then the arrows in Figure 2b], this will gradually go like this, this, this, and like this, this, this. Then this goes down, like, I don't know, here, then here, then here, then here, and so on [inserts the ticks on the axes and the points].
20 Tutor: So these points you've drawn are the point (A, B)? The path it followed?
21 Carlo: And then when A reaches zero, B is below, so it forms something like this. This drawing, this is the line that A makes, no, wait. This is the line it makes.

In line 19 Carlo responds to the TS identifying the correct graph between the five different printed graphs, and he justifies his choice. First, he describes the movement of the point (A, B) by looking at the selected graph on paper, and then he starts plotting part of it on the Cartesian graph [Figure 2b]. This utterance shows both flexibility (as multiple procedures can be implemented to respond to the task situation) as well as substantiability (with the focus on the product, the selected graph). So, his participation is toward the explorative side of the spectrum. Then Carlo decides to return to the tablet and summarize his findings, showing agency. Carlo's interpreted task (line 29) seems to be to plot the movement of the point (A, B): he draws Figure 2c, confirming his initial choice (substantiability).

29 Carlo: [draws Figure 2c] It looks like the movement it makes. So this […] because when A increases… goes towards, that is, it grows because it goes towards zero, B decreases, as you can see. B goes this way and A goes this way [inserts the left arrows in Figure 2d]."

31 Carlo: Then when A, when A is in the positive range, B is also positive, and gradually as A moves away, going this way, B decreases [inserts the right arrows in Figure 2d]. Indeed, you can see that it goes lower and lower.

Initially, Carlo refers only to the movements of A and B, which he indicates with arrows in Figure 2b. Then, he makes a first attempt, even if discrete, to dynamically represent some of the positions reached by (A, B). Finally, thanks to the new dragging action, he manages to represent the trajectory as a static object that an expert would recognize as resembling the Cartesian graph of the function (it is not the graph of a function, but it closely approximates the trajectory of the graph shown in Figure 2a). All of Carlo's interpreted tasks are commensurable with those of the expert.

Episode 2 – Carlo faced with TS2

Initially, Carlo hesitated (line 5, "it's a bit difficult"), and the tutor, in accordance with the design, suggested introducing input-output tables as a further realization.

25 Tutor: Maybe it could help if you noted down some values where ticks pass through.

Line 25 changed the task interpreted by Carlo, who began solving the task in an unexpected way.

28 Carlo: Alright, I'll set it to 2.
29 Tutor: Okay, for example, when A is 2, B is on…?
30 Carlo: [He explores the dynagraph and marks the points (2;0) and (0;-2), then draws the ray from the origin passing through the point (2,-2) as shown in Figure 3a] How many points?
31 Tutor: Great, let's test it with other points, perhaps, to see how it behaves?
32 Carlo: At -8?

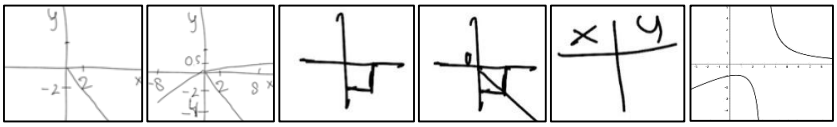

Figure 3: (a) (b) (c) (d) (e) Carlo faced with TS2; (f) expected Cartesian graph of TS2

Carlo marks -8 on the x-axis and -4 on the y-axis, then draws a ray from the origin to (-8, -4). He does the same for the point (8, 0.5), producing Figure 3b instead of the expected Cartesian graph (Figure 3f). The tutor tries to investigate his interpreted task:

37 Tutor: OK, so let's say what you drew what, what are these?
38 Carlo: Uh, various points, and I drew some lines
40 Carlo: All passing through zero
46 Carlo: [point (2;-2)] is an intersection
47 Tutor: Mmm, okay, so how do you find this intersection?
48 Carlo: By using these two numbers and drawing it like this [Figure 3c], you do something similar, and then this, being zero, makes a line like this [Figure 3d]
53 Tutor: Ok... Why did you draw the lines passing through the origin and that point?
54 Carlo: Because with a regular line… I didn't make a table like this x and y [Figure 3e], and I gave a value to x... I mean, I didn't have the equations; I just must look at the graph and take the values
55 Tutor: Okay, why do you make a table when you have the equations instead?
56 Carlo: Yes, I give a value to x, substitute it, that is, two values for x, two values for y, and it works out

By examining Carlo's implemented procedure, it appears that the interpreted task is related to plotting lines on a Cartesian graph, using an input-output table. Precedent identifiers that seem to elicit this

task are the tutor's request to "write down values" (line 25), the formulation of the tutor's question recalling the input-output procedure (line 29), and the tutor's suggestion to "test other points" (line 31). This inference is coherent with Carlo's mention of the input-output table in line 54 and Figure 3e. These precedent identifiers seem to trigger procedures that Carlo had previously memorized (at school), which he describes in detail, but that are not consistent with the TS proposed by the tutor. Since the very beginning, Carlo asks how many points he should consider (line 30) and whether starting with -8 is appropriate (line 32). In other words, he relies on the tutor to ask for validation of the procedure he is implementing. We interpret the tutor's question in line 53 as a request to explore the substantiability (using it to backtrack and address the task). Nonetheless, Carlo again goes through the procedure and compares it with another memorized one. The episode continues with Carlo plotting additional values on the graph and then exploring the behavior of the dynagraph near the vertical asymptote. At the end of the activity, the tutor explicitly asks him to clarify his use of the input-output table, and Carlo provides a detailed description:

99 Carlo: I put [the equation] in explicit form, so I write y equals and… then I change the value of x, perform the operation, and it gives me the result for y, and then with another value, it always gives me another result.

The tutor suggests giving an example for clarification, using the equation $y = x + 1$

105 Carlo: Like, for value 3, it becomes 4. Then another value is 4, and it becomes 5.

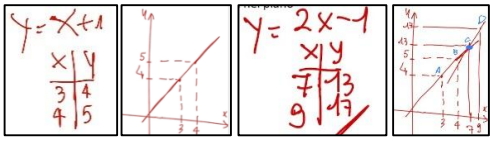

Figure 4: (a) (b) (c) (d) Carlo explains his procedure

Carlo writes Figure 4a and plots these points on a Cartesian plane [Figure 4b]. Then he asks the tutor for another equation to continue. The tutor suggests $\boldsymbol{y = 2x - 1}$.

113 Carlo: I put 7, so 7…13, and here 9,18, 17. So 7 and 9 and here [Figure 4c] 13, 17 [Figure 4d]. Uh, I do it like this, this would be like, so I need to connect these two points that are in the same table like this, and then find the common point they have, for example… this is the point they have in common.

Carlo's detailed description of the procedure allows us to infer that the task he interpreted might be about solving linear systems graphically. The procedure is described in lines 99-113 as a series of memorized steps, such as writing the line explicitly, substituting two x-values, finding the corresponding y-values etc. Carlo's focus is on the procedure itself, and hardly at all on its outcome - the point of intersection - which he mentions only once (line 113) when he repeats, upon the tutor's request, the procedure he had followed (lines 54 and 56). In line 55, the tutor's request is asking for substantiability; however Carlo's focus (line 56) remains on the procedure. So, the Carlo's participation in this TS is overall highly ritualistic.

Discussion

Carlo seems to perceive both tasks as unfamiliar with respect to what he was used to doing in school (where he certainly had never used a dynagraph). When facing an unfamiliar TS, he courageously

tries to respond, and in both TSs, Carlo recalls a precedent by that guides his discursive actions in the new TS he is currently facing. Let us take a closer look at what happens in each case.

Before addressing TS1, Carlo had already participated in activity sessions at CARME with dynagraphs involving parallel lines, where the TSs were mainly "describe the movement of the tick marks." He had also worked with dynagraphs with perpendicular lines, where the TSs were "imagine/describe/draw the trajectory of the point (A,B) in the Cartesian plane." Our hypothesis is that, when addressing TS1, despite it being unfamiliar, Carlo has sufficient prior precedents developed during the work at CARME, at his disposal. This allows him to recall a precedent consistent with TS1. His participation is therefore explorative, focused on the product, as intended in the design.

In TS2, however, Carlo's interpretation of the task does not align with the designed task (which is what the tutor had in mind). Hence, there appears to be a *commognitive gap* (a mismatch between the tasks interpreted by the participants in the same TS) between Carlo and the tutor. Carlo's procedure, which we only interpreted retrospectively, is similar to a procedure in textbooks for graphically solving systems of linear equations by identifying the intersection point of two lines on a graph. The tutor's intervention, which followed the design of the activities (line 25: “Maybe it could help if you noted down some values”) seems to offer Carlo a precedent identifier for the procedure he applies. Recalling such a precedent leads him to reinterpret (uncanonically) the task and carry out a routine ritualistically. We note that we can infer Carlo's interpreted task because we share his socio-cultural background (including typical school textbooks), and we are aware of the topics covered in Carlo’s class before the experimental activities.

Carlo’s different participation in the two TSs baffled us initially. However, the analyses carried out helped us reinterpret these episodes and make sense of them in a satisfying (at least for now) way. Summing up, in one case, Carlo recalls a precedent that is consistent with the TS and the designed task, probably thanks to his (brief) experience with the tutor and previous activities with dynagraphs. In the other case, he recalls a precedent from his school mathematics experience, which is not consistent with the TS and the designed task; such a precedent interferes with Carlo's success in our remedial intervention, locking him back into ritualistic participation.

Conclusion

Once we identified and described the phenomenon, we noticed that the interference of previous mathematical experiences that occurs as a student tries to act in an unfamiliar TS appears to be a significant factor for many of the students we worked with in our remedial interventions. In this sense, the present study is prototypical and it introduces a new perspective on previously observed phenomena (Funghi et al., 2023): students who, despite exhibiting both the capacity and willingness to create meaningful narratives through exploratory participation, nonetheless revert to a more ritualistic form of participation in certain task situations, in which previously learned mathematics seem to play a crucial role.

Although we cannot know for sure why Carlo's participation varied so significantly, we can advance some hypotheses. We inferred that the tutor's prompt, "find some values," serves as a precedent

identifier for the student and is, therefore, particularly significant from our perspective. This intervention occurs after a moment of difficulty for Carlo. We hypothesize that introducing new representations during challenging moments, along with a precedent identifier linked to a well-established ritual, may inhibit his authoring of endorsable narratives, preventing him from engaging in more exploratory participation (as observed in other instances, such as during TS1). This hypothesis encourages further research on the tutor's interventions during remedial interventions, with a specific focus on the timing of these interventions and the stability of the ritual routines.

In the DynaMat project we have only started to explore this direction, and hope to proceed in the future. For now we offer the notion of "interference phenomenon" as a potential dimension to consider when examining the effects of remedial interventions while taking into account the student's prior experiences.

Fostering the unitizing concept in array representations by interpreting unconventional terms

Kati Schroeder[1] and Daniela Götze[1]

[1]TU Dortmund University, Germany; kati.schroeder@math.tu-dortmund.de

Active work with rectangular arrays plays a crucial role in developing the unitizing concept, which is the core idea of multiplicative thinking. Learners should learn to interpret composite units in the arrays flexibly. The research presented in this paper deals with the multiplicative thinking of second graders at an early stage of their learning of multiplication. In qualitative interviews they were asked to identify composite units in rectangular arrays. Verbal, gestural, and visual data were recorded. In-depth analyses of three children showed that they tended to look at the arrays in seemingly superficial ways. Productive irritations, such as identifying unconventional terms, often led them to explore composite units in a more flexible way. The findings underline the importance of discursive meaning-making processes for composite units in multiplicative representations.

Keywords: Multiplication, unitizing concept, eye movements, rectangular arrays, unconventional interpretation.

Mathematical representations and conceptual understanding

Mathematical representations play an important role in the mathematical learning process, especially of primary school children, as they visualise the underlying mathematical concepts and thus support meaning-making processes (Arcavi, 2003). If students are to understand and articulate how different representations are related, they must learn to connect these representations to each other (Duval, 2006; Prediger & Wessel, 2013). Since representations do not automatically reveal a concept, students must be supported in developing an interpretation of the underlying structure (Arcavi, 2003). As Arcavi (2003) writes, "learning to understand and be competent in the handling of multiple representations can be a long-winded, context dependent, nonlinear and even tortuous process for students" (p. 235). In-depth discussions about different mathematical interpretations of representations are particularly important in this process, so that an active exploration of the underlying mathematical structure can take place (Duval, 2006; Greeno & Hall, 1997).

Exploring the mathematical structure of multiplicative representations

Multiplicative thinking requires the ability to think in composite units (Steffe, 1992). In this so-called process of *unitizing* (Lamon, 1994), single units are formed into increasingly complex composite units. This requires a distinction between the multiplier, the multiplicand, and the product, with the multiplier indicating the number of units, the multiplicand indicating the size of the respective units, and the product reflecting a new composite unit (Götze & Baiker, 2023). For example, a rectangular array with three rows of four dots each yields twelve dots (Figure 1). The product must therefore be conceptualised as an entity in itself (Lamon, 1994). The independent coordination of the triad of 1) *number of units*, *2) size of units*, and *3) unit size of the product* can be described as multiplicative thinking. Because of the complexity of unit coordination, the multiplicative learning trajectory follows three broad stages (Boyce et al., 2024): In Stage 1, learners can only handle units of one.

Subsequently, in Stage 2, several of these units of one can be combined into units of the same size. Thus, children can construct composite units in the sense of unitizing (e.g., three fours), but this unitizing concept is not flexible yet. They have not internalised that there are other possible units. This distinguishes children at Stage 2 from children at Stage 3. In Stage 3, learners can work flexibly with composite units (Boyce et al., 2024). This means that students have a deep understanding that whole numbers can be interpreted as multiples of composite units so that they can, for example, reinterpret three fours as two sixes as well.

Rectangular arrays as representation for multiplicative thinking

Rectangular array representations (Figure 1) play a crucial role in developing multiplicative thinking, as they visualise the core idea of unitizing. They also allow flexible actions of regrouping. For example, a 3 x 4 array allows identification of other composite units such as two sixes, six twos, four threes, or two times three twos. Moreover, they provide insights into central properties of multiplication such as commutativity and distributivity and can therefore be used for flexible computation (van de Walle, 2020). Rectangular arrays are universal in the sense that they can be extended to other numerical ranges or number systems; thus they play a crucial role in multiple areas of mathematical content (Prediger et al., 2023). Because terms such as "5 x 3" do not show the unitizing concept in a meaningful way

> students should not only translate the multiplication 5 x 3 into an array model with five rows of 3 points each, but also [actively] explain how to see the unitizing structure in the rows ('five threes' or 'five sets of three') in order to verbalize the meaning of multiplication as unitizing (Erath et al., 2021, p. 249).

Directly addressing multiplicative structures in rectangular arrays using meaningful expressions such as "five threes" or "three fours" has proven to be supportive for all learners (Götze & Baiker, 2023). Although rectangular arrays represent the core idea of unitizing, and expressions such as "three fours" help to describe these representations, some children do not develop the capacity to think in composite units and are held back by a superficial view of arrays. These children have learned that a cursory glance at the array is sufficient, so they focus solely on the first column and the first row of an array to find the appropriate multiplicative term (Bolden et al., 2015). It is crucial that the idea of unitizing is actively developed while working with arrays to support children in reaching Stage 2 of the multiplicative learning trajectory. In order to reach Stage 3, it is necessary to be flexible in interpreting and identifying different possibilities for unitizing within the arrays.

But how should we design the individual learning pathways of primary school children, moving from Stage 1 to Stage 3? To gain further insight into this overarching research question, we draw on qualitative data from primary school children who were learning multiplication in the second grade. In this article, we focus on the following research question: *How can children's attention be drawn to (flexible) composite units when talking about multiplicative representations?*

Method

In our research project, we investigated the multiplicative learning pathways of 15 second graders. In diagnostic interviews at three points in time we examined the children's awareness of composite units

in rectangular arrays. The first interview took place before multiplication was introduced in mathematics classes, the second after 2 weeks of teaching and the third after a further 3 weeks. In the mathematics lessons that took place between the interviews, multiplication was taught with a focus on conceptual understanding, meaning that children were repeatedly asked to identify and describe the unitizing structure in rectangular arrays (e.g., "three fours"). Considering the current state of research (e.g., Götze & Baiker, 2023; Siemon, 2019), such activities help to develop children's multiplicative thinking. In the interviews, the interviewer presented different rectangular arrays on a flat screen and the children had to name one or more multiplication tasks that fitted the representation. For some arrays, different symbolic terms (e.g., "3 · 4" or "2 · 6") were presented for selection. The children then had to explain which term or terms matched the array. They were explicitly allowed to use gestures to support their explanations. In addition, eye-tracking was used to collect gaze data during the interviews. Eye-tracking provides further empirical insights into children's thought processes (Strohmaier et al., 2020). As primary school children are often challenged when attempting to explain the unitizing structure in rectangular arrays, eye-tracking data can provide further insights into children's conceptual understanding. This is because the recorded gaze movements may allow inferences to be made about ongoing cognitive processes. It has been shown that gaze data cannot always be interpreted unambiguously, so it is advisable to take other data into account when interpreting them (Strohmaier et al., 2020). Therefore, in addition to eye-tracking data, we also included verbal explanations and gestures to gain deeper insights into the children's multiplicative thinking. The focus of the analyses was on the extent to which the children flexibly addressed the unitizing concept visually, verbally and gesturally.

Insights in the data

In the following, we give empirical insights into the data collected from three children (Noyan, Edda, and Lia) in the third interview, after 5 weeks of teaching multiplication in mathematics classes. These three children were chosen because we considered them to be representative of the whole group. Their multiplicative interpretations could also be observed in other learners.

In the following scene, Noyan was shown a 3 x 4 array. In addition, six different symbolic terms were presented (Figure 1). Noyan had to explain which terms he thought fitted the array. The gaze data showed that before naming the term 3 x 4, Noyan looked at the first row and the first column of the rectangular array and then at the symbolic term of 3 x 4 below the representation (Figure 1).

After naming the term 3 x 4, the interviewer asked Noyan why this term fitted the array:

Noyan:	Three times four.
Interviewer:	Why does it fit?
Noyan:	Because there are three rows of four dots here (*points to the first column and the first row*), so you could also say there are three fours.

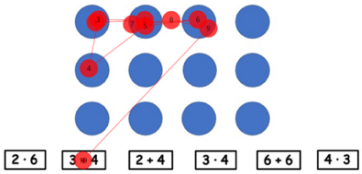

Figure 1: Noyan's gaze movement before naming the term 3 x 4 (the dot is typically used as a multiplication sign in Germany)

Noyan justified his choice by describing both the number of rows and the number of dots in the rows ("three rows of four dots") and emphasised this by saying "three fours". During this explanation, he pointed to the first column and the first row with his fingers. The eye-tracking data (Figure 1) showed that he focused visually only on the edges of the rectangular array. Since Noyan was gesturing to and visually focusing on the edges of the array, it was unclear at this point whether he was using the verbal expression "three fours" in an automated way because he had learned that he should use such expressions. However, the verbal data also demonstrated that Noyan may have had a deeper understanding of multiplicative structures. While his eye-movements and gestures could only reflect the process of identifying a task that fitted the array, Noyan's explanation of "three fours" indicated that he was aware of how the concept of unitizing was based in the array (Stage 2).

Aware of the problem that even triangulated data cannot always be interpreted unambiguously (e.g., Götze & Seidel, 2020), further questions were used to gain deeper insights into the children's multiplicative thinking. These were chosen to trigger "productive irritations" (Nührenbörger & Schwarzkopf, 2015, p. 319) that would help us gain further insights into the students' multiplicative thinking competencies at Stage 3. To this end, the interviewer asked Noyan if the term 2 x 6 also fitted the 3 x 4 array:

Interviewer:	Mhm. Would the term two times six also fit here?
Noyan:	(4 sec. pause) Yes.
Interviewer:	Why?
Noyan:	Because there are two sixes then.
Interviewer:	Where exactly?
Noyan:	So, if I do it like this (*points between the second and third column from top to bottom*), then there are six here and six there (*points first to the left and then to the right side of the array*).

Triggered by this question, gaze data showed that Noyan first looked at the two columns on the left side of the array and then at the first dot in the third column (Figure 2, left part):

Figure 2: Noyan's gaze movements while identifying (left) and explaining (right) why 2 x 6 fitted the 3 x 4 array

Noyan seemed to identify six dots in the left half of the array and the other six as a group in the right half, more or less simultaneously. After the interviewer asked why the term fitted, Noyan verbally

described “two sixes”. During this verbal explanation, he looked at the left half and the right half of the array with vertical gaze movements on the second and third columns, suggesting a vertical division of the picture into two sixes (Figure 2, right part). When asked where exactly these sixes could be seen, Noyan gesturally showed and verbally explained the vertical decomposition of the rectangular array. In summary, triggered by the impulse to look for an unconventional term in the array, Noyan's eye movements and thus the gaze data changed. He explicitly focused on multiplicative structures verbally, gesturally, and visually. He also showed that he was able to flexibly identify composite units in multiplicative arrays (Stage 3).

Other children in our data showed slightly different approaches. A typical example was Edda. Like Noyan, she perceived the 3 x 4 array by looking at the edges. She justified the fit between the array and the term 3 x 4 by saying “There are three fours.” During this verbal explanation, Edda glanced superficially at the edges of the rectangular array and did not focus visually on the composite units. In addition, she did not use any gestures. Again, it remained unclear whether she was aware of the units described (three fours) in the array or whether this was an automated response to the question of why the term fitted. However, the interviewer’s question as to whether 2 x 6 also matched the picture led Edda to take a different approach. The eye-tracking data showed that she focused on the first three dots in the first and second rows and then looked at the last column and the last row (Figure 3, left part) before verbally confirming that the term fitted the array. The gaze data suggested that she identified a six in the upper left part of the array and a six made up of the dots in the last column and row (Figure 3, right part).

Figure 3: Edda’s gaze movements when asked for an unconventional term in the array (left) and the compact interpretation of her data (right)

This visually generated interpretation was confirmed by her subsequent verbal explanation and gestures:

Interviewer:	Why?
Edda:	Because (...) if you (...) put these dots (*circles the first three dots of the first and second rows with her finger*) together, that's six and if you put these dots (*points to the last column and the last row*) together, that's also six.

Edda's verbal explanation, accompanied by her gestures and gaze movements during and before this explanation, showed that she reinterpreted the 3 x 4 array as representing two sixes. Triggered by the question of whether 2 x 6 fitted the picture, Edda structured the array individually and was able to reinterpret the three fours described at the beginning as two sixes in an individual way. As with Noyan in the previous example, the impulse to look for an unconventional term in the rectangular array led to a change in the gaze data and unfolded more flexible multiplicative thinking competencies (Stage 3). Edda explicitly focused on composite units verbally, gesturally and visually and was able to reinterpret the array in a multiplicative but in a slightly different way to Noyan.

While the two children described so far were able to move away from the seemingly superficial pattern of looking at the edges, this was not yet possible for Lia. She also focused on the edges of the rectangular array and named the term 3 x 4. Lia justified her choice in a very similar way to Noyan and Edda, while still visually focusing on the first row and column:

Lia: Eh, um, there are three rows and there are four dots in each row, so there are three fours.

From her verbal explanation it could be assumed that Lia, like Noyan and Edda, was thinking in composite units. Again, the question of whether the term 2 x 6 fitted the array was used for productive irritation:

Interviewer: Would the term two times six also fit here?
Lia: No.
Interviewer: Why not?
Lia: Because there are three rows and (…) yes.

The gaze data showed that Lia was still focusing exclusively on the edges of the array (Figure 4).

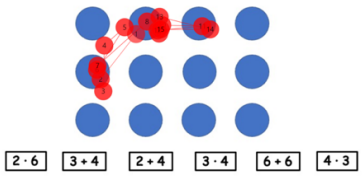

Figure 4: Lia's gaze movements when asked for an unconventional term

She verbally emphasised that there were "three rows," presumably meaning that 2 x 6 could not fit the array because there were not two rows. Consequently, unlike Noyan and Edda, Lia was not able to interpret the composite units in the array in a flexible way. Therefore, she had not yet reached Stage 3 of the multiplicative learning trajectory. The next learning step for children like Lia would be to disengage from such procedural approaches and focus on different possibilities of creating composite units represented in the array.

Conclusion

The data from the three children described in this paper and from other children in our study showed that many children take a superficial first look at multiplicative representations very early in their multiplicative learning trajectory. By asking for unconventional interpretations and thus by productively irritating them, these superficial glances can be transformed into deeper conceptual approaches that explicitly focus on different composite units in the rectangular arrays, which is indicative of Stage 3 of the multiplicative learning trajectory. Both verbal and visual data showed that requiring learners to make unconventional interpretations can be cognitively demanding. As a result, children often revise their initial interpretations and take an in-depth look at multiplicative representations. This creates learning opportunities not only to actively recognise and work with composite units in such representations but also to flexibly reinterpret them. In this way, a transition from Stage 2 to Stage 3 of the multiplicative learning trajectory can be achieved. Both Noyan and Edda changed their initial procedural approaches and were able to reinterpret the described "three fours" as "two sixes" by moving away from focusing solely on the edges of the array.

Moreover, Lia's example showed that even if learners can name a multiplicative term that fits an array, and even if they can justify their choice in a meaningful way, this does not automatically mean that they can identify those described composite units and handle them in a flexible way. The examples showed that array representations can run the risk of being superficial: Children may give a correct answer without full conceptual understanding. Lia's triangulated data showed that she was not yet able to identify composite units in the array as she was visually focusing only on the edges. She was somewhere between Stage 1 and Stage 2 of the multiplicative learning trajectory, as she knew that she needed composite units but could not identify them in the array representation. Teachers therefore need to be aware that to enable all learners to think multiplicatively in a flexible way, it is important to address composite units directly in concrete or graphical representations. Otherwise, there is a risk of developing and consolidating a superficial knowledge of composite units. This knowledge can prevent an in-depth understanding of composite units and prevent learners from reaching Stage 2 of the multiplicative learning trajectory. Consequently, the question "Which term fits the array?" combined with the request to show the units in the arrays with the help of gestures or markings seems to be essential.

However, this is not sufficient for achieving flexibility in unit coordination (Stage 3). Productive irritations and thus uncommon interpretations of multiplicative visualisations become necessary. Identifying different possibilities of grouping dots in a rectangular array and switching between these different interpretations seems to be very fruitful. Our data show that the unitizing concept in concrete or graphical representations must always be negotiated discursively, so that the different composite units become obvious. Otherwise, representations may become meaningless to children at an early stage of their learning and may inhibit further multiplicative learning. A limitation of our study is its small sample size. Future research should investigate whether the observed results can be applied to larger samples. In addition, because the interpretation of even triangulated data is not always clear, data should therefore be interpreted with caution and in the context of broader findings.

Negative impact of making a drawing on problem solving: An eye-tracking study on non-linear geometry problems

Gudula Volbers[1], Janina Krawitz[2], Stanislaw Schukajlow[1] and Gilbert Greefrath[1]

[1]University of Münster, Germany; gvolbers@uni-muenster.de

[2]University of Cologne, Germany

The ability to solve problems is an important part of the mathematical curriculum. Prior research has revealed that students often apply linear solutions to non-linear problems, a phenomenon known as linear overgeneralizations. Linear overgeneralizations were found to increase when students were asked to make a drawing. The present study aims to explore this negative effect by providing insight into the role of making a drawing in the solution process of non-linear problems. Eighteen secondary school students were asked either 1) to make a drawing or 2) to make a drawing and highlight the relevant area in the drawing before problem solving. Data were collected by recording the eye movements during task processing and using a stimulated recall interview. Analysis revealed difficulties with the scale of the self-generated drawings and a lack of conceptual content knowledge, which explained the observed negative effects of making a drawing on students' performance.

Keywords: Self-generated drawings, eye-tracking, non-linear geometry problems, linear overgeneralizations, problem solving.

Introduction

Promoting the ability to solve problems is an important goal of educational standards (Rott, 2015). Mathematical problem solving implies that a problem cannot be solved with directly available methods, i.e. barriers must be overcome while solving the task. Studies conducted by De Bock et al. (2007) revealed that students often have difficulties solving so-called non-linear geometry problems, where the area of similar figures has to be determined by a given scaling factor. Despite various teaching instructions examined in the past, many students try to solve such problems by linear overgeneralizations, i.e. by applying a linear model in an inappropriate context (De Bock et al., 2007; Krawitz & Schukajlow, 2020). Explanations discussed for this extensively researched phenomenon include the presence of a linear misconception that can make such tasks appear routine, but also the use of linear overgeneralizations as a surface strategy or in the absence of an alternative due to a lack of mathematical knowledge (De Bock et al., 2007; Greer, 2010; Modestou & Gagatsis, 2010). Self-generated drawings are considered a powerful heuristic for mathematical problem solving, with high drawing quality and strategic drawing knowledge being important indicators of a positive effect on performance (Krawitz & Schukajlow, 2020; Rellensmann et al., 2022). However, when solving non-linear geometry problems, De Bock et al. (2003) found that drawing had a surprisingly negative effect on task performance. Krawitz and Schukajlow (2020) confirmed this finding in a replication study, in which they also showed that improving drawing quality reduced the number of linear overgeneralizations, but did not improve performance. An in-depth analysis of the influence of drawing and drawing quality on students' solutions and the use of drawings revealed that calculating the area given in the drawing, which does not correspond to the measurements given in the task, was another source of errors. However, in most of the wrong solutions, no conclusions could be drawn about the role of the drawings in the solution process (Volbers et al., 2023). To clarify this research

gap, we designed a qualitative study using eye-tracking in combination with a stimulated recall interview to gain insight into the negative effects of making a drawing on performance and linear overgeneralizations. We pose the following research questions: 1. When and how do students use drawings in the solution process? 2. What are the reasons for linear overgeneralizations and what role do drawings have in the development of solutions that exhibit linear overgeneralization?

Theoretical background

Problem solving and non-linear geometry problems

Polya (1973) differentiates between (non-routine) problems and routine problems (p. 171). This article refers to the former as problems and the latter as routine tasks. A mathematical problem is a task that cannot be solved immediately using known solution methods and procedures, thus creating a barrier for the person who is supposed to solve the task. Mathematical problem solving describes the process of overcoming this barrier (Pólya, 1973). Important prerequisites for successful problem solving are, firstly, mathematical knowledge that has to be analyzed individually for each mathematical problem, secondly, the ability to select and use appropriate heuristics, e.g. by using self-generated drawings, and thirdly, metacognitive skills for planning, monitoring and reflecting on the individual solutions (Schoenfeld, 1985). In contrast, a task is a routine task, when a student can solve it by retrieving the solution directly from memory. The methods and operations for solving routine tasks are known and directly available. Whether a task is a problem or a routine task depends on the knowledge and skills of the task solver (Schoenfeld, 1985). The following model is based on the model of Pólya (1973) and describes the solution processes of mathematical tasks as follows (Figure 1):

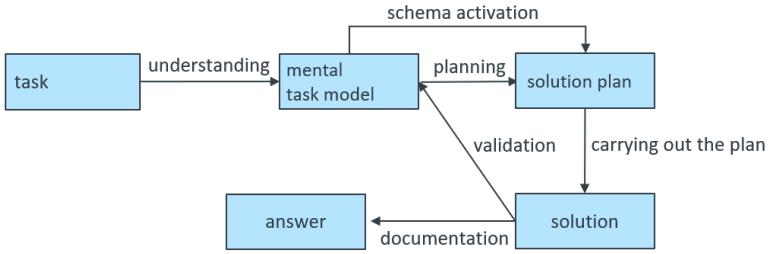

Figure 1: Problem-solving model based on Pólya (1973)

After reading the task, a problem solver creates a mental model. After that, one may activate a directly retrievable solution schema and stick to this schema for solving the problem, so that the planning phase can be skipped and a solution written down. This schema does not have to be correct and the task can be completed without a correct solution (Rott, 2015).

Non-linear geometry problems in this line of research usually involve calculating the area or volume of scaled surfaces or solids. In our study, we consider problems where the area of similar figures has to be determined by a given scaling factor. For example: “The side of square C is four times as large as the side of square D. If the area of square C is 1440 cm², what's the area of square D?” The solution to this problem can be found either by using the general scaling principle (when scaling by factor k, the area is enlarged/reduced by factor k^2, here D is 1440: $4^2 = 90$ [cm²]), or by identifying and applying appropriates formulae (e.g., $D = \left(\sqrt{1440:4}\right)^2 = 90$ [cm²]. These tasks are routine in the sense described above if one of these two solutions can be activated and executed directly as a schema. It has been

shown that students often have shortcomings in conceptual knowledge about areas and similar figures (Smith et al., 2011). Conceptual knowledge refers to an understanding of mathematical concepts, principles, and relationships and includes a deeper understanding of the ideas and structures on which operations and calculations are based (Rittle-Johnson et al., 2015). Conceptual knowledge about areas is based on the idea of measurement; it comprises an understanding of area formulas and their relationships as well as the ability to determine unusual shapes using appropriate paving strategies (Vollrath, 1999).

Linear overgeneralizations while solving non-linear geometry problems

Linear overgeneralizations are a widespread phenomenon that occurs in many content areas of mathematics, including solving the scaling problems described above, where the phenomenon has been shown to be resistant across different populations and countries. Several reasons are discussed for the occurrence and persistence of linear overgeneralizations: 1) There is a genuine linear misconception that is already present or is being developed while solving the problem. This misconception can be caused by the predominance of linear models for solving mathematical problems, which can give the impression that they are universally applicable, or by deficits in linear thinking itself (De Bock et al., 2007; Greer, 2010; Modestou & Gagatsis, 2010). 2) Linear overgeneralizations arise through the application of surface strategies, possibly facilitated by the processing of superficial task features. The root causes for this can be the intuitiveness of linear thinking on the one hand and the student's experiences in the context of school on the other hand: A decision about the operations required to solve a task is often successful when it is based on superficial task cues, such as certain keywords (e.g., “more” for addition or multiplication) or the given numbers (e.g. “all numbers have to be used for calculation”) (De Bock et al., 2007; Greer, 2010). 3) Linear solutions are given due to a lack of alternatives (Greer, 2010). If these reasons for linear overgeneralizations are related to the problem-solving model (Figure 1), a pre-existing misconception would imply the activation of an inappropriate schema (a schema for solving linear problems) and solving the task as a routine task. Linear overgeneralizations as a surface strategy or due to a lack of alternatives, as well as an acquired linear misconception, can be assigned to the planning phase. Concerning the above-mentioned skills required for problem solving, the use of linear overgeneralizations as a surface strategy can be seen in the context of difficulties related to metacognitive skills for planning, monitoring, and reflecting on the solutions. A linear misconception or linear overgeneralizations caused by a lack of alternatives may be due to deficiencies in conceptual knowledge about areas or the inability to activate appropriate heuristics.

Self-generated drawings as heuristics for problem solving

A drawing is an external visual representation, also called a visualization, that corresponds to the mathematical problem structure. If learners develop a drawing completely or in parts by themselves, these types of drawings are called self-generated drawings (Krawitz & Schukajlow, 2020; Van Meter & Garner, 2005). Like all visualizations, drawings have a product component, which refers to the visually represented result, and a process component, which refers to the process of creating the drawing (Arcavi, 2003). Learner-generated drawing describes the process and product of creating an illustration corresponding to objects and relationships described in a task (Rellensmann et al., 2022). Self-generated drawings are considered to be an important heuristic tool for problem solving as they can help in understanding the problem, in devising a plan, and in monitoring the solution process,

including validation of the result (De Bock et al. 2003; Pólya 1973; Stylianou, 2011). In the case of non-linear geometry problems, a scale drawing of the two areas could help to understand and analyze the situation. For example, learners may recognize which area is smaller or understand that the area does not grow linearly if the sides grow linearly. When planning and executing the plan, the scale drawing could support an appropriate paving strategy. Estimating the size ratio of the two sketches helps to validate the result (De Bock et al., 2007; De Bock et al., 2003). Studies investigating the effect of drawing on problem solving performance have produced mixed results: some studies have reported a positive effect of drawing, while others have found no effect or even a negative effect (Krawitz & Schukajlow, 2020). These inconsistent findings appear to be partly problem-specific and partly influenced by drawing quality and students' strategic knowledge about drawing (Krawitz & Schukajlow, 2020; Rellensmann et al., 2022). High drawing quality means that the drawing is correct and complete in terms of the important elements and their relationships (Krawitz & Schukajlow, 2020). Strategic knowledge about drawing includes knowing the characteristics that adequately represent the structure of the problem (Rellensmann et al., 2022).

Effects of making a drawing on linear overgeneralizations and performance

In line with the role of making a drawing as a heuristic for problem solving, De Bock et al. (2003) expected to improve performance in solving non-linear geometry problems through an intervention that made drawing an integral part of the solution process by asking students to generate a drawing before working on the non-linear geometry problem (see Figure 1, left). Surprisingly, the researchers found a strong negative effect of drawing on performance and an increase in linear overgeneralizations, despite drawings of good quality that students developed for solving problems. One possible explanation for the strong increase in linear overgeneralizations was that the students were focusing on linear activities by making a drawing (De Bock et al., 2003; Krawitz & Schukajlow, 2020). This negative effect of making a drawing was confirmed by Krawitz and Schukajlow (2020). Furthermore, it was shown that improving the quality of the drawing by highlighting the relevant area in the drawing (see Figure 2, right) did not improve performance, but reduced the number of linear overgeneralizations.

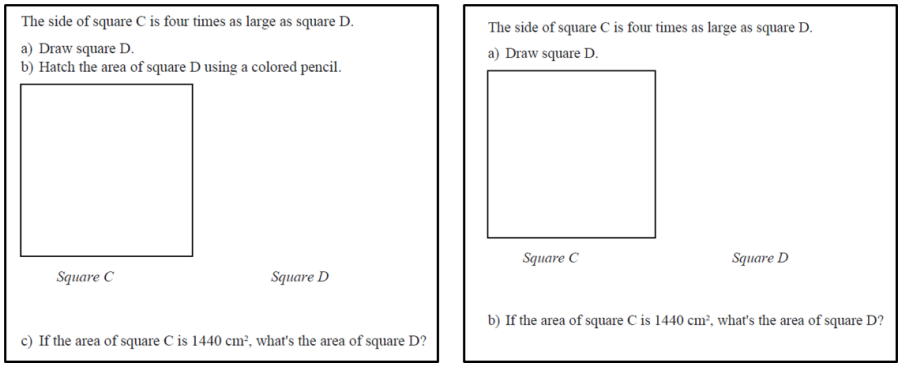

Figure 2: Sample items with drawing (left) and drawing with highlighting instructions (right)

A detailed analysis of the influence of drawing and drawing quality on the use of drawings while solving the non-linear geometry problem (such as paving or labeling with the information given in the calculation task) indicated the use of the self-generated drawing in only about 15% of cases (Volbers et al., 2023). In most of these cases, the students calculated the area of the figure in the

drawing, which does not correspond in scale with the measurements provided in the problem. This calculation of the area of the drawing (applied in about 10% of solutions) was found to be a second significant factor, after the linear overgeneralizations (applied in about 40% of solutions), that explained the negative effect of drawing on performance (Volbers et al., 2023). We did not find an explanation for this unusual error. For the majority of the solutions, and especially for the linear overgeneralizations, the role of the drawings in the solution process remained unclear.

Methods

The present study involved 18 students (10 female, mean age = 16.18 years) from upper secondary education, coming from two high-track schools and one comprehensive school. Students were randomly assigned to one of two groups. Before solving the problems, students in one group were asked to make a drawing, and students in the other group were asked to make a drawing and to highlight the quantity that they should calculate (see Figure 2). Both groups worked on a paper-and-pencil test. Students worked on the square problem described above (Figure 2), and then on a structurally similar problem about calculating the area of a circle (circle problem). We decided to include the circle problem because linear overgeneralizations occurred more frequently in circle problems than in square problems, and a paving strategy is difficult to apply to solve this problem (De Bock et al., 2003). Data were collected by recording student eye movements during task processing using Tobii Pro Glasses 3 and a stimulated recall interview (SRI) in which students were asked to explain their solutions using the gaze replay videos. To link eye movements and cognitive processes during problem solving, we used a qualitative content analysis following Thoemaneck et al. (2022). To minimize the ambiguity in interpretations of eye movements identified by the authors, the phases of problem solving (Figure 1) were taken into account. Eye movements were coded deductively-inductively based on category systems from prior research (Alemdag & Cagiltay, 2018; Thomaneck et al., 2022). Furthermore, the gaze data videos were triangulated with the statements from the SRI. The three categories of drawing use were “purely visual drawing use” (e.g., glances in the diagram area without corresponding action), “visual action drawing use” (e.g. measuring a side length), and “non-visual drawing use” (e.g. using the drawing lengths in calculations).

Findings and discussion

All students used one of the four solutions described in the theory section: They solved the problems by using formulas, applying the general principle, calculating the sketch area, or by linear overgeneralizations, which were the predominant solutions (17 of 36). Most of the drawings were correct. The analysis of students’ solution process to answer the first research question revealed the use of drawings by all students in at least one phase of solving the problem (see phases in Figure 1). Furthermore, we found evidence of the use of drawings for all phases of the problem-solving process. During the understanding phase, drawings were used purely visually to understand the task by recognizing which area is smaller, but not to recognize that the area does not grow linearly when scaled. During the planning phase, we observed the use of drawings, which were predominantly purely visual (Figure 3, left) and sometimes visually active, for each of the solutions described above. Students mostly explained these in the SRI by trying to remember calculation methods and formulas. This is in line with the tendency discussed above to solve area content problems by using formulas. Only one student developed the idea of paving as mentioned above when planning the solution to the

square problem (Figure 3, centre), but this student failed to transfer this strategy to the circle problem, which she explained as follows:

Elisa: Because the diagram didn't really help me much. I can't divide a circle in such a way that another circle results as with the square.

In addition, some other students expressed the idea of paving in the SRI but considered it suitable only for the square problem due to its shape. This result is in line with the shortcomings in the conceptual knowledge concerning areas and paving strategies described above. In the execution phase, this paving strategy was the only example of meaningful use of drawings. Eight students used the drawings to calculate the area of the smaller drawing for at least one problem. Five students recognized this error as part of validation by comparing the calculated result (2.25 cm²) or the size of the drawn figure with the information given in the calculation task (1440 cm²), but could not determine a correct result. Three students did not validate this incorrect result, indicating a lack of metacognitive skills to monitor the solution process. Some students who had determined the result using formulae or by linear overgeneralizations used the diagrams for validation by estimating the area ratios of the drawn figures (purely visual drawing use). For example, one student realized that the result of the linear overgeneralization must be wrong (Figure 3, right):

Niklas: I then realised that the result cannot be correct because the difference in size is relatively large.

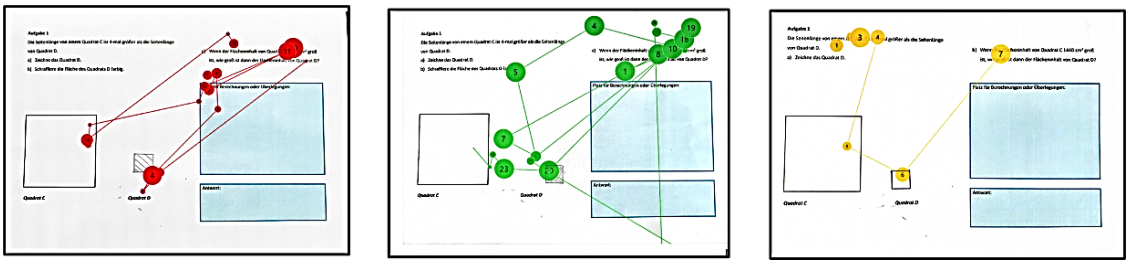

Figure 3: Examples for eye movements (purely visual drawing use)

With regard to the second research question (What are the reasons for linear overgeneralizations and what role do drawings have in the development of solutions that exhibit linear overgeneralization), we identified a plan development phase for all students who solved the square problem by linear overgeneralization; thus schema activation due to a genuine misconception and solution as a routine task was not identified. However, some students did not have a plan development phase and used linear overgeneralizations as schema by solving the circle task and justified this approach with the analogy between the two tasks. Concerning the square task we identified two types of 'linear solvers'. The first type applied linear overgeneralizations as a first and only solution strategy either as a surface strategy or due to a lack of alternative ideas for solving the problem. Three of these five students used the drawings unsuccessfully to remember calculation methods or formulas while planning their solutions. The second type applied linear overgeneralizations after an attempt to solve the problem using the drawing measures. After realizing the incorrectness of this solution, five students applied linear overgeneralizations due to a lack of alternative approaches. This seems to be another important cause of the increase in linear overgeneralizations after making a drawing, rather than an attentional bias towards linear variables caused by making a drawing, as suggested in previous studies (De Bock et al., 2003; Krawitz & Schukajlow, 2020). In only one case could the linear overgeneralizations be

reliably attributed to the expected transfer of linear reasoning from the drawing actions to the calculation of the area. Students of both types sometimes had doubts about the correctness of their solution and tried to validate it with the help of the diagrams. Three of them noticed that one figure was significantly larger than the other, but they did not realize their mistake. Two students recognized the incorrectness of the linear solution but were unable to correct it.

To summarize, for many students the mismatch between the scale of the drawings and the numerical values was a significant barrier to integrating information from the drawings and the text. A considerable amount of the incorrect solutions (calculation of the sketch area and some of the linear overgeneralizations) appeared to be due to this barrier. The main reason for this difficulty might be the lack of conceptual knowledge about areas and similar figures, which seems to be a major factor contributing to the negative effect of making a drawing. This lack of knowledge also led to a lack of positive effects of making a drawing. Although some students recognized their calculations as incorrect with the help of the drawings, they could not correct their mistakes. Furthermore, the paving strategy could not be transferred to the circle. Attempts to use formulas also limited the use of the drawings in planning, despite strategic knowledge of appropriate paving strategies. Other reasons are the lack of strategic knowledge about the use of a drawing during problem solving and a lack of metacognitive skills for problem solving. These results are in line with previous research and further extend prior studies by demonstrating that at least some students recognize their erroneous linear solutions but nonetheless adhere to them due to a lack of alternative approaches, with reference to specific content-related deficits. Our findings have both theoretical implications and practical consequences. The theoretical implications relate to the explanation of the negative effect of drawing in this particular task setting, which is related to a lack of conceptual knowledge rather than focusing on linear activities by making the drawing (De Bock et al., 2003; Krawitz & Schukajlow, 2020). A practical implication is a need to focus conceptual knowledge about areas in mathematics class, for example using visualizations to aid understanding.

From research to practice: Visual representations as research-based tools and pedagogical mediators for teacher learning

Merav Weingarden

Tel Aviv University, School of Education, Tel Aviv, Israel; weingardenm@tauex.tau.ac.il

Visual representations play a pivotal role in effectively conveying research findings in reports, papers, and other publications. Research has also highlighted their importance in provoking productive conversations among teachers about their practice. This paper investigates how the Realization Tree Mediator (RTM), a specific visual representation, can serve both research and pedagogical purposes. Findings show that the RTM functions as a dual-purpose tool: 1) as a research instrument that explicates mathematical objects at the core of a task and evaluates learners' mathematical engagement, and 2) as a pedagogical tool that facilitates teacher learning towards ambitious teaching practices. This dual functionality is discussed in light of bridging the gap between research and practice in mathematics education.

Keywords: Teaching representations, research visualization, teacher learning, teaching practices.

Introduction

Visual representations play a crucial role in mathematics education research and teacher learning. In research, graphs and diagrams effectively communicate findings and encapsulate complex theories and data (e.g., Dai et al., 2022). In teacher education, representations like concept maps and video clips facilitate pedagogical discussions and help teachers learn about complex teaching practices (e.g., Herbst et al., 2011). While the value of such representations in both domains is recognized, more research is needed to understand the benefits of using the same representation across domains, bridging the gap between research and teacher practice. This paper explores how visual representations developed for research purposes can also serve as learning tools for teachers.

Visual representations for research and teacher learning

The power of visual representations extends beyond mere illustration and communication of findings (McCrudden et al., 2015). Researchers use them to summarize complex data, highlight patterns, and elucidate theoretical components (Few, 2009; Knox & Kontorovich, 2023). Theory guides research by providing foundations for formulating questions, selecting methodologies, and interpreting results (Bikner-Ahsbahs, 2019). While theory serves as a cohesive force that helps research inform educational practice and interventions, practitioners often find theoretical constructs difficult to access (Trowler & Cooper, 2002). Visual representations thus become particularly valuable in educational contexts, making research implications accessible to practitioners (Cai et al., 2019).

Teaching representations, such as video excerpts (Crespo, 2016) and animated teaching stories (Herbst et al., 2011), are critical for enhancing teacher learning (Grossman et al., 2009). These representations facilitate understanding of teaching practices and their classroom implementation. In teacher learning, they contextualize teacher conversations within instructional realities, simulate real-world scenarios, and enhance pedagogical skills by linking teaching aspects to future work. However, while these representations effectively discuss teaching-learning situations and specific practices, we

lack understanding of how they incorporate research findings and align with theoretical frameworks. When teaching representations are not explicitly connected to research, their potential impact on classroom practice may be limited. This disconnect could restrict the translation of theoretical insights into effective teacher development tools and might not fully capture the complexity of teaching situations as understood through contemporary research. Given the importance of visual representations in both domains and the need to contextualize research within teaching practice, this paper aims to explore the dual functionality of a visual representation – the Realization Tree Mediator (RTM), as both a research-based tool and a pedagogical mediator for teacher learning.

The Realization Tree Mediator (RTM)

The Realization Tree Mediator (RTM) (Weingarden & Heyd-Metzuyanim, 2023) is a research-based visual representation grounded in the commognitive theory (Sfard, 2008), which views mathematical learning as the development of proficiency in participating in mathematical discourse. The RTM (e.g., Figure 3) visually depicts classroom discussions by illustrating three key elements: the *mathematical object* at the core of the discussion, its various *realizations*, and the *saming narratives* produced during the discussion. *Mathematical objects* are discursive constructs that emerge through learners communicating their *realizations* – the different ways the object is manifested in the discourse. For example, the mathematical object "function" can be communicated through various realizations, such as symbolic expressions, verbal descriptions, or visual patterns. Developing proficiency in discourse involves talking about different realizations of the object as the same. This process is defined as *saming* and is operationalized in discourse by learners producing *saming narratives*, which involve the translation between realizations. The RTM visually organizes these elements, enabling the evaluation of the realizations mentioned during lessons and analysis of how they are connected through saming narratives. The research question of this study is thus: *How does the RTM, as a visual representation of mathematical activity, bridge research findings back to participating teachers?*

Method

Context: Professional development for teaching in heterogeneous classrooms

This study was conducted within a Research-Practice Partnership project – Heterogeneous Teaching of Mathematics, which aimed at developing pedagogies for teaching in heterogeneous classrooms. In 2023-2024, three Israeli middle schools participated, with 6 to 8 7th-grade mathematics teachers in each school joining Professional Learning Community (PLC) meetings every three weeks with two project researchers. These PLC meetings focused on addressing challenges in teaching heterogeneous classes, introducing effective practices, experiencing student-centered activities, and planning lessons. Between meetings, teachers implemented these activities and reflected on their experiences. This study examines one school and two PLC meetings centered on the Hanger Activity. In the first meeting, teachers experienced the activity as learners. Subsequently, one teacher, Tamara, tried it in her classroom. The second meeting focused on reflecting and discussing the activity's effectiveness.

The Hanger Activity

The Hanger Activity, developed by *Illustrative Mathematics* (illustrativemathematics.org), introduces the concept of equivalency using scales and equations. It begins with students observing

a picture of socks on two hangers illustrating equal and unequal weights, and answering open-ended questions about what they notice and wonder. Next, students analyze balanced and unbalanced scales, exploring the relationships between shapes representing different weights. This paper focuses on the third part of the activity, where students match hanger diagrams to equations (see Figure 1).

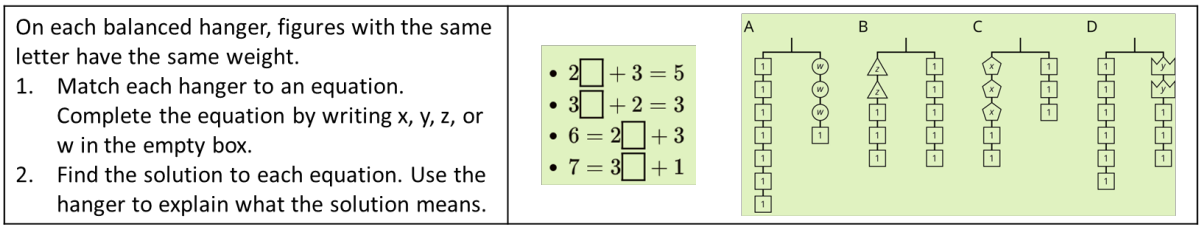

Figure 1: The third part of the Hanger Activity

Data collection and analysis

The two PLC meetings were recorded and transcribed. Field notes were taken during Tamara's implementation of the Hanger Activity in her classroom. Additionally, the data includes the full original lesson plan of the Hanger Activity as it appeared in *Illustrative Mathematics* (https://curriculum.illustrativemathematics.org/MS/teachers/2/6/7/index.html). The RTM was used as an analytic tool three times: 1) To explicate the activity's mathematical affordances by identifying the intended realizations and saming narratives; 2) To examine teachers' engagement as learners in the PLC meeting, explicating realizations and saming narratives they produced; and 3) To assess which realizations and saming narratives were produced during Tamara's lesson. The findings were then applied and redesigned as a pedagogical tool for teacher learning, resulting in two hypothetical RTMs depicting two Hanger Activity lessons (Figure 5), which were presented to teachers in the second PLC meeting. Teachers' conversations were analyzed based on their attention to different realizations and saming narratives appearing in the two contrasting RTMs.

Findings

As space is limited, I focus on Hanger A's analysis (Figure 1) and its matched equation $7 = 3w + 1$.

The activity's affordances: Saming between the balanced hangers and equations

The main mathematical idea of the Hanger Activity, as stated in the lesson plan, is to see how a balanced hanger is like an equation and how removing (taking off) weights is like solving the equation. It demonstrates two ways to show equality: a balanced hanger and an equation. The main concept embedded in such steps for finding the unknown amount relies on the idea of equivalency, through the principle of keeping the hangers balanced by "doing the same thing on both sides." The RTM, built for this study to analyze the task's mathematical affordances, shows how equivalency is reflected in different realizations of the unknown amount (Figure 2). At the top of the tree is the mathematical object at the core of the activity – the unknown amount. The branches show four types of realizations: hangers and equations in static situations (Branches 2 & 4), and in operational mode (Branches 1 & 3). The arcs between realizations show the potential saming narratives learners might produce while engaging with the activity, as depicted in the lesson plan.

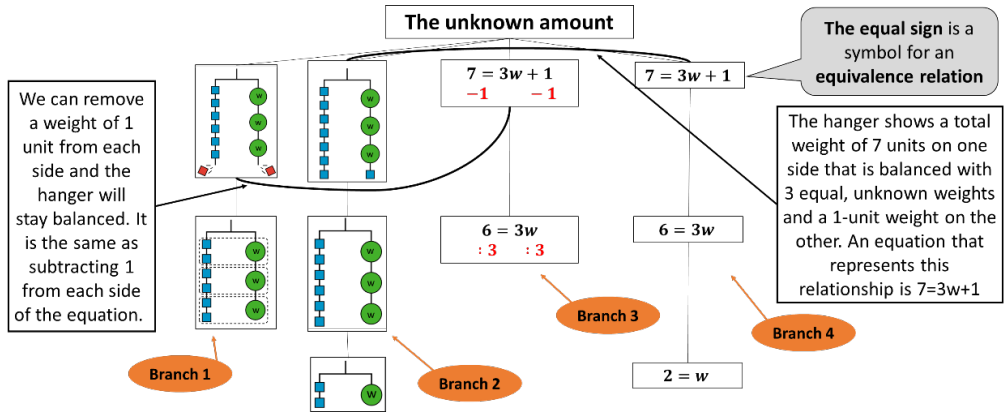

Figure 2: The RTM of the Hanger Activity: Emphasizing the mathematical idea of equivalency

Teachers experience the activity in the PLC: Unexpected evolvement of the covering method

Figure 3 displays the RTM depicting teachers' realizations and saming narratives produced as they engaged with the Hanger Activity during the PLC. Teacher-authored realizations are in black frames, with connecting arcs representing their saming narratives. Surrounding boxes provide examples of these narratives, such as Box 3-B-4 showing realizations 3 & 4 and the saming narrative (arc B) between them.

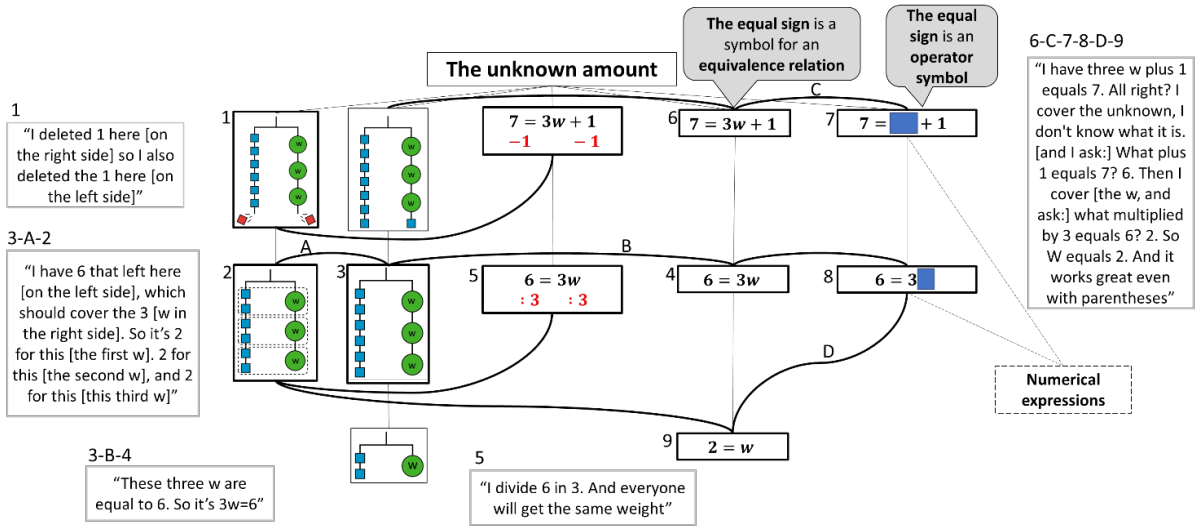

Figure 3: The RTM describing the realizations and the saming narratives teachers produced

Aligning with the lesson plan and the RTM in Figure 2, teachers found the unknown amount using both balanced hangers and symbolic notations. They operated on both hangers (e.g., Box 1) and equations (e.g., Box 5), producing saming narratives between symbolic expressions and hangers (Box 3-B-4), as well as between different hanger realizations (Box 3-A-2). The idea of equivalency remained consistent in teachers' discourse, whether working with equations or hangers. One teacher, for example, deleting a unit from each side of the hanger (Realization 1), explained: "What I do on one side, I do on the other side." In addition to equivalency narratives, the analysis revealed that teachers also produced narratives on numerical expressions, interpreting the equal sign as an operator

rather than a relational symbol (Figure 3, right branch). The numerical branch reflects the "covering method" – an additional method teachers introduced for solving equations. Box 6-C-7-8-D-9 (Figure 3) illustrates the covering method where teachers treat the equation as a sequence of operations to find a missing number, rather than as a relationship between equivalent expressions. While this method was valued by the teachers since it builds on students' familiar arithmetic operations ("they know this square from first grade"), it may emphasize a procedural view where the equal sign signals "find the answer" rather than expressing a relationship of equivalence between the expressions on both sides. This distinction matters because a relational understanding of the equal sign – seeing it as indicating that both sides have the same value – is crucial for advanced algebraic thinking. However, these distinctions in equation-solving methods and their implications for understanding the equal sign only became clear post-analysis. They were not discussed with the teachers during the PLC meeting.

Tamara implements the activity in her classroom: Insights from the classroom

After experiencing the Hanger Activity in the PLC, Tamara implemented it in her classroom. Figure 4 shows the RTM of her whole-class discussion. Similar to the PLC meeting, Tamara's class discussion involved three equation-solving methods. Guided by Tamara, her students first produced the covering method (Realizations 8-9) and algebraic manipulation (Realizations 6-7). As Tamara prepared to move on, two students introduced the balanced hangers approach (Realizations 3-4). Unlike the RTMs of the activity's potential (Figure 2) and the teachers' experience (Figure 3), the RTM of Tamara's lesson showed a few saming narratives. Students showed, for example, how the hanger (Box 2) can be written as a symbolic equation (Box 1), and how 6=3w (Box 7) leads to 2=w (Box 5) by dividing both 6 and 2w by 3. However, connections between balanced hangers (Boxes 3&4) and equations (Boxes 6&7) were absent. One of the explanations for such absence is in Tamara viewing the hangers as separate from "real mathematics," stating: "At some point, we have to say goodbye to the model of the hangers... In mathematical writing, I'm already building the equation, so I prefer the covering method."

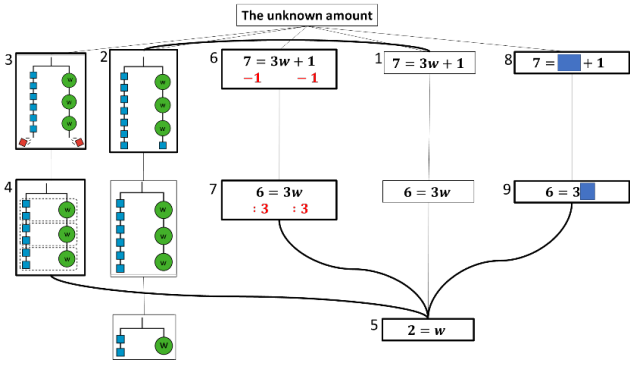

Figure 4: The RTM describing the whole-class discussion in Tamara's lesson

The RTMs for the activity's potential (Figure 2), teachers' experience (Figure 3), and Tamara's classroom (Figure 4) revealed two key findings. First, teachers valued the covering method and viewed it as a convenient approach to solving equations, overlooking the different functions of the equal sign in this method (as a numerical operator) versus identical operations on both sides (as an equivalency relation). Second, Tamara undervalued the hanger method, neither explicitly mentioning

nor connecting it to equations in her lesson. This suggests teachers may not recognize its potential for solving equations and communicating equivalency more accessibly (particularly in heterogeneous classrooms), potentially limiting students' meaningful engagement with core mathematical ideas.

Translating research outcomes into a visual representation for teacher learning purposes

The two findings—the equal sign's differing role in the covering method and using realistic representations in heterogeneous classrooms—are crucial for the project's participants as 7th-grade mathematics teachers who teach algebra in heterogeneous classrooms. Highlighting these mathematical and pedagogical insights can enhance their teaching practices, especially as they emerge from teachers' own experiences with the activity as learners and implementers. To effectively communicate these insights, two hypothetical RTMs of classroom discussion were created (Figure 5), conveying the analysis of teachers' experiences and Tamara's classroom implementation.

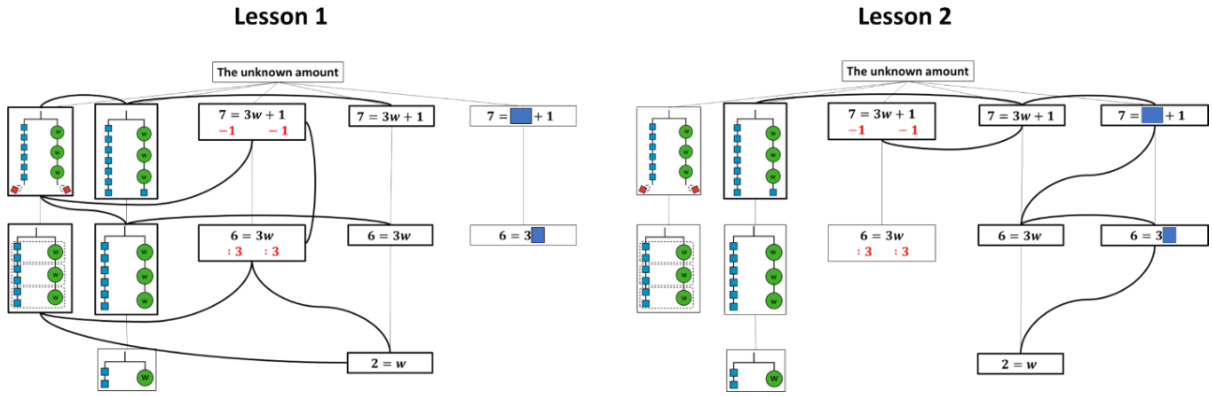

Figure 5: Two hypothetical RTMs used as a teaching representation for teachers' conversations

Lesson 1 exemplifies strong connections between balanced hangers and symbolic notations, emphasizing equivalency and accessibility for diverse students. Lesson 2 exemplifies the covering method alongside equations, minimizing hanger use. These hypothetical RTMs were presented at the next PLC meeting as a visual representation mapping imaginary students' mathematical engagement. Teachers discussed the differences between the two lessons and their mathematical opportunities. One teacher favored the covering method, stating that "it brings students back to a safe place... I love that the mathematics they learn is connected to what they've already learned." Another noted that the covering method does not emphasize "doing the same operations on both sides" as clearly as hangers and algebraic equations do. The PLC leader guided the conversation to focus on the different roles of the equal sign in each RTM. Teachers explored the learning opportunities and the added value of each method. A critical question emerged: "So, how should we teach it?" This prompted teachers to describe ideal lessons based on the realizations and saming narratives they deemed essential.

Discussion

This study explores the RTM as a dual-purpose visual representation for research analysis and teacher learning. Building on prior uses of realization trees for a priori task analysis of dynamic scale activity (Weingarden et al., 2024), the RTM was used in this study to examine the Hanger Activity's mathematical potential, teachers' experience with the activity as learners, and students' mathematical

opportunities when one teacher implemented the activity in her classrooms. The analysis revealed two main findings: First, in addition to operating on hangers and symbolic notations as described in the lesson plan, teachers unexpectedly mentioned the covering method when experiencing the activity. Second, Tamara primarily used numerical and algebraic equation-solving methods and made limited connections to the balanced hangers approach. The emergence of the covering method was surprising since it does not appear in the original lesson plan (Figure 2) and does not explicitly capture the activity's main mathematical idea of equivalency. While these findings are noteworthy, they primarily serve to illustrate the main goal of this paper: exploring how research outcomes, grounded in theoretical frameworks, can be effectively translated into teacher practices. This study shows how the RTM can visually translate theoretically-informed research into accessible, actionable, and practical knowledge for teachers. The utilization of research-oriented visual representations like the RTM demonstrates a dual potential contribution. First, it can help researchers better communicate complex research results and intricate theoretical constructs to readers – a crucial element in research dissemination (McCrudden et al., 2015). Second, and more pertinently to this study, it offers a means to address the research-practice gap – a concern raised by several researchers (Cai et al., 2019). These visual representations can be discussed in light of the evolving field of using theory in teacher education and its practical application (Lin et al., 2018). The theoretical foundations of the RTM played a significant role in revealing important insights about teaching practices, raising questions about how and to what extent theory should be made explicit in teacher learning programs. Visual tools like the RTM may potentially aid pre-service teachers in learning and applying complex educational theories, and ultimately improving their teaching practice. This study also contributes to the evolving landscape of teaching representations by exploring tools that are simultaneously visual, practice-oriented, and conceptually focused. These representations expand upon existing tools like video excerpts (Crespo, 2016) by integrating deeper, theoretically-grounded analysis within observed classroom practices. This approach creates a synergy between surface-level observations and deep conceptual analysis, providing a comprehensive view of teaching-learning situations and enhancing the current repertoire of teaching representations. While providing promising insights, this study is limited by its focus on a single activity and few teachers. Future research could explore the RTM and other research-based visual representations across various mathematical topics and with larger, diverse teacher groups. Comparative studies on the effectiveness of different visual representations in bridging research and practice could offer valuable insights for researchers and teacher educators.

Acknowledgment

The author would like to thank the Center for the Study of Pedagogy – Research-Practice Partnerships at Ben-Gurion University of the Negev and the Weizmann Institute of Science for supporting this project. Special thanks are extended to Boris Koichu and Ronnie Karsenty for their mentorship and guidance, and to Miriam Babichenko for our collaborative work.

Estimating area: strategies and internal representations

Terese A. Wendelborg, Eivind Kaspersen and Trygve Solstad

NTNU—Norwegian University of Science and Technology, Faculty of Social and Educational Sciences, Trondheim, Norway; terese.a.wendelborg@ntnu.no

Previous research provides extensive insight into the development of students' strategies for external area measurement. However, less is known about strategies for area measurement on internal representations. Therefore, we investigated which strategies people report using when estimating area on internal representations of square shapes. We interviewed five participants estimating the area of squares flashing briefly on a screen to avoid external measurement. The results show that the participants reported using similar strategies for internal as for external area measurement. Further, they reported using both formal knowledge, such as multiplication learned in school, as well as more intuitive skills, not explicitly taught at school, such as visualizing and manipulating shapes internally.

Keywords: Geometry, representations, measurement, strategies, estimation.

Introduction

Area measurement plays a central role in school mathematics. It connects with other mathematical concepts, such as multiplication and composition of geometric figures, and has real-world applications, like determining the area of a wall to buy the right amount of paint (Clements et al., 2018; Outhred & Mitchelmore, 2000). Consequently, there is extensive research on the effects of instructional practices (e.g., Clements et al., 2018; Zacharos, 2006), students' understanding and misconceptions of area measurement (e.g., Zacharos, 2006), the developmental stages in students' understanding of area (e.g., Clements et al., 2018; Outhred & Mitchelmore, 2000), and the specific strategies that students use to measure and estimate area (e.g., Cullen & Barrett, 2020; Zacharos, 2006).

A notable strand of this research has focused specifically on describing strategies and representations for measuring area. For example, students may calculate area by drawing square units covering an entire space before counting the number of units (Cullen & Barrett, 2020; Zacharos, 2006). A similar strategy involves using physical objects, such as tiles or cardboard, to cover a rectangular space (Clements et al., 2018; Zacharos, 2006). Students may also use rulers to measure two sides of a rectangle and multiply the lengths of the sides to determine the area (Clements et al., 2018; Zacharos, 2006). Moreover, students sometimes rely on formulas, even when they are inappropriate for the given shape (Zacharos, 2006).

An essential aspect of learning mathematics is bringing one's internal representations of a mathematical object into coherence with its corresponding (and culturally agreed-upon) external representations (Goldin & Shteingold, 2001). While previous studies in area measurement provide crucial insights into how students' area measurement strategies develop—for instance, in response to instructional practices—they focus primarily on external representations, including visual diagrams on paper, physical objects like tiles or Lego bricks, or real-world spaces such as schoolyards or fields. Less is known about how students use internal representations of area and measurement. Estimating an area from an internal representation means visualizing an object in the mind's eye before

performing some mental operation on that internal representation, a process requiring general spatial visualization skills (Harris et al., 2023). Understanding how individuals operate on internal representations of area is essential, not only because it complements existing research on external representations, but also because it addresses the role of visualization in mathematics education more broadly (e.g., Harris et al., 2023). Research on people's internal representations of area might also address the ongoing debate on whether people have an innate magnitude sense (Leibovich et al., 2017), or whether our impressions of magnitudes, such as length and area, primarily result from internalizing external tools and strategies acquired in a socio-historical context (Núñez, 2017).

As a step towards understanding the role of internal representations in learning and doing mathematics within geometry and measurement, the aim of this study is *to characterize the strategies people report using when estimating the area of their internal representations of squares*.

Theoretical background

Mathematical objects are abstract and must, therefore, be represented in some form to be understood. According to Duval (2006), a mathematical representation is "something that stands for something else" (p. 104). It involves one or more semiotic forms, such as symbols, drawings, graphs, or language, that stand for—and must not be confused with—the mathematical object itself. In this view, representations are the core of mathematical understanding. Mastery of the different representations of concepts and the transitions between them is necessary both to communicate mathematical ideas and to perform mathematical procedures.

To better understand how people learn and do mathematics, Goldin and Shteingold (2001) distinguish between external and internal representations. External representations, such as physical graphs, diagrams, and algebraic expressions, exist beyond the human mind and communicate mathematical ideas; they can be observed and discussed in the classroom. In contrast, internal (mental) representations exist in the individual's mind, invisible to the external observer. They include mental images, strategies, and understandings that students develop in their minds when working with mathematics, and can vary from student to student, depending on their experiences and understanding (Duval, 2006). From this perspective, learning and doing mathematics involves interactions between external and internal representations: External representations can be internalized into the individuals' internal representations, and vice versa (Goldin & Shteingold, 2001), so bringing internal representations of mathematical objects into coherence with the corresponding external representations is an essential aspect of mathematical activity (Goldin & Shteingold, 2001).

The didactical literature mostly deals with representations constructed in cultural-historic contexts, such as graphs and symbolic expressions. However, people might also have innate representations of mathematical concepts. According to *magnitude sense theory*, our understanding of numbers and arithmetic depends on an evolutionarily ancient sensory system that automatically detects variations in magnitudes—and therefore provides internal representations of the natural numbers—without using verbal counting or any other culturally developed tools or strategies (e.g., Halberda et al., 2008). The human repertoire may include both innate and culturally acquired internal representations. However, in this study, we mainly focus on culturally acquired internal representations as described by Goldin & Shteingold (2001).

Methods

The study was designed to investigate how people estimate area. Five adults who had completed higher education (age 24-27, three women) were interviewed while performing estimation tasks on a computer following a think-aloud protocol (Reinhart et al., 2022).

The experiment was programmed with *JsPsych*, a JavaScript library for digital experiments. The tasks displayed a white background with a black square varying in area and rotation between tasks. A red 1-unit square of constant size was visible on the screen throughout the experiment. On each trial, a fixation cross first appeared for 500 ms at the center of the screen, indicating where the participants should place their gaze. Next, the square to be estimated appeared for 300 ms, also at the center, followed by a visual mask and a response box. The purpose of the mask and the short display duration of each square was to study the participants' internal representations by allowing enough time for perception but preventing precise calculations during the presentation. The experiments consisted of 15 trials with squares of varying rotation and varying area from 1 to 2401 units in random order.

During the experiments, the participants were interviewed individually for approximately 25 min. Following Kvale and Brinkman's (2009) framework for qualitative interviews, we used an interview guide to give the participants the same instructions and follow-up questions during the interviews. Before the experiment, the participants were given the following instructions: "We would like you to think aloud as you complete the tasks. This means that we want you to verbalize your thoughts as they occur, regardless of whether you believe your answer is correct or not. Our primary interest is not in the accuracy of your responses but in understanding your thought process as you work through the tasks. This includes any thoughts, even those that might seem insignificant or unrelated". The participants' task was to estimate the area of a black square by answering the question: "If the red square above has an area of 1, what is the area of the black square?". The response time was unlimited, but participants were asked to answer as quickly and accurately as possible.

The interviews were analyzed based on Braun and Clarke's (2006) guidelines for theoretical thematic analysis (TA). Before the analyses, a set of initial codes was adapted from Siegel et al. (1982), Dietrich et al. (2019), and Gandini et al. (2008). Examples of such codes were *eyeball*, *guess*, *counting strategies*, *calculation-based strategies,* and *benchmark comparison*. Subsequently, the interviews were transcribed and read in detail to identify codes relevant to the research question. These codes were extracted either inductively or deductively from the initial codes. In this process, we allowed both *semantic* (i.e., explicit) and *latent* (i.e., interpretative) codes.

After this initial analysis, some codes were combined to form an overarching theme, some were combined to form sub-themes, and others were discarded because of their lack of relevance to the research question. For example, all codes on "comparing" were united into a main theme. The resulting themes were systematically reviewed and assessed for internal consistency by comparing extracts from each code. Next, each theme was defined in an explicit coding guideline (Table 1). The analysis resulted in 5 main themes and 13 sub-themes (Table 2).

The initial steps of the analyses were conducted by the first author alone. To ensure intercoder reliability, twenty extracts were selected randomly by the first author and coded by the second and third authors based on the coding guidelines. The percentage of agreement was 88%.

Table 1: Examples of coding guidelines for two codes

Code	Coding guideline	Examples
Compare current square to previous squares	Use for a comparison with one or more of the previous squares and then adjust their estimate on the current square.	"I think this one is the same one I saw two times ago. The one of 225. It was awfully similar."
Iterating the unit square by counting	Use for counting the number of unit squares that can be placed inside the larger square.	"I am trying to count how many red squares I can fit inside the black one."

Results

The aim of this interview study was to identify how people estimate the area of internally represented squares. We found five main themes and 13 sub-themes of reported area estimation strategies (Table 2), which we describe below.

Table 2: Themes and sub-themes

Theme	Sub-themes	Statements (N)	Persons (N)
Compare to	Mental image, Mental measurement unit, Previous squares, Reference square, Other references on the screen	211	5
Iterating by	Eyeballing, Calculating, Counting	101	5
Sense	Certain, Uncertain	20	3
Spatial transformations	Spatial transformations	13	3
Evoke a visual memory	Successful, Unsuccessful	15	5

Compare

Comparing the square to a reference was the most frequently reported strategy for estimating area based on an internal representation (Table 2). We identified five main types of references: Participants compared the square to (a) previously estimated squares, (b) a measurement instrument, such as a ruler, (c) a mental image, such as an imaginary square, (d) the red unit square provided on the screen, or (e) other references on the screen, such as the text response box.

All the participants reported comparing the current square to previously estimated squares for at least one task (Table 2). They reported comparing it with the first black square they saw, the previous square, or any of the other squares they had seen previously. Interestingly, this suggests that the

participants can recall—at least approximately—what previous squares look like for an extended period of time.

> Participant 5: I want to say that this one also was bigger than the last black one. And since this one was bigger than the last one, then I said four, so it must be more than four, I say six. [comparison to the previous square].

Some participants described how they compared the square to a mental measurement instrument, for example, by mentally measuring the side of the red unit square or the side of the black square to be estimated in absolute units such as centimeters.

> Participant 1: Then I estimate the length of the box to approximately 10 cm.

Some participants reported comparing the squares to a mental image, meaning that they created a mental image used to assess the area of the square.

> Participant 3: Now I must create an image of how big a 25'er can be inside my head, that is, 5x5. And it can be really big. I answer 25 in area, 5 in side length.

The red reference square was also used as a basis for comparison.

> Participant 5: It was bigger than the red one. Quite a lot bigger than the red one, yes. I'm writing 10.

Some participants reported comparing the black square to other references on the screen, such as the response box, the fixation cross, or the entire screen size, to help them estimate the area.

> Participant 4: It takes up so much space. It took up a lot of space between where I write and the top. First, I think it looked like it took up half the space.

Iterating

All the participants reported the iterating strategy for estimating (Table 2). This involves iterating the red unit square to calculate the total area. Through the analysis, we identified three ways of iterating: counting, calculating, and eyeballing.

Some participants reported using the red unit square as a unit and counted how many times it could fit inside the black square.

> Participant 2: I start at the bottom, 1, 2, 3, 4 from the left, I also count 1, 2, 3, 4 upwards.

Others reported calculating strategies, like multiplying the width and the length of the square, often leading to square-number answers.

> Participant 4: 10 times 10, 100! There can be room for 10 of the red on each side, because it was a diamond figure. I can have room for 10 there, and 10 there, of the red one, and then there were 100.

Some reported making a rough, more direct estimate by eyeballing the square.

> Participant 4: Maybe there were 50 small ones inside the big one.

Sense

When the participants could not explain their estimation process, we categorized their strategy as sensing. In some cases, when the participants expressed a feeling or a guess about their answer, we described their estimate as uncertain.

> Participant 2: No, I have no idea. No, I don't know, I think I just have a feeling it was so much bigger and then, I don't know, it's just an assumption, a guess.

In other cases, participants said that they "just knew" or immediately saw the answer, with an expression of certainty.

> Participant 3: Now it's so clear to me, when you hear a word, you don't think about what it means, you just know it. Now I just see that it is a 2x2.

Spatial transformations

When explaining how they compared or iterated, some participants described that they made spatial transformations on the internal representations in their visual memory. That is, some participants described spatially manipulating the elements in their "visual scene".

> Participant 3: If I had a square on the PC, I would have pulled from one corner and pulled up so that a new square appears inside it, the same size that I felt that it was.

Evoke a visual memory

The participants typically reported retaining a memory of the square that they could visualize and refer to after it disappeared from the screen.

> Participant 5: So, I kind of have to remember what it looks like while I try to figure out how big it is. I try to store what the black one looks like inside my head.

Maintaining an internal mental representation of squares allows further cognitive processing, but the participants may lose the visual memory along the way, as illustrated in the following example:

> Participant 4: Now I've forgotten what it looks like.

Personal preferences

Several participants reported adjusting their estimates based on factors unrelated to the square, such as how aesthetically pleasing they found the numbers to be. For example, after making a temporary estimate, participants would round off or adjust the estimate to achieve a "nicer" answer.

> Participant 4: Let's say it was 49, and that's an ugly number, so I'll take 50.

This personal preference strategy is not included as a theme, as it was infrequent and does not explain the actual process of estimation, but rather how an estimate is modified (response bias). All answers were given unprompted as whole numbers.

Discussion

We have investigated how people estimate area from internal representations. The participants reported using several strategies for estimating the area, including retaining a visual image of the

square, comparing the square to previous squares, iterating a unit square to assess the area, directly sensing the area, and using spatial transformations.

The reported strategies include both formal knowledge acquired in school, such as multiplication and counting, and more intuitive skills that may not be explicitly taught, such as visualizing, manipulating, and comparing internal representations of shapes in visual memory. While all representations are important for the teaching and learning of mathematics (Goldin & Shteingold, 2001), further research is needed to determine how much each contributes to students' mathematical achievements. Answers to this question are important because they guide didactical practices, such as whether and how we emphasize internalizing external representations to support mathematical thinking and understanding. For instance, some education programs encourage building intuition through repeated practice on estimation tasks (e.g., Halberda et al., 2008), whereas culturally grounded practices emphasize children's reflection on structure, shape, or pattern to develop efficient strategies and strategy choices.

The results of this study also address the ongoing debate on whether humans have an innate magnitude sense. The magnitude sense is the ability to perceive, discriminate, and estimate continuous quantities such as size, density, and area (Leibovich et al., 2017), and just like our senses for light, smell, and taste, it is sometimes regarded as being an intuitive sense, inaccessible to introspection. Indeed, some participants in this study reported simply having a feeling about the area of a square, consistent with an intuitive magnitude sense. However, in most cases, the participants explained their internal strategies in detail, such as iterating a mental image of the reference square along a mental image of the black square. This result indicates that people primarily rely on cognitive procedures acquired in school to estimate internal representations of area, and that additional research into the mental processes that generate a rapid sense or feeling about a specific area are warranted.

Here, we investigated the internal estimation of squares. Squares are familiar from the school context and often associated with specific, learned formulas. This likely influenced the results, as participants often reported using school-learned procedures such as counting and multiplication. Thus, to validate the results reported in this paper, it would be valuable to investigate how people change their area estimation strategies depending on the shapes, e.g., in tasks involving arbitrary closed shapes. This replication can help identify whether participants use more sophisticated school measurement procedures, or whether participants are inclined to rely more on their basic mental visualization skills.

[5]Leibniz University Hannover, Faculty for Mathematics and Physics, Germany

This paper reports on the work of the Thematic Working Group 25 (TWG25) at CERME14, focused on the teaching and learning of Calculus. It explores the challenges related to conceptual understanding, formalization, institutional constraints, and interdisciplinary applications. TWG25 contributions covered a range of topics from real numbers to single and multivariable Calculus, integrating theoretical perspectives such as APOS theory, ATD, and Commognition. The report highlights innovative task designs, technological tools, and implications for instructional practices in diverse educational contexts.

Keywords: Calculus, Conceptual understanding, Task design, Institutional factors, Mathematics education.

1. Introduction and scope of the Working Group

The Thematic Working Group 25 (TWG25) on the Teaching and Learning of Calculus is a new group proposed in order to create a new community that investigates the teaching and learning of Calculus both at secondary and tertiary level, and at the transition between secondary school and university. Calculus plays a key role in mathematics education, both for its interesting features *per se* – difficulties in learning Calculus and infinitesimal processes have been investigated since the 70s' – and for its transversal role in society. Due to its powerful concepts, tools and theories developed to deal with graphs, variations, trends, and accumulation processes, Calculus is relevant for many other disciplines and professional fields (the so-called *non-mathematicians*) and is taught in most countries at secondary school, college and in the first year of university. The undoubtable value and flexibility of Calculus in modelling practices and in the conceptualization and formalization of several real-world problems does not turn into the recognition of its values by many teachers and students. Addressing the issue of teaching Calculus to most students in several different contexts is challenging. Indeed, its intrinsic complexity— including semiotic, conceptual, and argumentative aspects—combined with the didactical habit to formalize from the very beginning its notions, moving to merely procedural computational tasks or to theoretical issues, usually leads students to experience several difficulties (Trigueros et al, 2021; Biza et al., 2022).

The difference between the conceptual and semiotic aspects of key notions like continuous function, derivative, integral, limit, and the formal and theoretical evolution of their definitions and properties is often stressed using two different terms – Calculus and Analysis – to refer to different mathematical practices and the related didactical issues. Separating Calculus and Analysis sharply and definitively is not easy and can, in some sense, be misleading. A relevant and rather interesting attempt has been made by Bergé (2008), who identified some features of Analysis that are meaningful to distinguish from Calculus from the educational point of view, since they have an impact on curricula at secondary and college level and on syllabi of university courses in different countries. In Analysis, the notions and main concepts are the same as in Calculus but the attention is posed to generalization and formalization using limits and to theoretical issue; the presence of theorems and their proofs, the use of the epsilon/delta formalism to formulate definitions and in the proofs of theorems and the use of generalized notion of functions are examples of the switch from Calculus to Analysis courses. To clarify precisely what Calculus is, and what is not, is less clear and deserves careful attention, in particular from the educational point of view. Indeed, while Analysis is related to more traditional habits of mathematicians to organize and teach advanced knowledge in their field, Calculus teaching should pay more attention to the meaning of mathematical concepts at stake.

2. The main motivations to propose a new group on Calculus

There are at least two motivations to make an effort to create a new community on the teaching and learning of Calculus. First of all, it is necessary to provide new research, both empirical, practice-based and practice-oriented, and theoretical, to grasp the main variables affecting the conceptualization process, in particular the phase of representation and interpretation, that is necessary to ground the formal knowledge on strong and appropriated personal meanings. The disconnection between concept image and concept definition (Tall & Vinner, 1981), the need to connect the three worlds of mathematics (Tall, 2013; 2004), the rupture between manipulation of symbols and reasoning are solid findings and many undesired effects due to promoting the learning of Analysis without a meaning-making process and conceptual regulation processes behind have been documented by several researchers (e.g. Dreyfus, 2002; for a systematic review Bressoud et al., 2016).

The second motivation is that pre-Calculus reasoning and notions and other Calculus-related advanced mathematical practices (multivariable Calculus, modelling processes based on rate of change and accumulation) have specificities that usually are lost while moving to the formal world of Analysis and can not be simply disregarded as informal knowledge and processed to be refined or formalized as soon as possible pursuing mainly the formal rigor (Bressoud et al., 2016; Martínez-Planell & Trigueros, 2021).

Several contributions on Calculus had been proposed in other groups (in particular, TWG14 on University Mathematics Education), but some specificities were not addressed

in a systematic and pertinent way. The main motivation for proposing a thematic group on the teaching and learning of Calculus is precisely to clarify the specificities of the challenges related to its teaching and to explore ways to support meaning-making processes. This is seen as a strategy to address the deep institutional issue that underlies students' persistent failure in the learning of Calculus at secondary and tertiary levels, in particular in courses aimed at non-mathematicians.

The group inherits the work developed by researchers who worked on this topic for several years, including the Calculus and Analysis working groups attending the INDRUM conference (Trigueros et al., 2021; Hanke & Martínez-Planell, 2024) and the Calculus Conferences (CalcConf1 in 2019 in Norway; CalcConf2 in 2023 in Norway and CalcConf3 in 2025 in Italy) and new fresh perspectives by researchers of several countries with different theoretical perspectives and goals.

3. State of the art about the teaching and learning of Calculus

Recent literature stressed that these issues, that mainly regard the epistemic and cognitive level, are intertwined with institutional, linguistic and affective variables that make the challenge even harder to address. The main results are summarized in a chapter of the first handbook about the INDRUM community (International Network on Didactics of University Mathematics), resuming the current challenging issues university mathematics education is facing (Durand-Guerrier et al., 2021) – in particular by Trigueros et al. (2021) – and in the systematic review by Biza et al. (2021). At the institutional level, two important phenomena have been stressed by researchers that have a strong impact on the teaching process and on the analysis of learning outcomes.

Artigue (2016) emphasized that, among the various theoretical perspectives on investigating students' difficulties in mathematics during the transition from secondary school to university—as well as on innovations in university-level mathematics teaching—the institutional dimension has been less frequently addressed in the past. However, over the last two decades, there has been growing attention to the analysis of this aspect. In particular, the research community engaged in the research program developed by Chevallard since the late 1990s—adopting an anthropological perspective on the investigation of mathematical practices within institutional contexts (the Anthropological Theory of Didactic, or ATD; Chevallard et al., 2022)—has made significant contributions to the characterization of mathematical practices at the secondary and tertiary levels across various fields (mathematics, engineering, physics, economics, etc.). A significant contribution is highlighting the mismatches between praxeologies —that is, the structured relationships between tasks, techniques, and their justifications—carried out in different contexts that can be a major source of difficulties for students and teachers. Moreover, these analyses allow the development of new and more suitable teaching praxeologies that fit the educational and didactical purposes of different institutions.

Among many contributions in this direction, the work by Gueudet et al. (2016) is particularly important since the authors highlighted relevant features of such a mismatch at the transition towards university and the related implications for research. A different use of ATD is the analysis of praxeologies across different tertiary institutions, in particular comparing praxeologies and stressing the difference between the structural praxeologies that characterize the world of pure mathematics and the mathematical praxeologies carried out in institutional contexts where mathematical knowledge is intertwined with methods, goals and discourses that has been developed by other professional or scientific communities.

Biza et al. (2021) presented a relevant issue that relates to the intention itself of teaching Calculus to non-mathematicians in courses of the first year and on the assessment practices. Calculus is one of the main causes of dropout. The filtering and scaffolding perspective orient teachers and students towards mathematics teaching and learning in completely different ways. Unfortunately, Calculus is often intended, and used, as a filtering tool to test if students are good enough to attend the university courses. Regardless the features of mathematical practices related to a specific field, the students' interests and needs, Calculus is taught in a "standard" way, without any attempt the reconstruct mathematical praxeologies to better fit the needs of the students or the purposes, or to take care of those linguistic or affective needs of the students that educators need to consider in order to make Calculus meaningful to different categories of students. Taking into account these needs would turn Calculus concepts and praxeologies into scaffolding thinking tools that support students in their journey as university students. Moreover, the timely problem of inclusion and diversity in Calculus teaching and learning, that deserves particular attention in courses for *non-mathematicians* (Diaz-Eaton et al., 2019) and needs suitable lenses to be framed and investigated, is still underexplored in mathematics education.

Even if in recent times more attention has been posed to these issues and more research has been developed that can support innovation in the teaching and learning of Calculus at secondary level (Biza, Gonzales-Martin & Pinto, 2022) more research is needed in order to investigate the learning processes more deeply and design and implement more effective teaching-learning activities at secondary and tertiary level to accompany the students in a smooth and meaningful learning experience across different institutions.

4. Overview of TWG25: research *foci* and theoretical perspectives

In this contribution, we summarize how the papers presented in TWG25 contributed to addressing these challenges, combining different theoretical lenses and addressing several of the aspects highlighted in the literature, and the new issues that emerged during the discussion groups that opened up new avenues for research. The group brought together a broad range of research contributions focused on the learning and teaching of calculus, bridging foundational secondary-level concepts and advanced topics in tertiary education.

The authors addressed the development of students' understanding of key calculus ideas and examined instructional practices, theoretical frameworks, and methodologies that inform this field, building on research traditions spanning decades while responding to current curricular, technological, and interdisciplinary demands. Several contributors emphasized the importance of early conceptual readiness, focusing on variables, covariation, functional thinking, and graphical reasoning. These ideas form the cognitive substrate for understanding the rate of change and accumulation—central themes in calculus. Some papers deepened core topics such as the derivative as rate of change, the integral as accumulation, differentials, and the continuity and integrability of functions.

Among the diverse contributions to TWG25, we can identify three macrocategories: students' conceptualization of properties of real numbers relevant to Calculus; single variable Calculus; and multivariable Calculus.

Concerning students' conceptualization of real numbers, Borji and colleagues used the Schema part of APOS theory to analyze the convergence of infinite series of real numbers and the role of partial sums, identifying persistent challenges in students' understanding and highlighting tensions between formal definitions and intuitive conceptions of infinite series. Grisendi and Asenova investigated upper-secondary students' spontaneous conceptions of the density of $\mathbb{Q}$ in $\mathbb{R}$, an underexplored yet crucial topic for understanding continuity in Calculus. Using a classroom activity on continued fractions and thematic analysis of student responses, they reveal diverse, dynamic reasoning processes.

The notion of derivative received significant attention. Weigand and colleagues explored students' interpretations of this core concept, using the lens of Basic Mental Models analyzing how graphical and dynamic representations influence their evolving understanding. Nguyen and Greefrath contributed two studies on the same topic: one examined students' conceptualizations of derivatives using technology-enhanced environments, and another explored the affordances of dynamic representations in fostering deeper engagement with rate-of-change concepts. Lax and colleagues addressed students' thinking around continuity and accumulation, stressing the importance of connecting procedural fluency with a more grounded conceptual awareness of accumulation processes over time or space.

Gunia and Knipping analyzed the design and implementation of qualitative-graphical tasks in calculus classrooms. Their study emphasized the potential of such tasks to promote flexible mathematical reasoning and to shift learners away from narrow algorithmic approaches. Elias and colleagues explored the role of extra-mathematical contexts in supporting students' interpretations of derivatives as rates of change, demonstrating that real-world modeling can deepen students' grasp of abstract concepts by anchoring them in meaningful experiences.

Abed and colleagues presented a comparative case study of two teachers' instructional approaches to the derivative, linking their pedagogical choices to distinct mathematical worldviews and highlighting the impact of epistemological beliefs on teaching practices. Tasara and Monaghan scrutinized teachers' use of notation for gradients, revealing inconsistencies that could hinder students' conceptual clarity and pointing to a need for greater coherence between symbolic language and instructional intent. Finally, Izsak explored the teaching of inverse proportion and integration by substitution from a measurement perspective, proposing a reconceptualization that emphasizes the role of foundational reasoning structures in supporting students' calculus learning trajectories.

Four papers addressed issues related to Multivariable Calculus: Martínez-Planell and colleagues explored students' understanding of double and triple integrals in rectangular coordinates and proposed a conjectured model of the constructions students may make when learning this topic. Gabel and colleagues addressed the complexities of multivariable limits, reporting the challenges students face when evaluating limits of functions of two variables. Radmehr and Strømskag proposed a study and research paths (SRPs) model tailored to pre-service teachers, emphasizing multivariable functions and mathematical modeling. Lepellere examined the use of GeoGebra applets in the teaching of double integrals, illustrating how dynamic, visual tools can scaffold student reasoning and bridge the gap between symbolic manipulation and spatial intuition.

Some transversal issues emerged that are rather innovative in the field, in particular:

Extra-mathematical contexts: Several papers investigated how calculus is taught and learned in extra-mathematical contexts, including interdisciplinary courses for non-mathematicians, modeling applications, and STEM education. Elias and colleagues for example, highlighted how real-world contexts can support the interpretation of derivatives.

Conceptual challenges in Task Design: Gunia and Knipping analyzed tasks that integrate graphical reasoning, noting how qualitative features promote flexible thinking. Radmehr and Strømskag presented a SRP study for pre-service teachers centered on modeling and multivariable calculus. A recurring issue was calibrating the cognitive demand of tasks—striking a balance between challenge and accessibility.

The role of context and representation: contextualized tasks were shown to aid conceptual development. The use of real-world problems, especially those involving modeling, was seen to support the transition from intuition to formal understanding.

Technology, visualization, and emerging tools: visualization was a key cross-cutting theme. Lepellere demonstrated how GeoGebra can scaffold students' reasoning about double integrals, while Nguyen and Greefrath examined how dynamic representations enhance understanding of derivatives. The difficulty of visualizing 3D motion and accumulation was noted, particularly in student work.

Teacher Knowledge and instructional practice: Abed and colleagues revealed how teachers' mathematical worldviews influence their instructional strategies. Tasara and Monaghan uncovered inconsistencies in teachers' symbolic usage, highlighting a gap between expert knowledge and classroom discourse. Izsak's work on inverse proportion and substitution from a measurement standpoint added further depth to this theme. The findings point to an urgent need for more research-informed professional development.

The contributions showcased a wide range of theoretical perspectives, including APOS theory, Commognition, ATD, Concept Image and concept definition, and Semiotic Approaches. While this diversity enriched the dialogue, it also raised questions about coherence and integration. Participants debated whether future work should aim for theoretical unification or respect and encourage pluralism. Methodologies varied from thematic and content analysis to grounded theory and discourse analysis (Creswell & Poth, 2018). Participants emphasized the importance of aligning research methods with theoretical assumptions. Analysis of students 'scratch work' was highlighted as a valuable yet underutilized method for gaining insight into student thinking. Several recurring cross-cutting themes emerged, with particular attention to:

1. The tension between conceptual understanding and formal definitions
2. The role of visual and embodied reasoning in fostering insight
3. The influence of institutional and cultural contexts on curriculum
4. The need to bridge the research-practice divide
5. The foundational role of pre-calculus knowledge
6. The difficulty in assessing the cognitive demand of calculus tasks

Some participants addressed how calculus serves as a gateway to higher mathematical reasoning, including differential equations. This raised philosophical questions about how calculus differs from formal mathematical analysis, both in practice and epistemology.

During the discussion session, we explored several important research questions and considerations that warrant further investigation. Examples include: How should various institutional conditions (e.g., cultural factors, prior knowledge, and experiences of both STEM and non-STEM students) be taken into account in the teaching and learning of calculus and multivariable calculus? How can we enhance accessibility to calculus education while considering subject-specific norms? Do task design principles in calculus differ from those in other areas of mathematics? If so, what are the key design principles unique to calculus? For instance, what types of contextual tasks are most effective for teaching and learning calculus? Even within calculus, do these principles vary across topics—such as derivatives, limits, and integrals—or do they remain consistent?

5. Conclusion and future directions

TWG25 provided a vivid opportunity for discussing how students come to understand calculus, how teachers facilitate learning through lesson planning—including the design of mathematical tasks—, and how mathematics education researchers can better support both. Future research should deepen its engagement with classroom practice, explore the use of new technologies, refine the theoretical foundations of the field and address the issue of inclusion, in particular in the case of the teaching of Calculus for other disciplines and professional fields. Future research should also consider the future potential of AI and large language models (LLMs) in analyzing student responses and designing adaptive tasks. Cross-institutional collaboration and attention to diverse educational contexts will be key to addressing the evolving challenges in calculus education.

Acknowledgment

We would like to sincerely thank Tommy Dreyfus for his inspiring suggestion to propose a Thematic Working Group on the Teaching and Learning of Calculus. His thoughtful advice and insightful suggestions provided crucial guidance throughout the development of the group and helped shape its identity and research focus.

Comparing two teachers' teaching approaches to the derivative concept with respect to mathematical worldviews

Amira Mohammad Abed[1], Michal Ayalon[1], and Anatoli Kouropatov[2]

[1] University of Haifa, Faculty of Education; amira.m.abed@gmail.com

[2] The Academic College Levinsky-Wingate

Our study explores different teaching approaches to the concept of the derivative in high-school mathematics. In this paper, we employ the Goals-Actions model developed at a previous stage of the study to compare two teachers' teaching approaches to the derivative concept. Specifically, we focus on the mathematical-challenge actions they used before introducing the formal definition of the derivative, considering their respective mathematical worldviews. Our findings reveal notable differences between the two teaching approaches, which in turn offer students varied opportunities to engage with the derivative concept during the initial stages of its instruction.

Keywords: Teaching approach, the derivative concept, analysis, Goals-Actions Model, mathematical worldviews

Introduction

The derivative is a fundamental concept in high-school mathematics and many university courses (Rasmussen et al., 2014). Understanding such a concept is essential for mastering other mathematical concepts; however, many students have difficulty dealing with it, especially in connecting different representations and understanding their broader meaning (Prihandika & Perbowo, 2024). Often, students focus primarily on the technical rules of differentiation (ibid). While most studies on the topic have investigated students' *learning* of the derivative, very few have explored its *teaching* (Rasmussen et al., 2014). The current study addresses this discrepancy by examining various teaching approaches to the derivative concept. Teaching approaches significantly shape how students learn, and the manner in which the derivative is taught in class facilitate students' learning and understanding (Kendal & Stacey, 2000).

Recently, Abed and Ayalon (2021) proposed the 'Goals-Actions Model in Teaching the Derivative Concept', which encompasses teachers' approaches in two key aspects: goals and the actions taken to achieve them. The model identified three categories of actions: those related to mathematical challenge, those demonstrating sensitivity to students, and those focused on managing learning. This paper focuses on the actions related to mathematical challenge used by two teachers, Anna and Maya, before the formal definition of the derivative was introduced in class. Using Grigutsch and Törner's (1998) construct of 'mathematical worldview' to characterize each teacher's approach, we highlight differences in their teaching approaches and the distinct opportunities they potentially offer students to engage with the derivative concept during its initial stage.

Our research question is: *What are the differences between teachers' approaches to teaching the derivative, specifically in relation to the mathematical-challenge actions used during the first stage of the teaching sequence, prior to introducing the formal definition of the derivative?*

Theoretical Background

The Goals-Actions Model of Teaching the Concept of Derivative

An analysis of interviews conducted with ten high-school mathematics teachers in a preliminary study (Abed & Ayalon, 2021) resulted in the development of a model titled by us 'Goals-Actions Model in Teaching the Derivative Concept'. This model encompasses teachers' approaches to teaching the derivative concept in two key aspects: goals and the actions that help achieve them. It comprises three main goals categories, defined via directed analysis, by adapting the Mathematical Potential framework (Leikin, 2021): (1) cultivating students' mathematical abilities connected to learning the concept of the derivative; (2) affording students learning opportunities when teaching the concept of the derivative; (3) considering the emotional elements accompanying the process of learning the concept of the derivative. Additionally, the model includes three main categories for teaching actions, defined via directed analysis using the Teaching Triad framework (Jaworski, 1992; Potari & Jaworski, 2002): (1) actions connected to mathematical challenge in teaching the concept of the derivative; (2) actions related to sensitivity toward students when teaching the concept of derivative; (3) actions connected to the management of learning in teaching the concept of the derivative. For each of the categories there are sub-categories that were identified through inductive analysis.

Apart from the goals and actions identified in the interviews, we found that all the teachers reported using a similar sequence for teaching the derivative concept: (1) the introduction phase, prior to the presentation of the formal definition of the derivative, (2) the presentation of the formal definition of the derivative and arriving at the derivative rules, and (3) the application of the derivative in investigating functions and finding a tangent equation. In this paper, we present two differing approaches to teaching the derivative, identified by applying the model while focusing specifically on the introduction phase, before the formal definition is presented. We chose to focus on this phase because we found that it is less formalized and institutionalized, thus allowing teachers more freedom of action and more space to develop their professional individuality. Within this phase, we concentrate on the category of 'mathematical-challenge actions' in teaching the derivative as outlined in the model.

Mathematical Challenge Actions in Teaching the Derivative

The category of actions related to mathematical challenge in teaching the derivative concept aims to provide students with achievable challenges, encourage conceptual understanding, and foster connections between conceptual and procedural knowledge of the derivative (Abed & Ayalon, 2021). In the initial stage of teaching sequence, before introducing the formal definition of the derivative, the following actions were identified: Generating dilemmas; Repeated practicing of concepts known from the world of functions without referring to their role in drawing graphs of new functions; Using concepts related to functions learned before introducing the derivative to sketch graphs; and Using concepts from the field of physics. Below we provide examples for these categories of actions, categories that will be used to characterize the teaching approaches of the two teachers, Anna and Maya.

Mathematical worldviews

Grigutsch and Törner (1998) identified four aspects that are crucial in shaping the individual's understanding and perception of the nature of mathematics, thereby influencing their mathematical worldview:

The process aspect emphasizes the dynamic nature of mathematics, focusing on its emergence and development rather than viewing it as a static set of axioms and proofs. Mathematics is viewed as an ongoing process involving the exploration of problems and the development of ideas. This process has two important sub-aspects: discovery, which involves finding new knowledge or concepts, and understanding, which involves mastering the material and making connections. Approaching mathematics in this way requires reasoning, creativity, and a willingness to experiment. Teaching the concept of derivative in this way makes learning more exciting and meaningful, moving from passive memorization to active discovery and understanding.

The application aspect highlights the practical utility of mathematics, suggesting that it has direct relevance and applicability. It underscores mathematical knowledge as being beneficial to students in their future lives, aiding in solving everyday tasks and problems, or being useful in virtually every career. Additionally, this aspect points out that mathematics serves a fundamental and broad purpose in society. Teaching the concept of derivative with an emphasis on their practical applications fosters a deeper and more meaningful learning experience. It prepares students not only for academic success but also for real-world challenges, highlighting the significant role that mathematics plays in numerous aspects of life and society.

The schema aspect views mathematics as a comprehensive "toolbox" of schemas and algorithms, focusing on memorizing and applying definitions, rules, and procedures to solve problems. Teaching derivation from this perspective can provide students with a foundational approach to effective problem solving. However, to ensure comprehensive understanding, this approach should be complemented with other aspects that emphasize comprehension, application, and formal reasoning.

The formalism aspect underscores the importance of logical and objective reasoning in mathematics, characterized by its focus on rigor, accuracy, and precision. It helps students develop a thorough understanding of mathematical concepts, enhances their problem-solving and analytical skills, and prepares them for advanced studies and careers in a variety of scientific and technological fields.

In this study, we chose to sort the actions related to the 'Mathematical Challenge Actions in Teaching Derivatives' category in the Goals-Actions model according to the definitions of "mathematical worldview" because we found that each action belongs to one of the worldviews, as explained in the next section.

Methods

This study employs a multiple-case study approach to explore contrasting approaches to teaching the derivative concept. Each case, representing one teacher, is based on the prior work of Abed and Ayalon (2021), allowing for in-depth exploration of individual instructional approaches. We (ibid) analyzed semi-structured interviews conducted with 10 mathematics teachers who teach 10^{th} grade in the advanced track. In this paper, we present two of these teachers: Maya and Anna. Both are

regarded as leading teachers who fill various roles in the Israeli mathematics education community. Anna and Maya are both mathematics teachers, Anna has 30 years of experience and a PhD in mathematics education, and Maya has 20 years of experience and a doctoral student in mathematics education. We focused on these two teachers as they were found to advocate different approaches to the teaching of the derivative concept at the first stage of the teaching sequence.

This study is limited by its reliance solely on teacher interviews without observational data, limiting insights into real-time classroom applications. Nevertheless, where available, interview details provide a richer understanding of each teacher's instructional approach. Specific examples discussed by the teachers have been included to contextualize each teaching approach

Study tools and data analysis

In the current study, we employed two tools: First, we employed the Goals-Actions model as a tool to analyze the interviews conducted with the interviewees and find out the actions in the first stage in the teaching sequence: Prior to the formal definition, which belongs to the "mathematical challenge" category. Second, we constructed an original tool (Table 1) by using the definitions of mathematical worldviews to associate each action with the appropriate worldview. The data analysis was performed with attention to the following two parameters:

1. We determined the time allocated to each stage according to the teacher's statements and according to the "Time allocation for each teaching sequence" section in the theoretical background.

2. We identified (by three steps) the mathematical worldview for the mathematical-challenge actions used in the first stage in the teaching sequence: Prior to introducing the formal definition. First, for each teacher, we identified the actions that belong to the category 'Mathematical Challenge Actions in Teaching the Derivative' in the Goals-Actions model. Second, we used definitions of mathematical worldviews to associate each action with the appropriate worldview according to Table 1. Finally, we identified the actions specifically linked to the first stage of the teaching sequence: prior to introducing the formal definition.

Time allocation for each teaching sequence

In the preliminary study (Abed & Ayalon, 2021) we found that all 10 participating teachers followed a similar sequence when teaching the concept of the derivative. This finding was reinforced by their interviews, where we observed variations in the duration of each stage. Specifically, the initial stage, "Prior to the introduction of the formal definition" varied in length among the teachers. They reported allocating a varying number of lessons to each stage, which we categorized as long, medium, or short duration. These categories reflect the relative importance each teacher places on these stages of teaching the derivative. Time allocation plays a crucial role in shaping mathematics lessons, as it influences both the depth of content coverage and the teaching methodologies used. Research suggests that increased instructional time positively impacts student achievement by providing greater exposure to essential academic skills and knowledge (O'Meara & Prendergast, 2018). The categorization of time allocation in this study reflects each teacher's instructional priorities, indicating 'Long' as exceeding four lessons, 'Medium' as 3–4 lessons, and 'Short' as 1–2 lessons. It represents the level of emphasis each teacher places on the derivative concept. This classification highlights the

differences in pedagogical focus, with 'Long' indicating extensive conceptual exploration, and 'Short' reflecting a more concise introduction. This categorization underscores how instructional time impacts teaching effectiveness and student engagement (O'Meara & Prendergast, 2018).

The connection between the 'Mathematical Challenge Actions in Teaching the Derivative' to the suitable worldview

In this section we will present (Table 1) the actions used by the two teachers, Maya and Anna, and we will explain the reason for associating each action with its corresponding worldview.

Table 1: Associating the 'Mathematical Challenge Actions' to the suitable worldview

Action	Example	Mathematical worldview	Explanation
Generating dilemmas	"Now what happens is that I write some polynomial on the board, usually fourth or fifth degree, and I tell them that I want to draw the graph of this function, and I ask them: what should I do now? … I evoke a need." (teacher Anna)	The process aspect	This action belongs to the process aspect because it describes a discovery, which involves revealing new knowledge or concepts.
Repeated practicing of concepts known from the world of functions without referring to their role in drawing graphs of new functions.	"According to the recommendation of the [Israeli] Ministry of Education, a basic introduction to analysis is taught as positivity and negativity, evenness and oddness … I do a kind of summative reminder of all the pre-analysis that they learned in middle school." (teacher Maya)	The schema aspect	This action belongs to the schema aspect because it views mathematics as a comprehensive "toolbox" of schemas and algorithms, focusing on memorizing and applying definitions, rules, and procedures to solve problems
Using concepts related to functions learned before introducing the derivative to sketch graphs	"So, first we start with a 'pre-analysis' segment; we learn from the quadratic function, absolute value, and polynomials. Basically, we get familiar with functions. We learn about functions in more depth, then we graph polynomials, working on graphs beyond the straight line and parabola. [In this way] we get to know other functions." (teacher Anna)	The process aspect	This action belongs to the process aspect because it highlights the dynamic nature of mathematics, involving continuous problem exploration and idea development. It fosters deeper understanding by promoting mastery of the material and facilitating connections between concepts.

Findings

In this section, we present findings regarding Anna's and Maya's unique approaches to teaching the derivative, specifically in relation to the mathematical-challenge actions used before the formal definition of the derivative is introduced.

Teacher Anna

Below we present a portion of Anna's description of her teaching before introducing the formal definition of the derivative. The index given in parentheses in the citation identifies the statement that will be referred to later in the citation analysis.

> First, I create in the students a sense of need for a new and effective tool like the derivative [i]. I don't just define the derivative as A, B, C, because that would sound completely foreign to them. I structure the classroom discourse so that concepts like the tangent or the slope of the tangent would seem useful from the outset. Therefore, I start by showing them the challenges of drawing a graph without the derivative. How do you draw a graph? We begin with a 'pre-analysis' segment, learning from quadratic functions, absolute value functions, and polynomials [ii]. We familiarize ourselves with various functions, delving deeper into their properties. We graph polynomials and explore graphs beyond just the straight line and parabola, getting to know other types of functions. This introductory phase takes more than two double lessons [iii]. By the end of the process, students understand the need for the tangent slope and begin searching for it. As we try to get as close as possible to the tangent slope, we naturally arrive at the formal definition of the derivative, through the concept of the limit of the difference quotient.

We can see that Anna uses two actions (i) *Generating dilemmas* and (ii) *Using concepts related to functions learned before introducing the derivative to sketch graphs*. From our point of view, as presented above, these actions are consistent with the *Process aspect* worldview according to the definition of this aspect (Table 1). The time allocation for this stage (iii) is considered "long".

Teacher Maya

Maya described her teaching before introducing the formal definition of the derivative:

> Following the Ministry of Education's recommendation, we start with a basic introduction to analysis, covering topics like positivity and negativity [of a function], evenness and oddness … [i]. This pre-analysis connects students to concepts they had learned previously, during the 9th grade. After 3-4 lessons [ii], we move on to the definition of the derivative. I also explain that when the function increases, the derivative is positive, and vice versa.

Table 2: **The differences between Anna's and Maya's teaching approaches, in the first stage**

	Anna	Maya
Actions	- Generating dilemmas - Using concepts related to functions learned prior to introducing the derivative to sketch graphs	Repeated practice of concepts known from the world of functions without referring to their role in drawing graphs of new functions
Mathematical worldview	The Process aspect	The Schema aspect
Time allocation	Long	Medium

We can see that Maya uses one action in this stage (i) *Repeated practicing of concepts known from the world of functions without referring to their role in drawing graphs of new functions*. From our

point of view, as presented above, this action is consistent with the *Schema aspect* worldview according to the definition of this aspect (Table 1), unlike Anna who uses two actions which belong to the *Process aspect*. Furthermore, the time allocation for this stage (ii) is considered "Medium". Table 2 summarizes the different teaching approaches of Anna and Maya.

Discussion

Recent studies on teaching the derivative concept highlight innovative strategies and challenges in student comprehension, providing a foundation for analyzing pedagogical approaches like those of Anna and Maya. These studies emphasize the importance of active learning, meaningful learning, and the use of technology in enhancing students' understanding of derivatives. The integration of these strategies can significantly impact students' conceptual understanding and application of derivatives in various contexts (Chavan & Kadam, 2022; Fazio, 2020). This study demonstrated differences between Anna's and Maya's approaches to teaching the derivative during the first phase, prior to introducing the definition of a derivative. In our interpretation, Maya's approach is related to the schematic mathematical worldview insofar as she focused on memorizing and applying definitions, rules, and procedures to introduce the derivative concept. In contrast, we regard Anna's approach as being related to the process mathematical worldview as she introduced the derivative concept in such a way that the students felt that there is missing information and felt the need for a useful tool to help them to be able to sketch any function graph. Following Grigutsch and Törner (1998), we argue that Anna's approach can imply more exciting and meaningful learning for students as it suggests moving from passive memorization to active discovery and understanding; furthermore, she provides her students with a foundational approach to effective problem solving. Maya, however, needs to ensure comprehensive understanding, so her approach should be complemented with other aspects that emphasize comprehension, application, and formal reasoning. Maya allocated a "Medium" time, i.e., 3-4 lessons, to teaching this phase, whereas Anna allocated a "Long" time, i.e., more than four lessons, to teaching this phase. Referring to the literature (O'Meara & Prendergast, 2018), we may conclude that Anna's approach is deeper, and the breadth of content coverage and the teaching methodologies employed surpass Maya's approach. This is because Anna spent more time introducing the derivative concept to her students, and it is generally observed that a longer allocated time may be associated with improved student achievement, as it provides more opportunities for exposure to key academic skills and knowledge development. It seems, therefore, that these two teaching approaches differ in terms of the opportunity provided to students to process and attain a sense of the importance of the concept of the derivative and build a need for using it, before presenting them with its formal definition.

The findings suggest that process-oriented teaching approaches, as demonstrated by Anna, may enhance conceptual understanding by fostering a sense of discovery. In contrast, schema-focused approaches, like Maya's, could benefit from additional application-based elements to enhance comprehensive understanding. These findings highlight potential areas for further research into balancing process and schema-based approaches in derivative teaching.

Our next step in the continuation of this research is to analyze interviews with additional teachers, focusing on the entire sequence for teaching the derivative concept, to explore further variations in

teaching approaches. Additionally, we are interested in examining whether expanding the study to different contexts and countries might reveal connections between teaching approaches and socio-cultural factors. Such an analysis could provide deeper insights into how local educational traditions, teacher beliefs, and classroom dynamics influence the teaching and learning of the derivative across diverse educational systems.

Students' understanding of partial sums and convergence of infinite series

Vahid Borji[1], Rafael Martínez-Planell[2] and Martin Rmoutil[1]

[1]Charles University, Faculty of Mathematics and Physics, Department of Mathematics Education, Prague, Czech Republic; borji@karlin.mff.cuni.cz

[2]University of Puerto Rico at Mayagüez, Puerto Rico

The research literature shows that calculus students often struggle with infinite series due to the abstract nature of convergence and the complexities involved in defining and determining their sum. We used APOS theory to explore students' understanding of two important notions related to infinite series: sequence of partial sums and convergence. We designed a genetic decomposition (GD) grounded in the concept of Schema to conjecture cognitive structures and relations students might develop to understand infinite series. The GD was evaluated through semi-structured interviews with twelve students who had completed a calculus course. We used the data to exemplify the types of constructions observed based on the APOS notions of Schema, the Schema-triad, and the types of relations between Schema components. This study contributes to a better understanding of the notion of Schema in APOS theory, focusing on infinite series, and has implications for teaching practice.

Keywords: Calculus, infinite series, partial sums, schema, APOS theory.

Introduction

Incorporating infinite series into mathematics education builds a strong foundation for students, preparing them for more complex topics and real-world applications. Studying infinite series helps students grasp the concepts of limits and convergence, which are essential for calculus and analysis. Many advanced topics, including Fourier series, power series, and Taylor series, rely on the principles of infinite series. Working with infinite series enhances analytical thinking and problem-solving skills. It involves understanding the behaviour of sequences and series, performing algebraic manipulations, and applying various convergence tests. However, the research literature shows that students struggle to learn infinite series (e.g., Eckman & Roh, 2024; Martínez-Planell et al., 2012). Generally, infinite series questions can be categorised into two distinct scenarios. The first involves students working solely with the sequence of terms a_n, for example, using the root test $\lim_{n\to\infty} \sqrt[n]{a_n}$ to determine convergence, while the second requires students to utilize the sequence of partial sums S_n, for example, deriving a formula for the sum of a geometric series.

Martínez-Planell et al. (2012) showed that students may construct two fundamentally different notions of infinite series: one as an infinite, unending process of addition (SERLIST) and the other as a sequence of partial sums (SERFUNC). They argued that students have difficulty understanding series as a sequence of partial sums, leading to challenges in problem situations requiring this interpretation. In a case study, Eckman and Roh (2024) investigated understanding of the sequence of partial sums and the importance of this notion in learning infinite series. Their results corroborated Martínez-Planell et al.'s (2012) description of two distinct student interpretations of partial sums, ranging from considering partial sums as an additive process to viewing them as a function with a

corresponding rule. We build our study on these ideas using the notion of Schema of APOS theory to further investigate students' understanding of infinite series. This study aims to address the following research question: What kind of cognitive insights on infinite series conceptualisation can be gained from students' Schema development?

Theoretical framework

We use Action-Process-Object-Schema (APOS) theory as outlined by Arnon et al. (2014), with particular emphasis on the notion of Schema. Given that the APO portion of the theory is well-established, we will focus on explaining the Schema component. A Schema is a coherent collection of Actions, Processes, Objects, and other previously developed Schemas, connected by various types of relations, that individuals apply when encountering a problem situation. A Schema can be considered coherent when its different components are interrelated in a way that allows the individual to discern between those problems that are within its scope and those that are not.

To study Schemas, researchers may begin by defining the component structures of the Schema and describing the interrelations between these components that students need to construct to understand the didactic phenomenon being examined (Trigueros, 2019). Relations constructed between the components of a Schema can be classified as correspondence, transformation, or conservation relations. A *correspondence relation* occurs when the individual notices out of habit or repetition that, in some circumstances, one or more component structures are used in relation to another but cannot yet justify the relation, or when he/she superficially compares some Schema's components in terms of differences and similarities. A *transformation relation* is evidenced when an individual discovers that changes in one Schema component induce changes in other components and can identify groups of related structures. This occurs when one component mediates or is applied to explain or justify the relation between two or more other components. A relation between components is considered a *conservation relation* when it is consistently and normatively used across various problem situations, allowing one structure to be interchangeably or fluently used in place of another. The development of Schema can be examined through the Triad model (Piaget & García, 1983), which includes a three-level developmental mechanism: Intra-, Inter-, and Trans-. We will consider that a Schema is at the Intra-stage of development when its components are unrelated or mostly related by correspondence relations. A Schema is deemed to be at the Inter-stage of development when relations among most Schema components are constructed, and and these are mainly transformation relations. At the Trans-stage of Schema development, most components of the Schema are interrelated through conservation relations, and there is evidence of Schema coherence.

Methodology

Based on the research methodology of APOS theory, we designed a preliminary genetic decomposition and then created questions for semi-structured interviews to test it. Each researcher analysed students' constructions, followed by discussions to share and negotiate their analyses until a consensus was reached. Genetic Decomposition (GD) is a foundational notion within APOS theory. It serves as a conjectural model for how students may learn a particular mathematical concept and, in the APO portion of the theory, is described using APOS structures and mechanisms. When considering Schemas, a GD is represented as a list of component structures, a description of relations

between them, which students are expected to construct, and the stages of Schema development. We consider the following components for the Infinite Series Schema and add, in parentheses, a code to identify them and subsequently to determine the relations among those components.

- Sequence (Seq) as an Object. This includes a SEQLIST object (McDonald et al., 2000) that allows students to think of a numerical sequence as an infinite list of numbers and a SEQFUNC object that allows students to think of a sequence as a function with domain in the natural numbers.
- Limit of sequence (Lim) as a Process, including the definition of convergence and basic properties of limits.
- Finite sums and sigma notation (FS) as a Process that allows students to imagine forming finite sums and representing them with sigma notation without having to do so explicitly.
- Convergence tests (CT) sub-Schema consisting of Actions, Processes, and/or Objects corresponding to the different convergence tests.

The following are the proposed relations between Schema components that students are expected to construct. Note that each relation includes a code in parentheses to designate it. This code was used in our data analysis.

- Sequence and limit of a sequence (Seq-Lim): This relation is evidenced by thinking of a series as an infinite, unending process of adding terms. This is the construction called SERLIST in Martínez-Planell et al. (2012).
- Sequence and finite sums and sigma notation (Seq-FS): evidenced by relating the sequence of terms a_n and sequence of partial sums S_n, by obtaining one from the other in any representation.
- Finite sums and sigma notation, sequence, and limit of a sequence (FS-Seq-Lim): evidenced by students' recognition that the convergence or the sum of a series can be determined by taking the limit of the sequence of partial sums, that this limit (when it exists) may be denoted by $\sum_{n=1}^{\infty} a_n$, and that this same symbol may be used to denote the corresponding sequence of partial sums (a completely different object). This is the construction called SERFUNC in Martínez-Planell et al. (2012). This construction may also be evidenced by the recognition of using partial sums to find an overestimate or underestimate of the sum of a series (e.g., alternating series).
- Sequence and convergence tests (Seq-CT): evidenced by classifying different types of series (e.g., geometric, p-series, telescoping, alternating) based on the sequence of terms with the intention of applying a convergence test.
- Limit of a sequence, sequence, and convergence tests (Lim-Seq-CT): This relation can be evidenced by students' use of limit on the sequence of terms a_n to test for divergence and other tests such as comparison, limit comparison, ratio, and root tests. In establishing this relation, the student may think of an infinite series of numbers as an infinite sum, as described by the SERLIST construction described in Martínez-Planell et al. (2012).

The Schema's development can be described as:

Intra-Infinite Series stage. The student may demonstrate isolated components and has established only correspondence relations between some of them, if any.

Inter-Infinite Series stage. The student has started developing transformation relations between the Schema components. These relations are evidenced by explanations and using one component to justify the relation between other components. The use of these relations is mostly according to normative practice but might be inconsistent in different problem situations.

Trans-Infinite Series stage. Conservation relations interrelate all Schema components. These relations may be evidenced by their fluent use consistent with normative practice across different problem situations, as well as the student's ability to implement and clarify a suitable strategy based on the characteristics of the problem. The coherence of the Schema is manifested by flexibly using either SERLIST or SERFUNC conceptions whenever applicable or necessary.

Twelve students, spanning the range from above-average (3 students), average (6 students), to below-average (3 students), as chosen by the professor, were interviewed three weeks after completing a lecture-based calculus course (involving the topic of sequences and infinite series) at a top-tier university in Czechia. Each interview lasted approximately one hour and was video and audio recorded. The interview instrument consisted of eight questions, some of which were multipart. In this report, we will be referring to the following questions. Their description is followed by the codes of the relations in the GD they were intended to examine.

Q1.a. What does it mean when it is said that "an infinite series converges or diverges"? [Seq-Lim, FS-Seq-Lim]

Q3.a. Consider the infinite series $\sum_{n=1}^{\infty} a_n$. The graph of the sequence of the terms a_n is presented in Figure 1. Is the series $\sum_{n=1}^{\infty} a_n$ convergent or divergent? [Lim-Seq-CT, Seq-Lim, FS-Seq-Lim]

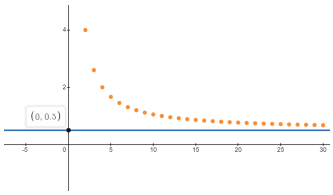

Figure 1: The graph of the sequence a_n

Q4. Given $\frac{1}{(1)(3)} + \frac{1}{(3)(5)} + \frac{1}{(5)(7)} + \cdots$. Let S be the sum of this series. Consider the following two arguments: a) The sum S of the series may be written as $S = \left(\frac{1}{1} - \frac{2}{3}\right) + \left(\frac{2}{3} - \frac{3}{5}\right) + \left(\frac{3}{5} - \frac{4}{7}\right) + \cdots = 1 + \left(-\frac{2}{3} + +\frac{2}{3}\right) + \left(-\frac{3}{5} + \frac{3}{5}\right) + \left(-\frac{4}{7} + \frac{4}{7}\right) + \cdots$ and one obtains that $S = 1$. b) $S_1 = 1 - \frac{2}{3}$, $S_2 = \left(1 - \frac{2}{3}\right) + \left(\frac{2}{3} - \frac{3}{5}\right) = 1 - \frac{3}{5}$, $S_3 = \left(1 - \frac{2}{3}\right) + \left(\frac{2}{3} - \frac{3}{5}\right) + \left(\frac{3}{5} - \frac{4}{7}\right) = 1 - \frac{4}{7}$, each of these partial sums may be written as $S_n = 1 - \frac{n+1}{2n+1}$, therefore, $\lim_{n\to\infty} S_n = S = \frac{1}{2}$. We have seen that for the series $\frac{1}{(1)(3)} + \frac{1}{(3)(5)} + \frac{1}{(5)(7)} + \cdots$, two results have been found: 1 and $\frac{1}{2}$. Is it possible that the series has two values? Clarify this situation. [Seq-Lim, FS-Seq-Lim]

Q5. If the nth partial sum of a series $\sum_{n=1}^{\infty} a_n$ is $S_n = 3 - n2^{-n}$, a) find a_n [Seq-FS] b) and $\sum_{n=1}^{\infty} a_n$. [FS-Seq-Lim]

Results

After analysing all the interviews, eight students were categorised in the Intra stage and four students in the Inter stage of Infinite Series Schema development. There were no students at the Trans stage. First, we examine Hana at the Intra stage, representing eight students, and then David at the Inter stage, representing four students. These two serve as paradigmatic examples of students whose Schemas were classified in the same category. In Q1.a, in which students explained their meaning of convergence or divergence of infinite series, Hana responded as follows:

> Hana: If the sum of all terms of the series equals a real number it converges, but if this sum equals ∞ it diverges. Usually the sum of an infinite number of terms is ∞ so they often diverge to infinity, but for some infinite series, like geometric series, we have a formula to find the sum as a real number. When we don't have a formula, it's very difficult to find the sum.

Hana explained the infinite series as the addition of infinitely many terms, showing evidence of the relation Seq-Lim. She understands that for some series, a direct formula can give their sum but does not mention the possibility of examining the sequence of partial sums in the absence of a formula. Her insistence on finding the sum of the series by adding all the terms or using a direct formula suggests that she has not constructed the relation FS-Seq-Lim. In Q3.a, where the graph of terms a_n was represented, Hana explained:

> Hana: Based on the graph, we can see the terms of the series become smaller and smaller, umm when we add them, the sum will have an upper limit. Therefore, the series converges to this upper limit.

We expected to see evidence of the relations Lim-Seq-CT, Seq-Lim, or FS-Seq-Lim in students' answers to Q3.a. Hana only demonstrated the relation Seq-Lim, but as a correspondence relation. She believed that the sum of an infinite number of decreasing terms, all of which are greater than 0.5, has an upper boundary. Now we consider Hana's response to Q4 (two values for the infinite series):

> Hana: I think the first one is correct because we are adding all the terms to find the sum. The second one isn't correct because instead of adding all the terms it used taking the limit of a sequence.

Hana once again (as in Q1.a and Q3.a) showed that she thinks of the value of the infinite series as the sum of its terms, providing evidence of the relation Seq-Lim. Even though a solution through partial sums was provided in the second solution, Hana's response further clarifies that she has not constructed the relation FS-Seq-Lim to see the sum of the infinite series as the limit of partial sums. In Q5 (finding a_n and the sum of the series through S_n), Hana responded as follows:

> Hana: I don't know how to find a_n, I only know that S_n is the sum of a_1 to a_n, the sum of this series is the sum of all of its terms, when we don't have a_n I don't know how to find the sum.

Hana was not able to find a_n from S_n, indicating she has not constructed the relation Seq-FS. Her understanding of infinite series is limited to the addition of infinitely many terms, as shown in all of her responses. Overall, considering Hana's responses to all the questions, which we did not have space to include in this paper, Hana showed evidence of having constructed some relations between Schema components, all of them as correspondence relations (e.g., Seq-Lim), while some components remained unrelated. We therefore concluded that Hana evidenced an Intra-Infinite Series

stage of Schema development. Overall, the students at the Intra stage encountered two significant cognitive challenges regarding the nature of series convergence. Some students believed that when terms in a series approach zero (i.e., $\lim_{n\to\infty} a_n = 0$), the accumulated sum would still increase indefinitely, meaning the series could not stabilize or converge. This misconception led them to wrongly conclude that a convergent series like $\sum_{n=1}^{\infty} \frac{1}{10^n}$ would diverge because the accumulated sum was perceived as perpetually increasing. Other students assumed that if a sequence a_n decreased and converged to a specific value, then the series must also converge. They believed that the decreasing nature of the terms would create an upper limit for the series, thus stabilizing the accumulated sum and causing convergence. They might mistakenly apply it to any series with decreasing terms, such as the harmonic series, which, despite smaller terms, actually diverges.

Now we consider David to represent the constructions of the students at the Inter-Infinite Series Schema development. In Q1.a (convergence and divergence of infinite series), David responded:

> David: If the limit of the sequence of partial sums of an infinite series is equal to a real number, I mean if it's a value, which is not ∞ or $-\infty$ then the series converges. If this limit is ∞ or $-\infty$ or doesn't exist the series diverges.

David clearly explained the convergence of a series by taking the limit of the sequence of partial sums. Furthermore, he was able to justify the conditions for divergence. This is consistent with having constructed the relation FS-Seq-Lim. In Q3.a, where the graph of the sequence a_n was given, David showed the construction of other relations:

> David: Here, we have terms a_n, umm they all are bigger than 0.5 but approach 0.5, so we have infinitely many numbers bigger than 0.5 so the sum of an infinite number of them can be as large as we want, approaching ∞, so the series diverges, or as a second solution we can use the test for divergence we can see $\lim_{n\to\infty} a_n$ is 0.5, umh it's not zero, therefore the series is divergent.

David first thought of a series as adding infinitely many terms of the sequence a_n, and using this construction (unlike Hana), he was able to explain why the series diverges. This gives evidence of the construction of the relation Seq-Lim. As his second solution, he realized the possibility of using the test for divergence by relating the components of limit of a sequence, the sequence, and convergence tests. This shows that in this question he related the components Lim-Seq-CT. Regarding Q4 (two sums for an infinite series), David explained as follows:

> David: It's not possible to compute the sum of infinitely many numbers of terms a_n just by adding, one by one umh the first solution isn't correct because we are ignoring something in infinity, umh to find the sum of the infinite series we need to find the sequence of partial sums and take the limit of S_n like the second solution, therefore the sum is $1/2$.

Once again, David demonstrated a SERFUNC construction of infinite series (Martínez-Planell et al., 2012) by justifying the computation of a series' sum through the limit of partial sums and highlighting the impossibility of summing an infinite number of terms directly. This question (along with Q1) suggests that David has constructed the relation for determining convergence or computing the sum of a series (FS-Seq-Lim) as a transformation relation. We continue the analysis of David's answers by examining his responses to Q5.a (finding a_n from S_n) and Q5.b (finding the sum of the infinite series using S_n).

David: [5.a] When we have a_n it's usually possible to find S_n by adding the first n terms, umh but I don't know how to find the general formula for a_n directly from S_n, umh maybe I can give some values to n and find a_1, a_2, a_3 and so on to find a pattern for a_n [David found $a_1 = 5/2$, $a_2 = 0$, $a_3 = 1/8$, $a_4 = 1/8$, $a_5 = 3/32$] but I can't find any pattern.

David: [5.b] We can find the sum of the series by taking the limit of its partial sums, the limit of $3 - n2^{-n}$ when n approaches infinity is 3 minus I think 0, because $n2^{-n}$ is n over 2^n and the geometric sequence 2^n grows much faster than the arithmetic sequence n, umh so the fraction $n/2^n$ approaches 0, therefore the sum is 3 minus 0 which is 3.

In part 5.b, David provided more evidence of the relation FS-Seq-Lim as a transformation relation. However, when asked to find a_n from $S_n = 3 - n2^{-n}$ (part 5.a), he demonstrated a correspondence relation between the components of sequence and finite sums and sigma notation (Seq-FS). David attempted to numerically determine the first few terms of the sequence a_n to identify a pattern for a general formula of a_n, but he was unsuccessful. For a student who has established a conservation relation between the previously mentioned structures (Seq-FS), computing a_n from S_n would be the same as finding a_2, a_3 and so on, by calculating the difference between the $(n-1)$th partial sum and the nth partial sum (i.e., $a_n = S_n - S_{n-1}$). However, David failed to establish this relation because in computing a_1, a_2, and a_3 he used the extended formulas $S_1 = a_1$, $S_2 = a_1 + a_2$, $S_3 = a_1 + a_2 + a_3$, rather than the difference between two consecutive terms of partial sums (e.g., $S_3 - S_2 = a_3$). In other questions not included in this paper, David showed evidence of the relations Seq-CT (recognizing the type of series based on the form a_n) and Lim-Seq-CT (applying suitable convergence tests by working with a_n) as transformation relations. In summary, considering David's responses to all questions, we can argue that the different Schema components were interrelated, some through correspondence relations and most through transformation relations. This led us to conclude that David demonstrated the construction of an Inter-Infinite Series stage Schema.

Discussion and conclusion

Considering that no student showed evidence of being in a Trans-Infinite Series Schema development and that eight out of twelve students were at the Intra-stage, it can be concluded that students have difficulties learning the notion of infinite series. Most participating students in our study interpreted the infinite series as an unending process of addition. This led them to fail to understand the sum of an infinite series as the limit of partial sums and, therefore, not construct the relation FS-Seq-Lim. Although some students, like David, used the interpretation of partial sums in their responses, none of the students were able to find a_n directly from S_n (in Q5), evidencing that they had not constructed the relation Seq-FS as a conservation relation. Some other difficulties frequently observed in this study include students' problems classifying the series based on the form of a_n (Seq-CT) and using a suitable convergence test (Lim-Seq-CT). The results suggest that to improve teaching practice, activities should be developed to help students construct the relations Seq-FS and FS-Seq-Lim and that more work is needed on the relations Seq-CT and Lim-Seq-CT.

Although we did not have any students at the Trans-stage of the Infinite Series Schema, a potential student at this stage, like an expert, would be able to flexibly determine when to work with the sequence of terms a_n and when to work with the sequence of partial sums S_n. In the former case, the expert would recognize the need to apply relations like Seq-Lim, Seq-CT, or Lim-Seq-CT, as in Q2,

where taking the limit of a_n helps assess the convergence of the series. In the latter case, the expert would understand the need to use relations such as Seq-FS or FS-Seq-Lim, as in Q4, where considering partial sums and taking their limit is essential to finding the series' sum. David mostly demonstrated this flexibility, except for finding a_n from S_n, and was able to transition between these two approaches based on the type of question.

The fact that Schemas were used in the analysis is in itself a contribution of this study, as it helps clarify the different theoretical notions involved. Our study extends the research carried out by Martínez-Planell et al. (2012), where the authors used the APO part of the theory. In this study, we used the Schema part of APOS, which enabled us to involve the components and their relations to better analyse students' understanding of infinite series in different problem situations. While Martínez-Planell et al. (2012) did not study the convergence tests, we examined some of them in our research. In this paper, we had space to present only one of the questions we designed about convergence tests, which was a geometrical interpretation of the test for divergence (Q3.a). Our study is also in line with Eckman and Roh (2024) in underscoring the importance of partial sums in learning infinite series. However, we further extended their study by considering other components such as sequences, limits, and finite sums and sigma notation. In future research, we aim to design activities based on the GD and implement them in class to help students understand the constructions and the relations between components of the Infinite Series Schema. As a limitation, although our instrument included some questions to study convergence tests, there are numerous convergence tests, which make it difficult for students to determine which test to use for different infinite series. In future research, we should include more questions related to convergence tests to further explore students' understanding of this important aspect of infinite series.

Characteristics of extra-mathematical contexts for introducing derivative as rate of change

Dafna Elias[1], Tommy Dreyfus[1] and Anatoli Kouropatov[2]

[1]Tel-Aviv University, Tel-Aviv, Israel; dafna.elias@gmail.com

[2]Levinsky-Wingate College, Israel

This paper reports on a study which aims to shed light on the ways, in which experts rate different extra-mathematical contexts (EMC) as appropriate for introducing the concept of derivative as rate of change (RoC), and what characteristics of EMC affect their choices. The result is a beginning of a taxonomy of EMC, based on a survey of opinions and attitudes about EMC in general, and specifically EMC for introducing the concept of RoC.

Keywords: Derivative, rate of change, extra-mathematical contexts.

Introduction

A central issue for mathematics educators is how to make fundamental ideas of calculus meaningful for students. With respect to the derivative, the concept of rate of change (RoC) is important for developing a meaningful understanding but is usually difficult for students. Using extra-mathematical contexts (EMC) may assist in grounding this abstract concept. This paper reports on a study which concerns the suitability of different EMC based situations for introducing the concept of derivative as RoC, and the characteristics which make these situations less or more suitable for this purpose.

Background

Extra mathematical contexts

In the approach known as Realistic Mathematics Education (RME), context problems are defined as problems where the problem situation is experientially real to the student (Gravemeijer & Doorman, 1999), meaning that students can imagine themselves acting within the context. Through this approach, students are encouraged to develop mathematical concepts by building on their own experiences and reasoning within real-world contexts. Freudenthal (1973) argued that real-world contexts should be the starting point for developing mathematical reasoning.

Rubel and McCloskey (2021) listed rationales to contextualize mathematics. These include affective benefits such as motivating learners and helping them see the practical value of mathematics, but also the potential to serve as conceptual anchors (Reinke, 2020) or foundations, on which students rely in making sense of abstract mathematical concepts.

Aspects to consider when designing EMC based problems, include authenticity (Cooper and Harries, 2002), previous knowledge and experience with the context (Palm, 2008), success in imagining how the quantities in a problem's context change together (Moore & Carlson, 2012) and time as a variable (Swan (1980) – "time independent relationships between variables are much more difficult to visualize and work with than the straight time dependent relationships of a single variable" (p. 217)).

Rate of change

Students often find the concept of the derivative difficult to grasp, a challenge compounded by the widespread misconception that calculus is merely a set of procedural tasks (Thompson et al., 2013). According to Carlson et al. (2015), students tend to develop a shallow understanding of derivatives, focusing on formulas and rules without grasping the underlying concepts. A key idea for understanding calculus, including derivatives, is the concept of RoC (Confrey & Smith, 1994). RoC can be viewed in several ways, including as an observable phenomenon and a formal concept that includes slope and the difference quotient (Stroup, 2002). To fully comprehend RoC, students must integrate the different perspectives (Confrey & Smith, 1995). However, research indicates that both students and teachers face challenges in linking RoC to slope and derivative.

Goal and methodology

The goal of this study was to identify characteristics that make an EMC-based situation more (or less) suitable for introducing RoC, and what are the reasons for this, with the long-term aim of creating a tool for characterizing EMC (for the specific case of introducing RoC). In a semi-structured interview, teachers and other experts from the mathematics education community were asked to rank different situations and say to what extent they think the situation is appropriate for introducing the concept of derivative as RoC, and why. When designing the interviews, we used pre-defined characteristics for EMC, from the literature and pilot interviews. These characteristics are: (1) Time as the independent variable, (2) Familiarity, (3) Tangibility – The situation concerns a concrete process that one can see and touch, (4) Mathematically "clean" situation - No other variables, apart from the independent variable, influence the dependent variable. Guided by this list, we drafted the following situations (three are detailed and explained, others are mentioned briefly):

1. Car – 'While I drove my car on the way to work this morning, the distance I travelled changed over time. The RoC is the speed of the car as seen on my speedometer' - A familiar time-dependent 'clean' situation, which is not tangible (distance is abstract).
2. Pool – 'Yesterday I filled up my kids' pool. The volume of water in the pool changed over time, according to the rate of water flow from the garden hose. When they finished using the pool, we emptied the pool. While emptying the pool the volume of water changed over time as well, with a negative RoC.' - A familiar, tangible time-dependent clean situation.
3. Temperature – 'Yesterday morning the temperature outside changed over time. In the early morning it was cold, but at noon it was already quite warm.' - A familiar time-dependent situation, which is not tangible, nor clean (influencing factors are humidity, clouds etc.).

Other situation were: Taxi – A situation in which the cost of the ride changes with respect to the distance travelled; Photosynthesis – A situation regarding the concentration of dissolved oxygen in ponds which changes over time; Ice cream – A situation in which the amount of ice cream that melts changes with respect to the temperature outside; Buoyancy – A situation about an experiment in class using eggs to investigate the relationship between the concentration of saltwater and buoyancy.

These situations cover different combinations of the characteristics. This gives the interviewee an opportunity to experience the differences between the situations and relate to their personal

preferences for the EMC. In the interview, each situation was presented, and the interviewee was asked whether the situation is suitable for an opening lesson on derivative as RoC, and why. The characteristics were not mentioned by the interviewer at any point. The interviews were audio-recorded and transcribed.

The analysis of the transcripts was conducted in two stages. At first, we collected quotes that relate to a characteristic of the situation presented—either one of the pre-defined characteristics or a characteristic that had not yet been mentioned. In the next stage, we summarized the interviewee's apparent opinion about that characteristic. The summary provided insights into how the interviewee perceived each characteristic and how important it was in assessing the effectiveness of each situation. Through this process, we identified which characteristics are significant for the interviewees, thus validating the defined characteristics and revealing others that emerge from the interviews.

Population – 10 high school mathematics teachers and 5 mathematics education experts were interviewed. All teachers have taught advanced track high-school mathematics. Our choice was to interview both teachers and experts, since teachers might be those directly involved in the classroom, implementing teaching strategies, while experts might be those with deeper or broader knowledge, potentially having more experience in curriculum development. Teachers may provide practical, classroom-based insights into how students engage with different situations, while experts may contribute more theoretical or research-based perspectives.

Findings and their interpretation

For every characteristic, a choice of relevant quotes from different interviews will be presented, followed by a summary of the characteristic. Following each name is a letter in brackets stating whether that person is an expert from the mathematics education community (E) or teacher (T).

Time as the independent variable

Jimmy (E): The variable we choose, the derivative variable, is very, very important. It must have certain characteristics, I don't know what they are yet, but it's likely that time has the desired characteristics. [...] It should be something that somehow changes in a perceivably independent way. Independent of what, I don't know. Now, time, it's always advancing, so it's fine.

Donna (T): I think it's easier to understand these things when... when the variable is time. [...] That I have something where the x-axis is time, it seems simpler to me.

Sheila (T): Distance is something like... I don't know how much people feel it. I feel more in relation to time, for example.

While all 15 interviewees spoke of time-dependent variables as easier to make sense of, Jimmy's point of view reflects the core of the issue. The choice of the derivative variable is crucial, and it needs to have specific characteristics that facilitate comprehension. Jimmy suggests that time likely meets the necessary criteria. It is a variable that changes in a perceivably independent way, meaning it progresses naturally and continuously without relying on other variables. Sheila mentioned the physical aspect – we as humans can feel time going by.

Is the situation familiar?

Keren (T): [Good situations] not only are they not complex, they're also relevant to everyday life. For example, the taxi is less relevant in my opinion, because students don't really ride taxis much, or bother to look at the meter.

Yuri (E): I would introduce motion, maybe of bicycles, something that speaks to them, I don't know, electric scooter.

Gil (T): I wouldn't go for a car. I would explain, 'You move!' [...] They understand that if they're late for school, they increase their pace. […]. That's their world."

Alon (E): It's the effort, the effort to understand the phenomenon, it won't be too big, because ultimately, you want them to understand the concept [...] But there's some connection that these intuitions come from... the bodily experience of the person.

Interviewees recommended to use situations from students' everyday lives, ("something that speaks to them", from "their world"). The advantage of such situations, as Alon's words can be interpreted, is that the student has the knowledge required to understand the situation, and the effort is focused on understanding the new mathematical concept. Alon adds that the student has "intuitions" about such situations. Jimmy offered a nuanced view regarding the role of familiarity - the primary factor is not whether a situation is genuinely familiar, but rather how realistic the situation appears to them. While familiarity typically ensures a situation is realistic, a situation may be unfamiliar, yet still possess a high degree of realism if it can be easily imagined. Thus, according to Jimmy, realism, rather than familiarity alone, plays a critical role in the student's cognitive engagement with a task.

Is the situation tangible?

Grace (E): Why do I think about the pool much more than about temperature and it's because I see the water. Temperature I don't see, […], I feel, it fills up fast, it fills up slowly.

Jimmy (E): You feel the speed you're traveling at, and the speedometer reflects it as a number, which is excellent.

Donna (T): It's like here you say an experiment, you can really bring it to the classroom.

Jimmy (E): I would say that the height of the water in the pool, maybe I would choose that first, and not the amount of water in the pool, because the height of the water in the pool is something I see, I feel it with my senses, …

The quotes reveal a recurring theme regarding the relationship between visual and sensory perception and the abstract concept of RoC. Grace emphasized this distinction by comparing her ability to understand changes in water level versus temperature. She noted that she "sees" the water in the pool and can physically sense how fast it is filling up, whereas temperature lacks such a sensory aspect. The visual and tangible presence of the water, contrasted with the abstract nature of temperature, highlights how sensory engagement enhances understanding of dynamic processes. Jimmy emphasized how the "speed you're traveling at" can be physically felt, and this sensation is reinforced by the numerical feedback from the speedometer, connecting between physical sensation and numerical representation of RoC. Making a similar point, Jimmy reflects on the importance of sensory feedback when he distinguishes between perceiving the "height of the water" in the pool, which he can see and feel, versus the volume, which remains abstract. This distinction is significant because, while both height and volume measure water, only the height can be directly observed and felt, making it a more immediate representation of the process. Some interviewees offered representing invisible or abstract phenomena, such as temperature, with technical aids. Another idea in bridging the gap between abstract and concrete is physically experimenting, as Donna mentioned

Are there many external influencing factors?

Jimmy (E): Maybe I would, instead of my driving to work, I might construct a model, a situation that quiets down the noise, perhaps thinking about a racing track or a straight road or something. [...] I might try to minimize the things that hinder to the minimum.
Or (T): It depends quite a bit on other things, [...]it opens the opportunity to jokes and cleverness, and not necessarily something to conclude from the information.
Keren (T): I feel like these examples are less suitable, because they have a lot of considerations, which make these things much less absolute.

These quotes represent a common concern about simplifying the situations. Jimmy emphasized the importance of constructing models that "quiet down the noise" by removing unnecessary distractions, an focus attention on key variables. Or highlighted the risks of complex situations, which can lead to unproductive distractions ("jokes and cleverness") rather than meaningful conclusions. Keren reinforced these ideas by noting that certain examples, burdened with "a lot of considerations," become less effective for teaching, as they introduce complexities. Together, these reflections suggest that minimizing external factors is important. Specific situations raised these considerations (‘Taxi’ and ‘Ice cream’ the most). This also connects to the issue of whether time is the independent variable, since when some other factor is the independent variable, it is usually influenced by time, making the situation a complex function.

Emerging characteristics

In addition to the pre-defined characteristics, others emerged during the analysis of the interviews, among them the following three.

Is the situation interesting?

Donna (T): There's no... excitement in that [the Car situation]. What do I care.
Gil (T): When you try to present a non-mathematical position, at least it should be an interesting non-mathematical position. Okay, so the temperature changed, so what?

These quotes illustrate the importance of making examples engaging for students. Donna's comment, "There's no... excitement in that", underscores the need for examples that capture students' interest rather than mundane situations. Gil stated the bottom line – if EMC is to be used, it should be interesting. The topic and the phrasing of the situation should engage students’ interest.

Is the situation linear?

Or (T): But the rate of change here is constant, there is no change in the rate.
Alan (E): We need to look closely if this isn't a linear situation.

A characteristic which came up in several interviews was whether the situation is linear in real life, in the expert’s point of view, and thus less suitable for derivatives where we stress instantaneous RoC.

Is the situation authentic?

Grace (E): That it truly reflects reality and doesn't ridicule the connection between mathematics and reality.
Jimmy (E): The question needs to be authentic. That means, the questions we ask in our activities, they are questions that in some sense arise naturally from the context.
Gabriel (T): Let's say you have something sensitive in your house, that has difficulty to stand very large temperature changes, maybe because it shrinks, I don't know what. And

> you want to build some device that, let's say, alerts or beeps if there's too much of a sudden change in temperature.

Authenticity is a known characteristic from the literature, and several experts highlighted it as an important issue. It addresses the likelihood of asking the same question, not just within the context of a math class, but in studying a problem that is relevant to an actual real-world situation. Authenticity emphasizes the importance of ensuring that problems reflect real-world practical relevance, avoiding superficial or arbitrary examples. Gabriel provided a concrete example, involving a practical issue with temperature changes, which illustrates how even a temperature context that might seem unappealing can be used to formulate meaningful mathematical questions. Together, these quotes underscore that authentic problems are crucial for demonstrating the applicability of RoC in real life.

Discussion

The findings validate that the four key characteristics play a crucial role in the design of EMC based situations for introducing derivative as RoC in teachers' and experts' opinions. Additionally, several other characteristics emerged during the analysis, highlighting the complexity and subjective nature of contextual learning. In this discussion, we summarize the findings about the characteristics and suggest how EMC problems having these characteristics can effectively support students in constructing RoC as an abstract mathematical concept. The validated characteristics are:

1. Time as the Independent Variable - Time as the independent variable emerged as a critical characteristic that aligns with students' natural perception of events unfolding over time. This continuous and smooth progression of time allows students to see functions as evolving processes, rather than fixed objects, helping them better understand how variables co-vary. This dynamic view makes interpreting RoC more intuitive, as it connects directly to real-world experiences of change over time. When the denominator in the difference quotient represents a time interval, students may have less difficulty grasping the concept of two changes occurring over that interval.
2. Familiarity - Familiarity, was a key characteristic in interviewee's considerations. Previous knowledge of the situation frees cognitive resources to focus on the mathematical concepts rather than on the context itself. Jimmy argued that while familiarity helps, realism is important — students don't necessarily need firsthand experience but must be able to easily conceptualize the situation. When the situation is familiar, students are more likely to construct a mental image of it, as Thompson et al. (2022) describe. Whether the situation is something they have seen or can imagine vividly, this ability to mentally visualize the situation enhances students' understanding of how different variables interact. This supports their ability to connect abstract concepts to real-life interactions between variables.
3. Tangibility - The tangibility of a situation, referring to its physical and observable nature, further supports the learning process. When students can see and touch a process, they are better able to grasp the relationships between variables. Tangible situations, connected to what was just referred to as realistic, bridge the gap between abstract mathematical concepts and real-world experiences, making the learning process more concrete. We learned from the experts that it is beneficial to make the situation more tangible if needed – filming a video, using an app etc. Some experts emphasized bodily sensations, as feeling the speed.

4. Mathematically "Clean" Situations - A situation where no external factors influence the dependent variable, simplifies the learning process by removing unnecessary complexity. This characteristic ensures that students can focus solely on the relationship between the independent and dependent variables, free from the distractions of external influences. Such clarity helps to avoid idle discussions, or cleverness.

In addition to these validated characteristics, several others emerged during the study:

5. Interest - Engaging students' curiosity and motivation.
6. Presentation: How the lesson around the situation is built.
7. Nonlinearity: The potential for incorporating nonlinear relationships into the context.
8. Authenticity: The situation's relevance in the real world, beyond the classroom.

Among these characteristics, nonlinearity stands out as particularly important for introducing the concept of RoC, which involves instantaneous change. On the other hand, ‘Interest’ emphasizes emotional benefits, which is less crucial for the specific goal of understanding derivative as RoC. The way the lesson around the situation is built is a topic for further research.

The analysis reveals the subjectivity in how familiar a situation appears to different people. The 'Car' situation was intended to be familiar, assuming most people in the Western world have seen cars and experienced car rides. However, several interviewees argued that it wasn't familiar enough for students, suggesting alternatives like walking, biking, or riding electric scooters, which they felt were more relevant (“I would introduce motion, maybe of bicycles, something that speaks to them,”). It is important to recognize that some characteristics, like familiarity, are subjective and exist on a spectrum unlike time, which is either the independent variable or it is not. What is familiar to one student may not be to another, emphasizing the need for flexibility when designing context problems.

Furthermore, certain characteristics tend to overlap. For instance, less familiar situations are often more complex; contexts that are not time-dependent may never be ‘clean’; and situations that are familiar are generally more engaging and interesting to them. Possible dependencies among the characteristics, such as time-dependence making a situation more tangible, require further research.

This study contributes to the development of characteristics that guide the design of situations aimed at introducing the derivative as a rate of change. By considering both established and emerging characteristics, educators can design learning experiences that connect students' real-world experiences with the new abstract mathematical concept. For a first lesson on the derivative as a rate of change, these characteristics help ensure that the problems support students in understanding the concept. While later lessons should expose students to other contexts that may not include all of these characteristics, for an initial lesson, they are crucial in aiding students' comprehension.

A key contribution of this study is bringing order and structure to a topic that has not been systematically addressed before. Although some individual characteristics have been discussed in various studies, no prior work has proposed a consolidated, organized list of characteristics specifically aimed at a particular pedagogical goal. The framework presented provides a foundation for future research on characteristics for other pedagogical goals.

Student strategies for deciding the limit of a multivariable function

Mika Gabel[1], Arielle Leitner[1] and Yonutz Stanchescu[1]

[1]Afeka - Tel Aviv Academic College of Engineering, Tel Aviv, Israel; MikaG@afeka.ac.il

This is a grounded research study focusing on strategies students use to establish the limit of a multivariable function at a point, and student misconceptions. Open coding was used to analyze 688 exam answers in a multivariable calculus course. We provide a fine-grained analysis of 9 categories of student strategies, with a discussion of student understanding or misconceptions in each one. Most students approached the point along different curves or split the function as a sum of terms. Those that chose curves were twice as likely to succeed. Prevailing misconceptions were that checking only several paths approaching the point guarantees a limit, and an automated misuse of the sandwich theorem. We also detected misconceptions regarding the relations between the existence of a limit, continuity, partial derivatives and differentiability in multivariable functions.

Keywords: Multivariable calculus, function limit, student strategies, student misconceptions.

Introduction

Studying calculus teaching and learning is an ongoing line of study in mathematics education. Extensive research, dated as far back as the 1980's, explores student understanding and misconceptions of fundamental subjects such as limits, functions, continuity, derivatives and integration (Thompson & Harel, 2021). The growing body of research on tertiary mathematics teaching and learning has further extended the inquiry about calculus learning in different levels and disciplines, and research groups that focus on that subject are being established (e.g., the new TWG25 in CERME14). However, much of this research concerns single variable functions. Students' understanding of multivariable functions has been explored far less (Martínez-Planell & Trigueros-Gaisman, 2012; Mamona-Downs & Megalou, 2013). This study aims to provide new information concerning this issue, by studying strategies that students employ when trying to decide whether a function $f: \mathbb{R}^2 \to \mathbb{R}$ has a limit at a given point, namely whether the limit $\lim_{(x,y)\to(x_0,y_0)} f(x,y)$ exists.

Literature Review

There is a wide agreement that the concept of limit is one of the most fundamental concepts of calculus, whose comprehension is crucial to students' mastery of calculus. Yet, there is ample evidence that this concept, and its formal definition, presents major difficulties for most students (Cottrill et al., 1996; Thompson & Harel, 2021). Some difficulties arise because students attach colloquial meanings to the word 'limit', and those meanings obstruct both student conceptual understanding of limit and its definition. For example, students perceive 'approaching' a value as getting progressively closer to an unreachable value and interpret the term 'limit' as a boundary that cannot be passed (Denbel, 2014). Bezuidenhout (2001) found that students have conflicting conceptions of limit and continuity and claimed that these conflicts might have a negative influence on developing understanding of other calculus concepts. In addition, many first-year calculus students' "knowledge and understanding rest largely on isolated facts, routine calculation, memorizing algorithm, procedures and that their conceptual understanding of limits, continuity and

infinity is deficient" (Denbel, 2014, p. 38). Bezuidenhout (2001) adds that "the stereotyped exercises that are a feature of several calculus texts often encourage an instrumental approach…" (p. 498).

Alcock and Simpson (2004) explored approaches of first-year students who include visual imagery in their reasoning to solving problems about convergence of sequences and series. They conclude that "…visual images provide students who focus on them with a strong sense that they understand the material and can correctly answer questions about it. This can mitigate against any perceived necessity to seriously examine the complex formal material" (p. 29). Conversely, students who are internally motivated do successfully integrate visual and algebraic representations to support formal work. Consequently, it is unclear whether the common pedagogy of mathematics lecturers to refer regularly to visual images in real analysis courses has a positive or a negative outcome for students.

It is natural to inquire whether the documented difficulties of students regarding limit of a single variable function at a point persist in multivariable functions, and if so in what ways. Or, are there new misconceptions which arise, and their sources. However, there is considerably less research about students' difficulties regarding multivariable functions in general (Martínez-Planell & Trigueros-Gaisman, 2012) and about limits of multivariable functions at a given point in particular (Mamona-Downs & Megalou, 2013). Research on multivariable functions focused on students' mathematical knowledge and understanding and on students' mental constructs and schemas, using, for example, the theoretical framework of APOS (Martínez-Planell & Trigueros-Gaisman, 2012; Tatira, 2022), possibly following the work of Cottrill et al., (1996).

The studies on students' understanding of limits of multivariable functions were mainly based on task-based interviews of a relatively small number of students. Mamona-Downs and Megalou (2013) interviewed 4 students and asked them to examine whether the limit $\lim_{(x,y)\to(0,0)} \frac{7xy}{5y^2 - x^2}$ exists. Although they were not guided how to approach the problem, all 4 students chose a 'directional approach' (either approaching along lines passing through the origin or converting into polar coordinates). Tatira (2022) analyzed written assignments of 194 students seeking to characterize undergraduate students' conceptualization of multivariable limits. In the written assignments students were asked whether the limits of similar rational functions exist. Most of the students answered correctly, approaching the point (0,0) along lines and computing different limits. Tatira then interviewed 14 students who gave a partial or wrong answer and showed that students concluded the existence of a limit after considering only a few paths, such as lines passing through the origin (e.g., $y = 0$, $x = 0$, $y = mx$). Indeed, Tatira states that this is a common difficulty, as many students struggle to understand the nature of the infinite number of paths or curves along which a point in the plane can be approached, what can be deduced (nonexistence of limit if along different paths the function approaches different limits) and what cannot be deduced (existence of limit if along a single or along few different paths the function approaches the same limit).

Rationale and Research Questions

The authors teach a large calculus course at an engineering college. At this college, calculus is taught over two semesters (I/ II), where calculus I focuses on single variable functions and calculus II on multivariable calculus. The final exam for calculus II included a question about the limit and

continuity of a multivariable function at the origin. While grading the exam, the authors encountered a rich collection of strategies used by the students, that were not documented in previous research. This motivated an analysis of student strategies and misconceptions as they appeared in the written answers in the exam. Here, the term 'misconception' is used to indicate a mistake done consciously, and is the result of a misunderstanding, where a student believes a false concept or strategy to be true. The term 'strategy' is used to indicate the general way a student approached the problem. The authors analyzed students' written exam answers, to answer the following research questions:

1) What were the most common strategies students used to evaluate limits of multivariable functions?
2) Which of the strategies that students used were most likely to be successful?
3) What misconceptions did students have about the existence of limits of multivariable functions?

The study embraces the paradigm of grounded research theory, which was designed to generate theory from existing data, for example by using qualitative coding techniques. Czocher and Melhuish (2024) identify two kinds of what they name *Coding studies*: *Inductive studies* that "generate initial codes for analytic units, group like codes together into categories…" and *Deductive studies* that "apply an already-existing or literature-derived framework to analytic units or otherwise categorize analytic units according to clearly defined concepts" (p. 148). Thus, the current study is an Inductive study since it focuses on an initial categorizing of a new phenomenon.

Method

The study was conducted in a multivariable calculus course, taught in an engineering college. Students are in 7 different engineering majors, but all the students take the same calculus sequence with the same entry requirements. The course is large (~800 students), split between different lecturers and teaching assistants. A total of 688 students took the exam. In the final exam, students freely chose 5 of 6 questions to solve and be graded. One of the exam questions was as follows (translated): Does the function $f(x,y)=\begin{cases}\dfrac{3y^9+y^4x^2+x^5}{y^8+x^4} & (x,y)\neq(0,0)\\ 0 & 0\end{cases}$ have a limit at (0,0)? Is $f(x,y)$ continuous at (0,0)?

The definition of the limit at a point taught in the course is that "a function has a limit at a point if and only if the function yields the same limit when approaching the point along all possible curves". In the lessons, the instructors typically use a rational function similar to the exam question, and examine its limit at (0,0), to demonstrate that if along two (or more) curves approaching the point the function has different limits, then the function does not have a limit at the point. In the exam question, approaching (0,0) along straight lines produces the same limit, however a approaching along a parabolic curve produces a different limit, thus the function does not have a limit at (0,0). This is a challenging function, but students see similar examples in lectures and homework problems.

Our data was students' written answers in the exam. The analysis focused on strategies that students used to decide whether the limit exists, and students' misconceptions. Continuity was considered only if it was used as an argument for existence of a limit. Although the authors are experienced lecturers, they analyzed students' answers disregarding their own initial assumptions about common student

misconceptions. Instead, they scrutinized the written answers to find what strategies students used (and successfully), and what types of misconceptions were common. An open coding methodology was implemented: (i) 20 random student answers were examined by two authors and initial codes were set; (ii) the rest of the exams were split between the authors; any new code was discussed and agreed upon by all authors; (iii) each author coded students' answers and marked answers that did not fit neatly into one of the codes; (iv) two of the authors re-examined the marked ambivalent answers and decided how to classify them. At the end of this process there were 25 fine-grained codes, belonging to 5 main categories and 9 subcategories (we present only subcategories that appeared on more than 2% of the exams). Table 1 presents categories and subcategories of student strategies.

Table 1: Codes for Strategies – Main categories and subcategories

Category C - Use of different curves or paths to approach the origin	
C_✓ *Correct*	Approaching (0,0) along different paths (lines and parabolas) gives different limits so the limit does not exist.
C_part	Approaching (0,0) along some paths or lines (*x*,*y* axes or $y = kx$) gives a limit L=0 Or: Approaching (0,0) along $x=y^2$ gives a limit L=0.5
C_P	Improper use of polar coordinates
C_cts	Approaching (0,0) along a path ($x = y^2$ or another) that gives a limit L; since $L \neq 0 = f(0,0)$ the function is not continuous and hence the limit does not exist
Category D - Use of partial derivatives ($f_x(0,0) = 1, f_y(0,0) = 3$)	
D_exist	The partial derivatives exist so the limit of *f*(*x*,*y*) exists (not clear what the limit is)
D_neq	The partial derivatives exist but are not equal, so the limit of *f*(*x*,*y*) does not exist
Category T - Splitting the function into a sum of two/three terms and determining the limit of each term	
T_✓ *Correct*	Term 1 and Term 3 have a limit zero (using the sandwich theorem correctly) and Term 2 has no limit (argument using paths)
T_part	Term 1 and Term 3 have a limit zero (using the sandwich theorem correctly), Term 2 converges to 0.5, so the limit is 0.5 or does not exist
T_sand	All three terms have a limit zero (using the sandwich theorem correctly for Term 1 and Term 3, and incorrectly for Term 2), so the limit is zero

Strategies were classified in three main categories: (C) use of different curves or paths approaching the origin, (D) use of partial derivatives, (T) splitting the function into a sum of terms (e.g.,

$\frac{3y^9+y^4x^2+x^5}{y^8+x^4}=\underbrace{\frac{3y^9}{y^8+x^4}}_{Term\,1}+\underbrace{\frac{3y^4x^2}{y^8+x^4}}_{Term\,2}+\underbrace{\frac{x^5}{y^8+x^4}}_{Term\,3}$) and examining limit of each term separately. There were two other categories: question not chosen (X); scratch work not leading anywhere (0).

As a final comment we wish to stress that the analysis did not evaluate the quality of students' argumentation or writing but focused on the chosen strategy. For example, students who split the function into three terms, demonstrate that two terms have a limit zero and the middle term does not have a limit thus conclude correctly that the function does not have a limit (T_✓), need to support this conclusion by adding an argument about the sum of functions with/without a limit. The lack of this argument was expressed in their exam grade but was not reflected in the analysis of strategies.

Findings

Out of 688 students who took the exam, 592 students (86%) chose to attempt the limit question. This suggests that students felt confident that they would be able to answer the question, at least partially. Table 2 presents the number and percentage of the students in each main category: paths of curves, partial derivatives, and sum of terms. Percentage in Tables 2 (and Tables 3-4) is computed relative to 592 students who tried to solve the question (i.e. N/592*100). For each category we also present the number of students for whom the use of this strategy produced a correct answer.

Table 2: Breakdown of main strategies

Category	C (Correct)		D (Correct)	T (Correct)		0	Total
N	278	(152)	49 (0)	178	(44)	87	592
%	47		8.3	30.0		14.7	100

Table 2 shows that of those who did answer, only about 15% made insufficient progress to classify a strategy (Category 0), so this leaves roughly 85% of the exams (505 students) to be assessed for strategies. Less than 10% chose to look at partial derivatives. 54.7% of the students who used the curves strategy answered the problem correctly. For students who tried a sum of terms (Category T), only 24.7% answered correctly. So, students who tried the curve strategy had twice the success rate over students who used the sum of terms strategy. This answers Research questions 1-2.

Table 3: Success and failure rates

Category	Correct	Partially correct	Wrong	0	Total
N	196	260	49	87	592
%	33.1	43.9	8.3	14.7	100

Table 3 presents the percentage of correct, partially correct and wrong answers. Partially correct are students in Category T who split the function to two/three terms and reached a correct conclusion about the limit of the first and third terms, and students in Category C that calculated correctly the limit of the function along different curves or paths but determined the limit incorrectly. We see that

approximately 52% of the students managed to make progress towards a solution (not counting the correct answers or the students who submitted scratch work), split over the different misconceptions.

Table 4: Breakdown of main Strategies by subcategories

Category	C_✓	C_part	T_sand	T_✓	D_exist	T_part	C_cts	D_neq	C_P
N	152	90	90	44	22	20	15	14	13
% (of 592)	25.7	15.2	15.2	7.4	3.7	3.4	2.5	2.4	2.2

Table 4 presents the number and percentages of each subcategory (above 2%, descending order). Each subcategory represents a slightly different strategy as explained in Table 1. Each of the strategies that led to a wrong answer represents a misconception, answering Research question 3. Of the students who tried paths of curves (Category C), the most common misconception was C_part, indicating students were not aware that they needed to check more paths. Understanding that checking only some paths does not guarantee a limit is one of most difficult ideas for students when learning multivariable limits. This misconception is echoed in T_part, which together with C_part gives 110 exams under this misconception, for 21.8% of the 505 who made progress. Of the remainder, the 2.5% of the students who used strategy C_cts, have the misconception that if the function is not continuous, then the limit does not exist. This misconception should have been treated in first semester calculus. Of the students who tried to split into a sum of terms, T_sand was the most common for 15% of the students trying to use the sandwich theorem incorrectly on Term 2.

Of the students who used the partial derivatives strategy (Category D), D_exist was the most common strategy, indicating that these students did not understand the limit definition of partial derivatives. This is particularly disturbing since the partial derivatives have different values, so it is not clear what these students believed the limit to be and why they were not conflicted. Students who used strategy D_neq had a similar misconception regarding what the limits they computed represent but relied on a wrong version of the argument that different limits indicate that the limit at a point does not exist.

Discussion and Conclusions

This study is an inductive coding study (Czocher & Melhuish, 2024). Open coding was used to analyze 592 written exam answers of 592, to determine whether a given multivariable rational function has a limit at a given point. We found most of the students tried either a strategy of analyzing the function along curves (Category C) or presenting the function as a sum of terms (Category T). Around 8% of students based their answer on the existence of partial derivatives (Category D).

Tatira's (2022) study also analyzed a large number of exam answers, rather than interviews, on the existence of limits of multivariable functions. Tatira found that over 74% students succeeded in proving that the given functions did not have a limit at the origin. In our study only 33.1% of the students got a correct answer. This might be because Tatira's rational functions required considering only straight lines through the origin to deduce that the limit does not exist. In our exam straight lines produced the same limit and proving nonexistence of the limit required parabolas. Overall, we agree with Tatira (2022) that "many students study multivariable limits evaluation without really

understanding indeterminate rational functions" (p. 160). Tatira categorized students' exam answers as correct/partially correct/wrong, whereas our open coding produced finer categorization, classifying different strategies within the categories of partially correct or correct. Still, since our study relates to a single rational function, our findings merit further investigation with other types of functions.

The most common misconception among students who analyzed along curves (Category C), is that checking only one path, or several paths, guarantees a limit (C_part, Table 4). This misconception was documented in previous studies based on a small number of task-based interviews (Mamona-Downs & Megalou, 2013; Tatira, 2022). Our analysis of a large body of data supports the prevalence of this misconception. Interestingly, for students who split the function into terms (Category T) the prevailing misconception was different: that all three terms have a limit 0 based on the sandwich theorem (T_sand, Table 4). We interpret this as procedural thinking about using the sandwich theorem, without understanding how to prove that a rational function is bounded. Finally, the success rate of students who split the functions was 24.7%, whereas for students who tried the curves strategy it was 54.7%. We suspect that students that provided a correct answer after splitting the function into terms have a deeper understanding of the limit concept, since they: (i) correctly detected the "problematic" Term 2; (ii) they did not automatically used the sandwich theorem for Term 2 like they did for Term 1 and Term 3, and (iii) used a complete path strategy to deduce that Term 2 does not have a limit at (0,0). Their analysis involves inquiry and proper use of mathematical theorems.

Another misconception that we found among 2.5% of answers, is that students claimed that if $f(x,y)$ is not continuous, then the limit does not exist. This misconception was also documented by Bezuidenhout (2001) in single variable functions. This misconception, together with the misuse of the existence of the partial derivatives (8.3%) reflects a confusion about the intricate relations between the existence of a limit, continuity, existence of partial derivatives, continuity of partial derivatives and differentiability. The use of derivatives to determine a limit of a function was not documented in other studies. We conjecture that since we analyzed written answers in the final exam, the students were already acquainted with all of these concepts, knew that differentiability is a sufficient condition for continuity and perhaps solved questions that combine the question on limits and continuity with the question on differentiability in preparation for the exam. Perhaps this, together with their previous knowledge about single variable functions, for which differentiability implies continuity, provided the basis of this wrong strategy. This is a matter for further research.

A major difference between single variable and multivariable functions is that students (and most instructors) can only visualize or sketch simple multivariable functions. For single variable functions there is a strong intuitive advantage to understanding the limit concept using the graph of the function. However, with a multivariable function most are "blind" in the sense that the intuition is gone, and students must rely on purely algebraic techniques without the ability to visualize what they are trying to compute. They have no conception of the infinite number of paths that approach a point, and how these level curves look on the graph of the surface. As noted by Tatira (2022), citing Fisher (2010), for multivariable functions even the use of computer graphics does not alleviate this problem. Alcock and Simpson (2004) stated that students get used to base their understanding on visual images and this somehow impedes their ability to solve problems relying solely on formal arguments. Overcoming this obstacle is a worthy goal for future research.

Overall, our study serves as a primary exploration and our findings can be used to design a pedagogical intervention addressing the misconceptions that were found or to plan learning activities that encourage student inquiry. Another future research direction is probing deeper into students' understanding of the concepts of limit and continuity using an appropriate theoretical framework, for example APOS that was used by Cottrill et al. (1996) and by Mamona-Downs and Megalou (2013), taking into account the new strategies that were documented. It seems that for students, the concept of limit in multivariable functions is not a simple extension of this concept for single variable functions but entails other challenges that are well worth exploring.

Dynamic conceptualisation of density of $\mathbb{Q}$ in $\mathbb{R}$: Upper-secondary school students' spontaneous conceptions and arguments

Chiara Grisendi[1] and Miglena Asenova[2]

[1]Pisa University, Faculty of Mathematics, Pisa, Italy; chiara.grisendi@phd.unipi.it

[2]Free University of Bozen-Bolzano, Italy

While research in Mathematics Education has mainly focused on density of $\mathbb{Q}$, little is known about density of $\mathbb{Q}$ in $\mathbb{R}$, despite its importance in grasping fundamental Calculus concepts such as continuity. This study investigates upper-secondary school students' spontaneous conceptions and arguments regarding the density of $\mathbb{Q}$ in $\mathbb{R}$. A classroom activity and group interviews focused on continued fractions, which provide a unified representation of rational and irrational numbers, were carried out. The data consist of the students' written and spoken statements, and the data analysis strategy follows a thematic analysis approach with some specific modifications. The research findings indicate that students' spontaneous conceptions are dynamic processes that range over different categories supported by different arguments and warrants.

Keywords: Density of $\mathbb{Q}$ in $\mathbb{R}$, spontaneous conceptions, arguments, continued fractions, warrant.

Rationale

The concept of density of $\mathbb{Q}$ in $\mathbb{R}$ is crucial because it ensures that irrational numbers can be conceived of as limits of sequences of rational numbers, guaranteeing that each point of the real line corresponds to a number. Students encounter the concept of density already when dealing with rational numbers, but while the set of rational numbers is dense, the set of real numbers is both dense and complete. If the density of $\mathbb{Q}$ becomes an intuitive model for the density of $\mathbb{Q}$ in $\mathbb{R}$, students may struggle to grasp the difference between $\mathbb{Q}$ and $\mathbb{R}$ and the role of completeness for $\mathbb{R}$ as the ideal domain for central Calculus phenomena such as continuity and completeness.

As research shows (Branchetti & Durand-Guerrier, 2018; McMullen & Van Hoof, 2020; Putra, 2019), exploring the transitions between numerical sets is crucial to avoid obstacles in future mathematical learning and the density-concept is crucial in this sense. Nevertheless, according to the literature, while the concept of density of $\mathbb{Q}$ is widely investigated (e.g., Hannula et al., 2012; Kim & Kwon, 2019), the density in the transition from $\mathbb{Q}$ to $\mathbb{R}$ – the one of density of $\mathbb{Q}$ in $\mathbb{R}$ – has received little attention from research in Mathematics Education (Marmur et al., 2020). Marmur et al. (2020) investigate how first-year mathematics undergraduates grasp the concept of density of $\mathbb{Q}$ in $\mathbb{R}$. However, students face this concept, at least intuitively, already in upper-secondary school. In this context, spontaneous conceptions, intended as intuitive beliefs formed from experiences in various contexts, including everyday life (Fujii, 2014), serve as a foundation for future institutionalised concepts. This paper, based on the first author's master's thesis (Grisendi, 2024), examines the spontaneous conceptions of the density of $\mathbb{Q}$ in $\mathbb{R}$ of two classes of Italian upper-secondary school students (aged 17/18). The students' spontaneous conceptions, the kind of arguments and justifications they use to support their reasoning in working on this concept, are categorised and integrated, focusing on the following research questions: (1) What are students' spontaneous

conceptions regarding the concept of density of $\mathbb{Q}$ in $\mathbb{R}$, and what arguments do they use to support them? (2) How do these arguments and spontaneous conceptions support students' reasoning processes as they evolve during a classroom activity focused on the concept of density of $\mathbb{Q}$ in $\mathbb{R}$?

Theoretical framework

The theoretical framework is composed of two elements: Balacheff's (1988) classification of different approaches to proof and Toulmin's (1958) concept of warrant. These two components are first introduced, and then their interrelations in the present investigation are discussed.

Balacheff (1988) distinguishes between *pragmatic proof* (based on actions) and *intellectual proof* (which employs verbalisations of the properties of objects and their relationships). Additionally, he identifies a taxonomy for the types of proof conceived as steps between *pragmatic proof* and *intellectual proof*, characterised by increasing sophistication: *naïve empiricism* (examples proposed are considered self-evident); *crucial experiment* (a paradigmatic example is used, suggesting that if it holds in one case, it holds in all cases); *generic example* and *thought experiment* (an example is used as a "support," but the reasoning is general).

According to Toulmin (1958), an argument has three constituent parts: claim, datum, and warrant. The claim refers to the main assertion one is attempting to prove; the datum includes the reasons, evidence, facts, and/or information that support the claim; the warrant represents the logical connection linking the datum to the claim supporting the provided argument. Our analysis focuses specifically on the warrant; instead, the claim and the datum are provided in the task and do not vary.

Balacheff's (1988) classification of different approaches to proof accounts for what students consider a reliable validation and the soundness of their inference and Toulmin's (1958) idea of warrant provides critical insights into the type of justification used to support the validation. In this sense, the two components mentioned above collectively support the analysis of student conceptions and arguments.

Research method

Our research is guided by an *ad hoc* constructed strategy based on different investigation themes. These themes include students' general arguments, with a specific focus on students' mathematical arguments, and finally, students' conceptions. To stimulate the emergence of spontaneous conceptions, an activity focused on continued fractions, which facilitates the transition from the countable ($\mathbb{Q}$) to the continuous ($\mathbb{R}$), was designed. Two classes for a total of 42 upper-secondary school students were involved. The activity, divided into two parts, was conducted under the lead of the first author in the presence of the classroom teachers but without their intervention. In the first part (two hours), students respond anonymously, working in small groups. This part involves a worksheet, which begins with a brief contextualised introduction to continued fractions, where a hypothetical student proposes a continued fraction as an approximation of an irrational solution of a second-grade equation; then, students are asked to argue for or against the statement: "[...] given any real number, can I always find a rational number that is as close to it as I want?" After reading the initial part of the worksheet, students complete two parts, called Assignment 1 and Assignment 2. In Assignment 1, students write down a points list of arguments for or against the statement read before,

while in Assignment 2, starting from the generated list, students are asked to produce a discursive response by writing an argumentative text. These tasks were chosen to track students' reasoning processes and identify the kinds of arguments they use to support their conceptions. Finally, students are interviewed by the researcher a few days later via semistructured group interviews, inviting them to deepen the arguments presented in their group. In this sense, the collected data were written or spoken sentences produced by the students while trying to argue their position concerning the task-claim.

The data analysis strategy used in this research partially overlaps with the thematic analysis described in Xu and Zammit (2020). However, it differs from the latter in several aspects, as it was constructed ad hoc for the data decoding process. Below, we explain our approach, showing analogies and differences to the thematic analysis approach. As revealed before, an *ad hoc* strategy was constructed because of the data set's complexity. We designed a structured data analysis process, i.e., a flowchart, that guides the coding of the data through structured questions. Thanks to this tool, some of the thematic analysis steps are unnecessary for our analysis.

The first step of our data analysis corresponds with the first step of the thematic analysis. We reviewed the students' sheets and prepared targeted questions for each group to explore their reasoning further. These questions are used to guide the initial part of the semistructured interviews. Indeed, only one question was repeated identically for every group: "How can you define, in your own words, a dense set?"

Also, our second step is analogous to the second step of thematic analysis (Xu and Zammit, 2020). We constructed a category structure, the theory-driven code, developed through both deductive (drawing from the relevant literature) and inductive (drawing from the data) approaches (Mayring, 2015), and we elaborated the above-mentioned flowchart as the data-driven code to simplify the process. The flowchart guided the classification process of the statements through structured questions. Following the flowchart's questions multiple times with the same students' statement, we explored its possibly different interpretations. This flexibility enabled us to observe a single statement considering different aspects of students' conceptions and arguments.

Below, we describe the category structure. Initially, we focused on classifying the types of arguments students proposed. Deductively, we referred to categories identified in the section Theoretical framework; inductively, we identified the remaining warrant-categories, supposing that each has a dual category. In this sense, a distinction was made between *pragmatic warrant* (related to utility and efficiency) and *theoretical warrant* (related to properties and definitions). Subsequently, for each of Inglis' (2007) warrant-categories – *inductive warrant* (the use of a certain number of examples), *intuitive warrant* (the use of observations or examples that reflect some underlying cognitive structure), and *deductive warrant* (the use of deduction from axioms, algebraic manipulations, and counterexamples), a distinction in *operational warrant* (related to a procedure) and *structural warrant* (related to properties and relationships between objects) was made. Finally, we categorised the spontaneous conceptions of density of $\mathbb{Q}$ in $\mathbb{R}$ that emerged during the activity. These conceptions were categorised inductively into two types: *analytic conception* (based on a fundamental idea of sequences, intuitively linked to the construction of the set $\mathbb{R}$ through Cauchy sequences), *synthetic*

conception (based on geometric-spatial concepts and related to the number line, intuitively linked to the construction of the set $\mathbb{R}$ through Dedekind cuts).

The following three steps of thematic analysis refer to using a thematic map developed in the third step, revised and refined in the fourth step, and organised "into a coherent and consistent account" (Xu & Zammit, 2020, p. 7) in the fifth step. Because our analysis develops by referring to the flowchart, the process is structured and makes the analysis shorter. Indeed, thanks to the data analysis thematic code, immediately after classifying a statement in the category structure and tracking how students move towards a new statement, we can reconstruct and represent the group's reasoning through specific kinds of thematic maps, called schema and graphs. In the following section, we show two different kinds of maps used to represent the groups' reasoning.

The last step of thematic analysis coincides with this paper's Discussion and conclusion section.

Results

Below, we provide a summary analysis of just one of the twelve groups examined in the thesis, suitable to exemplify the methodology of data analysis developed and used to this end. We focus on Group 10, whose responses are particularly interesting regarding the reasoning process the students proposed. Before Group 10's detailed analysis, we present two examples of the thematic maps used in our research. These maps are designed to represent "the meanings in the data set as a whole" (Xu & Zammit, 2020, p. 6) and "to fit each theme into a broader overall story about the data" (Xu & Zammit, 2020, p. 7), effectively facilitating the visualisation of data analysis for each group.

Figure 1 shows the schema that presents the analysed categories for Group 10's spontaneous conceptions and arguments. Each category is represented by a box with a distinct shape and colour. The coloured rectangles provide information on the context of data collection (group number, Assignment 1, Assignment 2, Interview).

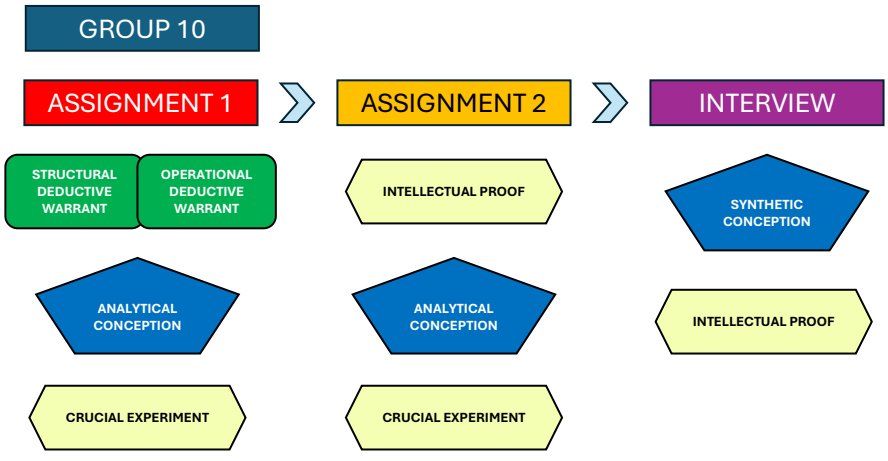

Figure 1: Schema of Group 10 students' arguments and spontaneous conceptions

Moreover, Group 10 students' reasoning can be effectively represented by a graph (Figure 2).

In the graph in Figure 2, coloured circles indicate the vertices, while dark blue arrows represent the edges. The logic behind the connections between the two statements is as follows: (1) If the edge

between two statements, *i* and *i*+1, is a head-tail arrow, it indicates a temporal sequence (i.e., the arrow's tail represents the statement at time *i*, while the head represents the statement at time *i*+1); (2) If the edge is a head-head arrow, the two statements are semantically similar, as they reflect analogous reasoning expressed at different moments, possibly with variations in wording. The students' statements are displayed in light blue rectangles; the coloured circles indicate when the statement was made during the activity, and the coloured triangles indicate the category in which the statement was classified.

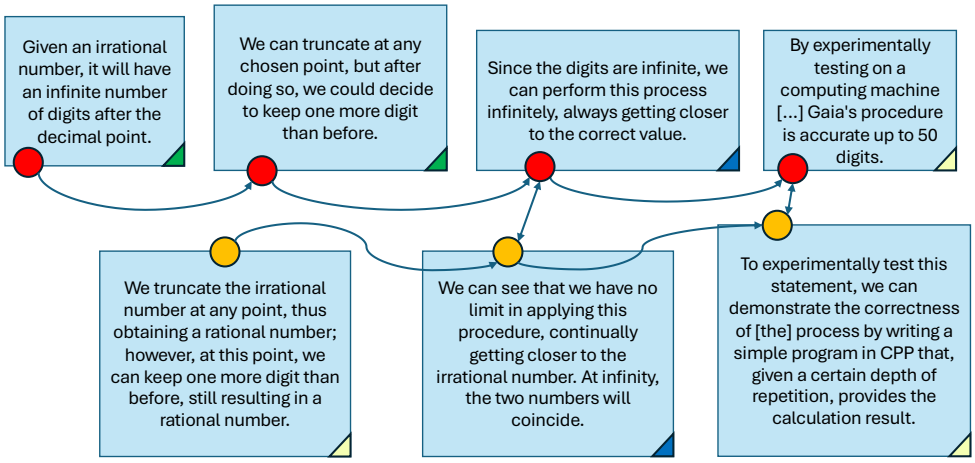

Figure 2: Graph of Group 10 students' arguments and spontaneous conceptions

With the support of the two previously presented schemas, we analyse Group 10's data collected. The students of this group initially employed a *deductive warrant* (Assignment 1). It first provided them with a theoretical reference (*structural deductive warrant*). Indeed, the statement, *Given an irrational number, it will have an infinite number of digits after the decimal point* (Figure 2), represents a fundamental property of irrational numbers. Additionally, an operational process (*operational deductive warrant*) was the foundation of their reasoning. Indeed, this is evident in the statement: *We can truncate* [the irrational number mentioned before] *at any chosen point, but after doing so, we could decide to keep one more digit than before* (Figure 2), which outlines a specific procedure.

Subsequently, in Assignment 2, Group 10 demonstrated a natural progression from a *theoretical warrant* (of which the *deductive warrant* is a specific case) to an instrument for justifying an *intellectual proof*. The statement classified as an *intellectual proof* is the following: *We truncate the irrational number at any point, thus obtaining a rational number; however, at this point, we can keep one more digit than before, still resulting in a rational number* (Figure 2). We can observe that, while in the *theoretical warrant* it is possible to distinguish between the reference to the theoretical concept and the proposal of an operational procedure, in the *intellectual proof*, the two components are no longer distinctly separable, producing a unified and coherent reasoning process.

It is evident that Group 10 is aware of the problem of generalisation. To validate their reasoning, the students conclude their analysis by providing a paradigmatic example, specifically a CPP program. Since the program is designed to generalise the process, Group 10's statements regarding this program are considered in the *crucial experiment* category.

The procedure proposed by Group 10 is further supported by the *analytical conception* that the students have regarding the concept of the density of $\mathbb{Q}$ in $\mathbb{R}$. In Assignment 1, the statement – *Since the digits are infinite, we can perform this process infinitely, always getting closer to the correct value* (Figure 2) – suggests a conception based on the image of a sequence of rational numbers obtained by the "truncation" process, converging towards the "*correct value*". In Assignment 2, the statement – *We can see that we have no limit in applying this procedure, continually getting closer to the irrational number. At infinity, the two numbers will coincide* (Figure 2) – intuitively expresses the idea of a sequence of rational numbers as a single number that "transforms" over time.

During the Interview, the *analytical conception* evolves into a *synthetic* one. Student A's statement – *There is a value at every point.* […] *You have a value for every point; you can always divide a point in half* (Figure 2) – explicitly refers to spatial and geometric concepts, as indicated by the terms "value *at every point,*" "value *for every point*," and "*divide a point* in half," which imply a correspondence between $\mathbb{R}$ and the number line. Furthermore, student B's statement – *I know that the cardinality of natural numbers and rational numbers is the same; whereas, for real numbers, it is different.* […] *It is larger. Between natural and rational numbers, we can find a "correlation," so we can say they have the same cardinality. However, real numbers are dense, meaning there is no space between one number and another* (Figure 2) – explicitly refers to a property of $\mathbb{R}$ set, namely the cardinality of the continuum. This becomes clear when student B states that the cardinality of $\mathbb{R}$ set is "*different*" from that of $\mathbb{N}$ and $\mathbb{Q}$ because it is "*larger*." This statement is classified as *intellectual proof* since the property of $\mathbb{Q}$ is used to argue that $\mathbb{Q}$ is a dense set. Moreover, it supports the emergence of the *synthetic conception*, as indicated by the terms "there is no *space* between one number and another".

Discussion and conclusion

In the Rationale section, we pointed out that only one of the referenced studies specifically addresses the concept of the density of $\mathbb{Q}$ in $\mathbb{R}$: the research conducted by Marmur et al. (2020). Marmur et al.'s (2020) findings are twofold. Firstly, the findings demonstrate "unconventional student understandings" (Marmur et al., 2020, p. 7) of the concept of density of $\mathbb{Q}$ in $\mathbb{R}$, e.g., some students use the concept of infinity only as a process, as authors write: "attend to the process of creating infinitely many rational numbers [...], rather than to the existence of these numbers" (authors' italics) (Marmur et al., 2020, p. 5). Secondly, rather than attending to general reasoning, students concentrate "on specific examples, contexts, processes, and personal meanings, consequently reducing the intended abstraction level of the task" (Marmur et al., 2020, p. 7). These authors' study focuses on university students, while our research participants are upper-secondary students. As the participants' linguistic and cognitive tools in the two investigations differ, the research findings differ, as detailed below.

On the one hand, according to our analysis, the students' understanding cannot be classified as "unconventional," as highlighted by Marmur et al. (2020). In our research, each group presents a different pathway and the term "unconventional" loses its sense. In particular, the groups that produced a less comprehensive conceptualisation tended to rely on categories of argument and proof that did not require intricate sentence structures or advanced reasoning (such as *crucial experiment*). Moreover, their spontaneous conceptions reflected only the *analytical conception*, likely because it

aligns more closely with the thesis presented in the worksheet, guiding their reasoning. Addressing the first research question, it becomes evident that the *analytical conception* is perceived as more intuitive and, therefore, primary compared to the *synthetic conception*. However, the coexistence of both conceptions ultimately facilitates significant advancements in the conceptual understanding of density of $\mathbb{Q}$ in $\mathbb{R}$.

On the other hand, our results shed light on when and why students need to refer to different kinds of warrants, e.g., a specific practical example or, instead, some intuitive properties of a mathematical object. So, we recognised that using examples is only sometimes about reducing abstraction, as suggested by Hazzan (1999); but, in some cases, students feel obligated to present an example, even if their reasoning is general because they do not have suitable linguistic tools to express their ideas in another way. This leads us to the second research question. We can state that the students' reasoning varies across different groups, each beginning from distinct starting points.

Moreover, groups capable of navigating the various typologies of arguments and proofs demonstrate a more in-depth reasoning process. It is important to note that some elements of the dual categories of warrants (e.g., the *intuitive theoretical warrant*) never appeared in the data. This is likely because these categories require cognitive and linguistic tools that are not yet fully accessible to upper-secondary students. During the written phases of the activity (Assignment 1 and Assignment 2), almost all categories of arguments were explored at least once in the students' responses. However, during the Interview, no categories related to warrant typologies emerged. This discrepancy may be attributed to the fact that the cognitive and linguistic tools available to students are less developed in oral communication than in written tasks. Additionally, during the written phases, students had the opportunity to collaborate in groups, allowing for the emergence of more complex and well-articulated arguments.

Ultimately, the data analysis reveals that students' spontaneous conceptions are dynamic and evolve during the activity. The categories employed in this analysis help identify connections between different conceptions and the arguments that connect them. A potential future research development is extending the investigation, using the developed methodology, to concepts contiguous to the one being examined, such as continuity.

Challenging students' argumentations towards a flexible use of the concept of change in a qualitative-graphical approach to calculus

Luisa Gunia[1] and Christine Knipping[1]

[1]University of Bremen, Germany; gunia@uni-bremen.de

Students' reasoning about functions and rate of change is challenged, when they face dynamic contexts, in which they have to predict how a quantity unfolds over time. We illustrate this by analysing high-school students' graphical and verbal solutions for dynamic problems, where population growth is dependent on population sizes (not on time). This touches several fundamental notions of calculus, including topics such as rate of change and ideas of differential equations. Our findings indicate that students need to develop flexible ways, how to use their concepts of function and rate of change in this context. This requires classroom mathematical practices, in particular argumentations that encourage transitions between the real-life context and graphical and verbal representations of the given situation. Negotiations of such argumentations seem promising for students' flexible use and deeper development of a concept of change.

Keywords: Calculus, functions, differential equations, concept formation, argumentation.

Introduction

Mathematically and in real-life applications, dynamical systems play an important role. For describing dynamical systems mathematically, autonomous ordinary differential equations are an important means. These equations establish a functional relationship between a quantity and its instantaneous rate of change. This perspective, relating a function and its derivative, is often still untypical in school contexts. Yet, it allows to address several fundamental concepts and notions of calculus, as well as possible application contexts. The concepts of derivative as a rate of change, integral as an accumulation and different ideas of differential equations can be related in this context.

Understanding these concepts requires more than procedures and computational routines, but meaningful contexts, in which a qualitative-graphical approach is emphasized. This approach, emphasizing the discovery and exploration of fundamental concepts of calculus in a qualitative way, has been characterized as 'qualitative calculus' in mathematics education (e.g., Stroup, 2002).

However, arguing qualitatively and in a 'differential equation perspective' also entails conceptual challenges that need to be addressed so that students can work successfully with this perspective. Students have to overcome several 'epistemological obstacles' in this context, as Sierpinska (1992) points out. For example, assuming that all changes of a variable are changes in time, is a typical functional understanding of students, which is mathematically an obstacle they need to overcome. Further, a qualitative-graphical approach requires argumentations based on graphical as well as verbal representations of a given situation, which includes constant transitions between these, when arguing in a real-life context. We illustrate how challenging this can be for students in this contribution.

Our central research question is: How do students' argumentations support their 'meaning-making' of fundamental concepts in calculus within a dynamic system context?

State of the art: A qualitative-graphical approach to calculus

In mathematics education, students' difficulties with functions and functional thinking are a broad area of research. The articles in Dubinsky & Harel (1992) provide an overview of typical misconceptions and problems of students related to functions. Tall (1993) gives such an overview for calculus. Especially, when it comes to real-life applications and the use of central concepts of calculus in different contexts, a flexible concept of change and other calculus related concepts are needed.

A qualitative-graphical approach has been suggested for the teaching and learning of calculus, with the intent to foster central concepts and conceptual reasoning instead of calculations and procedures (e.g., Hußmann, 2010). In this approach, which has been labelled as 'qualitative calculus' (e.g., Stroup, 2002), concepts and contexts are mainly represented graphically and verbally and according to their quality, rather than symbolically and quantitatively. The emphasis is not on numbers and computational routines, but on qualitative aspects of the given contexts in order to stimulate conceptual and visual reasoning and argumentations. Starting from real-life contexts, the development of context-related ideas is meant to encourage an understanding of basic concepts of calculus (e.g., Hußmann, 2010). This way, a concept-oriented perspective on calculus is intended.

In this tradition of a qualitative approach to calculus, Rasmussen and colleagues have suggested to introduce the idea of differential equations, to foster the flexibility of students' concepts of functions, derivatives and (rates of) change (e.g., Rasmussen & Keene, 2019). Engaging students in argumentations can help them to clarify the underlying concepts. Argumentation can also become a useful heuristic device here for the discovery of new mathematical concepts (e.g., de Villiers, 1990).

Theoretical framework: Argumentation as a means of discovery

The importance of argumentation in this context is not only that it may be a goal of learning, but that it becomes a means for learning mathematics and learning mathematical concepts (e.g., Knipping & Reid, 2019). Argumentation is seen here "as a means for discovery" (de Villiers, 1990, p. 21), which entails recognizing and exploring connections between new and existing knowledge. The assumption that social and communicative processes not only underlay learning processes, but constitute them, has widely been accepted in mathematics education. This led since the 1990s to a growing scientific interest in argumentation theory in mathematics education (e.g., Krummheuer, 1992). Following this line of research, reconstructing argumentation processes has become a methodological framework for the analysis of learning processes, with established methods. This approach allows to get deeper insights into the processes, by which students establish relationships between already existing knowledge to construct new concepts. Combining argumentation analyses with an epistemological perspective, has been suggested by several scholars (e.g., Tabach et al., 2014). We pursue such an integrative approach in our research to describe students' challenges, when they construct and negotiate meaning of the concept of change in a qualitative-graphical approach to calculus.

Content-related interpretations of mathematical objects and their negotiation occur in collective argumentations and are related to *framings*. This concept has widely been used by Krummheuer (1992). Krummheuer, referring to Bruner, conceptualizes 'framing' as a standardized and routinised definition of a situation that emerges from an individual experience in similar situations

(Krummheuer, 1992, p. 24). Since students' individual framings often do not align with each other, differences in framings not only become apparent in collective argumentations, but also constitute starting points for students' negotiations and collective argumentations, which may lead to substantial conceptual development. In this sense, the coordination and modification of framings is, what characterises mathematical argumentations and learning from this perspective (Bredow, 2023).

From an epistemological perspective, research on students' qualitative reasoning about graphs and functions goes back to the 1980s. Leinhardt et al. (1990) analysed interpretation and construction tasks associated with functions and their representations. A qualitative interpretation of a graph here means looking at the graph and gaining meaning related to the two variables displayed in the graph and related to their pattern of covariation. In this sense, interpretation tasks refer to an interactive meaning-making-process. The meaning gained by interpretation and argumentation can either reside within the symbolic space of the graph, or it can shift to a different *space* (e.g., the situation space or the algebraic space). Leinhardt et al. (1990) refer to these shifts as a type of *translation* between different spaces. Construction tasks refer to the act of generating a new representation from data or another representation. In this sense, also construction tasks build on an interactive interpretation and collective argumentation. Combining these theoretical perspectives is our aim in order to describe students' challenges, when deepening their understanding of function and rate of change.

Methods

The design experiment

In the presented research project, a learning environment addressing different perspectives on quantities, change and their interplay was designed. It was then implemented with 15- to 17-year-old students in different secondary schools in Bremen, Germany. The students were already familiar with the concept of derivative and the derivation rules. Change, in this context, had often been considered as a function of time. During five 90-minute lessons, the students worked in class and in groups on various tasks, and the lessons and group work were filmed. Since the analysis is focused on students' understanding and argumentations in classrooms, the students' work is reconstructed by argumentation analyses with an epistemological focus (e.g., Tabach et al., 2014). The corresponding mathematical learning processes are analysed from an interpretative-interactionist perspective. In this paper, the focus is on the students' interpretations of the given situation and their negotiations of the concepts of function, derivative and change that become visible in their argumentations.

Design of the learning environment

The learning environment used in this study is divided into three sections, each focusing on a different perspective on change. In the first perspective, the focus is on the development of a quantity over time ('perspective of quantity'). In the second perspective, statements about the change of a given quantity are the starting point for the students' investigation ('perspective of change'). The third perspective, which is the focus of this contribution, then focuses on the interdependence of a quantity and its instantaneous rate of change (as a function of quantity) ('differential equation perspective') (see also Gunia & Knipping, 2023). The task discussed in this paper is shown in Figure 1. It is used in the last of the five 90-minute lessons and addresses the 'differential equation perspective':

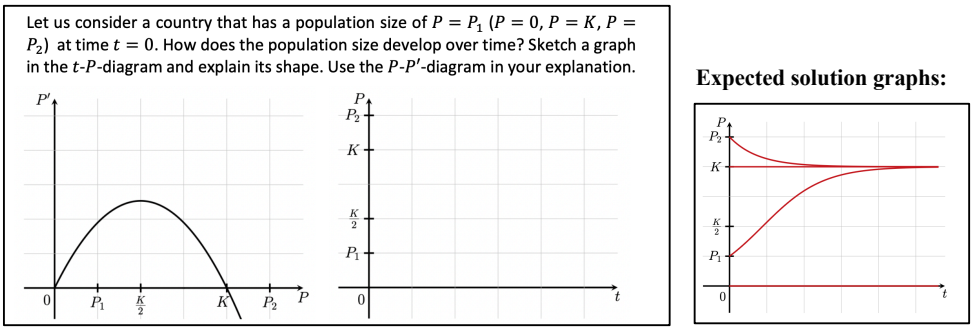

Figure 1: Task - "The growth of a population"

The graph in the P-P'-diagram describes a functional relationship between a population size P and its instantaneous rate of change P'. Independent of time, each population size P is attributed a certain instantaneous rate of change P'. For $P = 0$ and $P = K$, the corresponding rate of change is 0, which means that a population does not change for these values of P. This corresponds with a constant graph in the t-P-diagram (see Figure 1). For P-values $0 < P < K$, the instantaneous rates of change are positive, meaning that a population increases, if it reaches a population size in this interval. For $P(0) = P_1$, the resulting graph in the t-P-diagram represents a logistical growth. For P-values $P > K$, the instantaneous rates of change are negative, represented by a decreasing graph for $P = P_2$.

Results

When students in our research tried to solve this task, they faced various challenges and came up with diverse arguments to provide meaning to the given situation and overcome their struggles in this. The following example illustrates a typical approach, how students attempted to draw graphs into the t-P-diagram. Starting with $P(0) = 0$, the two students Lucy and Chloe discuss the following:

11 Lucy: In the beginning, the growth is zero. And then it is very steep up to K/2 and then it becomes flatter again.

12 Chloe: Yes, it first becomes steeper and steeper up to K/2, then it is at K/2 and then it becomes flatter again and then it has reached K.

13 Lucy: It first rises up to K/2 and then it does the same thing again, only reverse. Somehow like this. I now have an "S" somehow. [...] First, the slope increases, because P' also increases in the other diagram. And then the slope decreases again.

For drawing a graph into the t-P-diagram, Lucy starts by interpreting the P-P'-diagram for the initial value of $P = 0$. She translates her observations of the P-P'-diagram into the t-P-diagram by describing a solution graph (11). In doing so, she offers a temporal view, which is expressed in terms such as "in the beginning" and "and then". She also indicates a graphical view, when she uses terms such as "steep" and "flatter". Chloe adopts this temporal-graphical view in her comment (12). Both students do not talk about the context here, but start drawing the solution graph (see Figure 2).

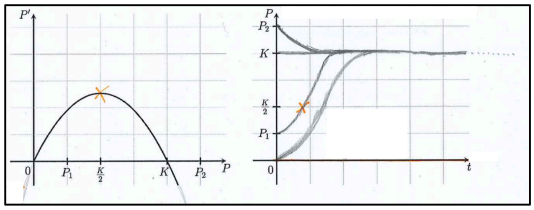

Figure 2: The students' graphical solutions for $P(0) = 0$, $P(0) = P_1$, $P(0) = K$ and $P(0) = P_2$

In turn 13, Lucy characterizes the emerging graph as an "S"-shaped curve and refers to the P-P'-graph for a justification. In the P-P'-diagram, she refers to the first increasing and then falling graph. She explains, what this means for the solution graph in the t-P-diagram, the "slope increases, because P' also increases" and then "the slope decreases" (13). The students start with an interpretation of the P-P'-diagram for the initial population size $P = 0$, which seems mathematically correct ("In the beginning, the growth is zero"). But then, they seem to read a time dependency into the first diagram ("And then … and then …"), instead of using the information about the current state of the system and its changing behaviour to make a prediction about the system's future behaviour (which would accordingly not change). The idea of representing change as a function of time becomes dominant in their interpretation of the P-P'-diagram. For the two students, a shift to the right on the horizontal axis seems to correspond here with a progression of time. When the students talk in the following about, what happens after the population size has reached the value $P = K$, this idea comes up again, but turns out to be problematic:

47 Lucy: And now the question is: If it goes above K, then the slope becomes negative. Then it should actually fall, but that's not possible.
48 Chloe: But, why isn't that possible?
49 Lucy: Because P is becoming more and more. P becomes more, but P' becomes less. That's not really possible. So, if it is negative, P', then P cannot become more. [...] Realistically, there can be no population size above K, as K is a growth limit. For values above K, the rate of change in the P-P' diagram becomes negative, but the population size still increases.

Lucy considers what happens, when P is bigger than K. She translates this information, given in the P-P'-diagram for P-values $P > K$, now into the t-P-diagram. Again, she adopts a temporal-graphical view by describing P-values next to $P = K$ as values following the state $P = K$ in time. According to her rationale, the slope is negative "above K" and the corresponding graph in the t-P-diagram should fall (47). She instantly describes this as impossible as "P becomes more, but P' becomes less" (49). Lucy's argument is based now on the assumption that the population size P is increasing over time. So, a contextual argument comes in here now, but the argument of time and population growth remains. Change is presented here as a function of time, which leads to a temporal interpretation of the horizontal axis in the P-P'-diagram. Accordingly, a progression in time corresponds with a shift to the right on the horizontal axis, which also means a growth in the population size. It seems that Lucy interprets the horizontal axis of the P-P'-diagram as both, a time axis and a population size axis. When Lucy interprets her temporal-graphical argument in the context of the given situation, she now talks about the meaning for the population and its growth (49). The temporal-graphical and the contextual view both occur as conflictive views at this point of their discussion, but remain in parallel.

When talking about the solution that starts in $P(0) = K$, Lucy and Chloe notice a lack of time dependency in the P-P'-diagram and start to solve the conflictive views:

71 Lucy: It should actually be constant there. First. But is it then falling or does it stay there? […] If you look at that point now, there is no time in it. But/ If there is no more growth at K, then P cannot increase anymore.
72 Chloe: Yes, so it is constant. Because it doesn't get bigger, which means the slope can't change either.
73 Lucy: Exactly. The graph is constant, because the instantaneous rate of change is zero.

Lucy states that the solution graph starting in $P(0) = K$ should be constant, at least in the beginning (71). She wonders, whether the graph then decreases or not. In her following (pointwise) interpretation of the P-P'-diagram, she notices the lack of time dependency on the horizontal axis and then starts with a contextual interpretation of the given situation: When there is no growth for $P = K$, the population size does not change and that means that the graph is constant. This observation illustrates a flexible transition between the real-life context and the graphical representation of the given situation. The two students succeed now in translating the information given in the P-P'-diagram into the real-life context and then to re-translate this contextual information into a graphical information in the t-P-diagram.

When they finally go on to the solution that starts in $P(0) = P_2$, the above-mentioned conflictive views related to the population size, which is bigger than K, comes up again:

106 Lucy: But, actually that doesn't work. It doesn't work in any world that P increases, but the rate of change is negative. The rate of change means that there are fewer people. But, you look further to the right on the axis, which means that there are more people. That doesn't work at all.

Lucy again interprets the function in the P-P'-diagram as a function of time. She also describes the function in the P-P'-diagram as a function of quantity, when the progression in time corresponds with a growth in the population size (106). Chloe on the other hand, describes the functional relationship represented in the P-P'-diagram as a given quantity and its dependent instantaneous rate of change, concentrating on a point-by-point interpretation of the graph:

107 Chloe: This is only about one point, which you might find here. If you have P2, right? That's a very huge population size. Then it is very far in the negative range. That means the slope, eh, the instantaneous change, is very strong. In the negative range, but it is still very strong. That means the decrease is very strong. But, since you can't go forward as here, when there is a decrease, because the population is then no longer increasing, but decreasing, you have to read the graph backwards. That means we are now going somehow backwards on the graph. That means, you go from steep to flat. And then it ends at K again.

For a P-value of $P = P_2$, Chloe identifies a very high negative rate of change. She directly transfers this information about the rate of change into a graphical information (when talking about the slope) and into a contextual information ("the decrease is very strong"). Next, she re-interprets the contextual information concerning the population growth into a graphical information concerning the P-P'-diagram. A decrease in the population size here means that one has to read the graph "backwards". Despite their different interpretations at the beginning, Chloe and Lucy finally develop a complete argument for the solution that starts in $P(0) = P_2$ together:

327 Chloe: For P=P2, the slope in the P-P'-diagram is very strongly in the negative range. The instantaneous rate of change is very strongly in the negative range.

328 Lucy: Thus, the population size decreases so that the x-axis has to be practically read backwards.

329 Chloe: Since P becomes smaller. [...] Then it is closer to the x-axis again, the graph in the P-P'-diagram, which means that the instantaneous rate of change is not so much in the negative range anymore and is getting closer and closer to zero, which is why the graph in the t-P-diagram becomes flatter.

Lucy adopts the aforementioned interpretation of the P-P'-diagram of Chloe. Together, they flexibly shift between graphical and contextual arguments. Their negotiation process is guided by the

question: “What does a negative rate of change mean for the development of a population size?” Related to the real-life context, the two students translate between the graphical representation of the given situation and its contextual meaning. This contextual interpretation is then again translated graphically into the t-P-graph, where the actual population growth over time is represented.

Discussion

The presented student approaches illustrate challenges students face, when confronted with a dynamic situation, in which change is depended on quantity (and not on time). Students have to overcome epistemological obstacles and conceptual difficulties, when looking at population growth, dependent on population sizes and not on time. This requires a shift in the students’ *framing* of the concept of change. Our data indicate, how challenging it is for students to interpret change as a function of quantity, not time. Students need to conceptualize this functional relationship to determine the change over time in a dynamic system. As students are not familiar with this perspective, this is challenging for them. Also, this conceptualization of change breaks conventions on how to read a graph: Following a “time dependency logic” of change, the students first read the graph from “left to right”. Reading the graph “backwards”, detached from a temporal point of view, is completely new to them.

In the course of the here presented group work, a significant shift in the students’ argumentations occurs. The students recognize the lack of time dependency in the P-P’-diagram, when they construct the solution that starts in $P(0) = K$. This constitutes a significant breaking point in the students’ interpretation and constructing process as described by Leinhard et al. (1990). From this point on, the students switch from a temporal-graphical interpretation of the given situation to a contextual-graphical perspective. In this sense, they *translate* between different *spaces*. This motivates the students to pursue a new direction in their argumentation, which takes into account the real-life context of the task. This shift supports a constant transition between the real-life context and the graphical and verbal representation of the situation, which is essential for their successful solution of the task. These transitions between the real-life context and a graphical and verbal representation of the given situation are challenging for the students, but allow them to adopt a new perspective.

Conclusion

The here presented results illustrate, how students can mobilize their knowledge about functions and rate of change, when working on the given task. This indicates, how tasks in dynamical contexts can support functional thinking and the discovery of new functional relationships. The students’ argumentations deepen and consolidate their understanding of functional dependency and change. Our findings also indicate that students are challenged, when they face dynamic contexts and that they need to develop flexible ways, how to use their concepts of function and rate of change in this situation. We provide evidence that argumentations help the students to develop more flexible ways to use these concepts, when they transit between different representations of the given situation.

The ways in which students deal with the challenges they face are diverse, as our data indicate. Looking closer into the arguments different students come up with and how these help them to overcome the described challenges, is our research goal. Characterizing distinct breaking points in the students’ negotiation processes and their argumentations will be a next milestone in this research.

Opportunities for pre-structuralist reasoning at the crossroads from calculus – a case study on the equivalence between the continuity of a function and the path-connectedness of its graph

Erik Hanke[1], Reinhard Hochmuth[1] and Thomas Hausberger[2]

[1]Leibniz University Hannover, Faculty of Mathematics and Physics, Hannover, Germany; hanke@idmp.uni-hannover.de

[2]University of Montpellier, Alexander Grothendieck Montpellier Institute, Montpellier, France

Mathematical reasoning based on definitions and theorems and the attention towards generalisation are important for the transition from calculus to analysis or topology. We analyse proofs of a task about the equivalence of the continuity of a real-valued function on an interval and the path-connectedness of its graph. In doing so, we examine elements of "pre-structuralist praxeologies" at the crossroads from calculus to more advanced courses. The proofs take pre-structuralist aspects into account in different ways. This holds for the mobilisation of levels of pre-structuralist praxeologies as a means of generalisation. Thus, we contribute to calculus education by focusing on the transition from a more intuitive to a more formal way of reasoning based on underlying structures about functions and graphs.

Keywords: (Pre-)structuralist praxeologies, calculus, real analysis, continuity, path-connectedness.

Introduction

Many students have heard or emphasise themselves that the graph of a continuous real-valued function $I \to \mathbb{R}$ ($I \subseteq \mathbb{R}$ interval) – now called a *real function* – can be drawn "without lifting the pen from the paper" (Hanke, 2018). This intuitive characterisation is used to strengthen pupils' intuition for continuity in school, too. Research has also shown that one of the dominant strategies students at university follow to identify continuity is based on the appearance of the graph of the function (Hanke & Schäfer, 2017). One way to make this intuitive statement rigorous is the equivalence that a real function is continuous if and only if its graph is a path-connected subset of $\mathbb{R}^2$, which means that any two points on the graph can be joined by a continuous path in the graph. Here, the intuitive idea is made precise with the notion of path-connectedness of the graph, which is a more specific notion than connectedness. In particular, this formalisation underlines the importance of mathematical exactification of intuitive ideas into precise properties. This is relevant at the transition from calculus, where the more intuitive aspects are located, to more advanced courses. The context of our investigation are study programmes for mathematics majors or pre-service teachers that include the transition from calculus to more advanced courses. Furthermore, the equivalence is relevant for pre-service teachers as it provides background knowledge on how intuitive ideas as promoted in calculus at both university and school can be made precise.

Proving the equivalence is however rather challenging, at least when compared to the tasks posed in (school) calculus or in introductory calculus or real analysis courses. In particular, from a bird's eye view, continuity and path-connectedness are topological notions. One concern of this paper is thus to

highlight different approaches for reasoning about this statement that might be backed with structures from analysis or even topology. Specifically, we consider the following task:

> t: *For an interval* $I \subseteq \mathbb{R}$, *a function* $f: I \to \mathbb{R}$ *is continuous if and only if its graph* $\Gamma_f = \{(x, f(x)) : x \in I\}$ *is path-connected.*

This equivalence appears in sources, which are either explicitly devoted to real functions (e.g., van Rooij & Schikhof, 1982), which embed the notions of continuity and path-connectedness into metric space topology (e.g., Ross, 2013), or in sources on topology (e.g., Gathmann, 2023). This article's aim is to analyse proofs for t, rooted in real analysis as a formalised variant of calculus, with respect to their potential to foster students' awareness for possibilities to use definitions and propositions for verification of properties of objects (here: continuity and path-connectedness) and for possible generalisations to more abstract structures. In our analyses of proofs for t, we highlight to what degree the considerations could be interpreted as contextualised general principles, that is, structuralised ideas that can be more or less expressed verbatim in the context of metric or even topological spaces.

The paper is embedded into our previous work on this task (Hanke, 2018) and structuralist reasoning in real analysis (Hausberger & Hochmuth, 2023). In our novel methodological approach to the potential of tasks for generalisation, we draw on the concept of *(pre-)structuralist praxeologies* (Hausberger, 2018) in the *Anthropological Theory of the Didactic* (Chevallard & Bosch, 2020; Hausberger & Hochmuth, 2023; Laukert et al., 2023). More precisely, we extract so-called *techniques* and *technologies*, that is, ways to solve tasks and their mathematical underpinning, which constitute the architecture of proofs. These relate to reasoning based on the use of definitions and theorems in terms of two levels.

Theoretical framework

The *Anthropological Theory of the Didactic (ATD)* (Chevallard & Bosch, 2020) considers the relationships to an object of knowledge by praxeologies where the object intervenes at the level of at least one of the following components: "The anthropological theory of didactics considers that, *in the end*, all human activity consists of *accomplishing a task* t of a certain *type* T by means of a certain *technique* τ, *justified* by a *technology* θ which at the same time makes it possible *to think about* it, or even *to produce* it, and which is in turn *justifiable* by a *theory* Θ" (Chevallard, 2001, p. 3, own transl.).

Hausberger (2018) introduced the notion of *structuralist praxeologies* in the context of abstract algebra: They are praxeologies $P_s = [T^g, \tau, \theta, \Theta_{\text{structure}}]$, where the type of task T^g is a generalisation of T from a not-yet-structuralist praxeology $P = [T, ?, ?, \Theta]$ (at least not when compared with the structure for P_s). Here, the adjective "structuralist" refers to the use of structures in the sense of Bourbaki (1950) rather than concrete instances (e.g., mobilising results about general metric spaces rather than a specific metric space) (Hausberger, 2018). In real analysis courses, generic objects such as real functions, sequences, or series may appear, but properties of functions and their domains ($\mathbb{R}$ or $\mathbb{R}^n$) that play a role may not be fully elucidated at that moment in terms of, for example, topological concepts. In this context, praxeologies were therefore called *pre-structuralist* (Laukert et al., 2023). That is, these praxeologies may be generalised with respect to a certain, not necessarily unique, structure (e.g., sets appearing in a pre-structuralist praxeology may be generalised to metric or

topological spaces). The structure may not have been made explicit in the institutional context of the pre-structuralist praxeology though and lurk in the background but may be made explicit in building up a structuralist praxeology. Regarding pre-structuralist praxeologies, we distinguish between *level 1*, where structuralist aspects mainly appear through definitions or as vocabulary, from *level 2* praxeologies, where a technique invokes general results on structures (Hausberger, 2018; Laukert et al., 2023). Accordingly, our research question is: *Which techniques and technologies can be enacted in proofs of t to foster the development of (pre-)structuralist praxeologies?*

Method

We performed a content analysis of German, English, and French textbooks and lecture notes on calculus, analysis, and topology for the equivalence in the task t and similar characterisations of continuous functions, as well as research literature and mathematics online forums. Based on these sources (e.g., JOJO, 2020; van Rooij & Schikhof, 1982; Ross, 2013), the first author broke down the argumentation in two proofs for each direction of t into techniques and technologies similar to a coding procedure (see Tables 1 and 2 below). Regarding reliability, the analysis of the proofs in terms of these techniques and technologies were discussed with all authors until a consensus was reached.

We emphasise that we do not present full praxeologies here in a *specific* institutional context. In fact, every institutional context gives rise to its own praxeologies. Rather, we focus on techniques and technologies and trace options for generalisation (e.g., as specified in different theories such as real analysis or topology). This aligns with our objective of exploring solutions that may be enacted in mathematics curricula with respect to the use of structures. This also means that the techniques and technologies we present contain *didactic variables*, that is, unspecified elements that are indeed specified within a full praxeology. As a result, the analysis below is presented in terms of chains of propositions like a skeleton and the linkages between these propositions are explained in terms of the techniques and technologies.

Results: Praxeological analyses of different proofs for the task

We denote the implication "f continuous $\Rightarrow$ Γ_f path-connected" in t by $t^{\Rightarrow}$ and the other by $t^{\Leftarrow}$. We recall that a subset A of a topological space X is called *path-connected* if for every $x, y \in A$ there is a path (i.e., a continuous function) $\gamma\colon [a, b] \to A$ with $\gamma(a) = x$ and $\gamma(b) = y$. For contextualisation, we also recall that A is called *connected* if it is not the union of two non-empty disjoint sets that are open in A (with respect to the relative topology), and that every path-connected set in every topological space is connected, but not the other way around.

The task t is a special case of two types of tasks, which may be embedded either in real analysis or topology, T_1: *Prove that a set Y is path-connected* and T_2: *Prove that a function is continuous*. Specifically, $t^{\Rightarrow}$ is an instance of T_1 for $Y = \Gamma_f$ and $t^{\Leftarrow}$ is an instance of T_2 for $f\colon I \to \mathbb{R}$. From a structuralist perspective, t also belongs to a type of tasks that is even currently investigated in research in analysis and topology, T: *Characterise properties of a function in terms of properties of its graph* (see Hausberger et al., these proceedings).

We will now present two proofs for $t^{\Rightarrow}$ and $t^{\Leftarrow}$. Tables 1 and 2 show techniques and technology that back these proofs and in which they occur. The analysis after each proof shows how these techniques

and technologies are enacted and highlight pre-structuralist levels and further aspects. We emphasise that different institutional contexts and theories lead to more exactified versions of the techniques and technologies we list here. For instance, θ_4 could mean "definition of continuity for a map $U \to \mathbb{R}$ for subsets $U \subseteq \mathbb{R}$" in a single-variable real analysis context or "definition of continuity for a map between two metric spaces" in a metric space context. In this sense, the techniques and technologies contain didactic variables to be concretised within each institutional context and theory.

Table 1: Techniques and their use in the proofs

τ_1: *Verify the definition of path-connectedness for a set*	$P_1^{\Rightarrow}$
τ_2: *Show that a set Y is the image of a path-connected set Z under a continuous function F*	$P_2^{\Rightarrow}$
τ_3: *Assume the discontinuity of a function and find a contradiction*	$P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$

Table 2: Technologies and their use in the proofs

θ_1: *definition of path-connectedness*	$P_1^{\Rightarrow}$, $P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$
θ_2: *product functions are continuous if and only if their component functions are continuous*	$P_1^{\Rightarrow}$, $P_2^{\Rightarrow}$, $P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$
θ_3: *continuous maps preserve path-connectedness* (i.e., if Z is path-connected and F is a continuous map on Z, then $F(Z)$ is path-connected)	$P_2^{\Rightarrow}$
θ_4: *definition of continuity*	$P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$
θ_5: *Bolzano-Weierstraß theorem* (bounded sequences in $\mathbb{R}^N$ contain convergent subsequences)	$P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$
θ_6: *the intervals $[a,b] \subseteq \mathbb{R}$ are bounded and closed*	$P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$
θ_7: *intermediate value property (IVP) for real-valued functions f defined on intervals $I \subseteq \mathbb{R}$* (i.e., for all $w_1, w_2 \in \mathrm{im}(f)$ and $c \in \mathbb{R}$ between w_1 and w_2 there is a $\xi \in I$ with $f(\xi) = c$)	$P_2^{\Leftarrow}$
θ_8: *intermediate value theorem for real functions* (i.e., every continuous function has the IVP)	$P_1^{\Leftarrow}$, $P_2^{\Leftarrow}$

Analysis of $t^{\Rightarrow}$: "f continuous ⇒ Γ_f path-connected"

Proof 1 ($P_1^{\Rightarrow}$) (Ross, 2013, p. 182):

1. Let $\big(a, f(a)\big), \big(b, f(b)\big) \in \Gamma_f$, and without loss of generality assume that $a \leq b$. The function $\gamma\colon [a,b] \to \mathbb{R}^2$, $x \mapsto \big(x, f(x)\big)$, is a path from $\big(a, f(a)\big)$ to $\big(b, f(b)\big)$ (i.e., γ is continuous and satisfies $\gamma(a) = \big(a, f(a)\big)$, $\gamma(b) = \big(b, f(b)\big)$ and $\mathrm{im}(\gamma) \subseteq \Gamma_f$).
2. Hence, Γ_f is path-connected.

The task $t^{\Rightarrow}$ is solved with the technique τ_1 to verify the definition of path-connectedness with the technology θ_1 for Γ_f. That is, this argument is on level 1. The continuity of γ is supported with θ_2 because $\gamma = \mathrm{id}_{|[a,b]} \times f_{|[a,b]}$ is continuous since $\mathrm{id}_{|[a,b]}$ and $f_{|[a,b]}$ are. The definition θ_4, although

part of theory blocks backing this technology, is not used explicitly. No structuralist proposition about path-connectedness is involved and the used technique corresponds to a property of product maps that happen to be needed as the codomain of the image of the path is in $\mathbb{R}^2$.

Proof 2 ($P_2^{\Rightarrow}$):

1. Γ_f is the image of the continuous function $\mathrm{id}_I \times f: I \to \mathbb{R}^2$, $x \mapsto \big(x, f(x)\big)$.
2. I is path-connected.
3. Hence, $\Gamma_f = \mathrm{im}(\mathrm{id}_I \times f)$ is path-connected.

Here, the technique τ_2 to identify Γ_f as the continuous image of a path-connected set, namely $\mathrm{im}(\mathrm{id}_I \times f)$, points to level 2 pre-structuralist reasoning. The application of this technique is backed with the technology θ_3 that asserts that path-connectedness of Γ_f is preserved under continuous maps for $Z = I$ under $F = \mathrm{id}_I \times f$. As in $P_1^{\Rightarrow}$, the continuity of the map $\mathrm{id}_I \times f$ is backed with θ_2.

We emphasise the different architectures of these two proofs: While the first proof amounts to a verification of the definition, the second is based on a pre-structuralist theorem (with respect to the metric space structure). It turns out, however, that the technology used to verify either the definition τ_2 and recognising Γ_f as a continuous image is in both cases θ_2. We note that the second more structuralist proof is, broadly speaking, not "more efficient", but that the work done is fundamentally different: verifying a defining property vs. verification the prerequisites of a theorem. We further note that the technologies θ_2 and θ_3 are also in principle valid in the context of general metric or topological spaces (e.g., for any path-connected topological space Z and continuous function F on Z). Hence, the specific properties of the spaces I and $\mathbb{R}^2$ are not important in $P_2^{\Rightarrow}$. As such, $P_2^{\Rightarrow}$ could be seen as an example for a proof, which is backed with real analysis and which mimics a more general metric space theory. In a similar spirit, the proof $P_1^{\Rightarrow}$ may be transformed into a proof of θ_3 for the context of metric or topological spaces. Hence, the argumentation in this proof of $t^{\Rightarrow}$ could, at least in principle, serve as a case to illustrate how a real analysis-based technology (i.e., if θ_3 is backed with real analysis) may be transformed into a more general structural one.

Analysis of $t^{\Leftarrow}$: "Γ_f path-connected ⇒ f continuous"

Proof 1 ($P_1^{\Leftarrow}$) (JOJO, 2020):

1. Assume that f is not continuous at some $x_0 \in I$. Then, there is an $\varepsilon > 0$ and a sequence $(x_n)_{n\in\mathbb{N}}$ in an interval $[a, b] \subseteq I$ such that $\lim_{n\to\infty} x_n = x_0$ and $|f(x_n) - f(x_0)| > \varepsilon$ for all $n \in \mathbb{N}$.
2. There is a path $\gamma = (u, v)$: $[0, 1] \to \Gamma_f$ with $v = f \circ u$, $\gamma(0) = \big(a, f(a)\big)$, $\gamma(1) = \big(b, f(b)\big)$.
3. There is a sequence $(t_n)_{n\in\mathbb{N}}$ in $[0, 1]$ with $u(t_n) = x_n$ for all $n \in \mathbb{N}$.
4. There is a convergent subsequence $\big(t_{n_k}\big)_{k\in\mathbb{N}}$ of $(t_n)_{n\in\mathbb{N}}$ with limit $t_0 \in [0, 1]$ such that $\lim_{k\to\infty} \gamma\big(t_{n_k}\big) = \lim_{k\to\infty} \Big(u\big(t_{n_k}\big), v\big(t_{n_k}\big)\Big) = \big(u(t_0), v(t_0)\big) = \Big(u(t_0), f\big(u(t_0)\big)\Big) = \big(x_0, f(x_0)\big)$.
5. In particular, $\lim_{k\to\infty} f\big(x_{n_k}\big) = f(x_0)$; contradiction to 1 (hence, f is continuous).

Here, the technique τ_3 is used and the discontinuity of f is assumed in a proof by contradiction. Mobilising the definition of continuity θ_4, here using sequences, and taking the logical negation, the numbers x_0 and ε, the interval $[a, b]$, and the sequence $(x_n)_{n\in\mathbb{N}}$ are initialised. Mobilising further the

technology θ_1 for $\Gamma_f \subseteq \mathbb{R}^2$, the points $\big(a, f(a)\big), \big(b, f(b)\big) \in \Gamma_f$, the path $\gamma = (u, v)$, and a sequence of preimages $(t_n)_{n\in\mathbb{N}}$ of $(x_n)_{n\in\mathbb{N}}$ for the first coordinate function of γ is constructed using θ_8. Throughout, as in $P_1^{\rightrightarrows}$ and $P_2^{\rightrightarrows}$, θ_2 connects the continuity of γ to the continuity of the coordinate functions u and v. A convergent subsequence of these preimages is $\big(t_{n_k}\big)_{k\in\mathbb{N}}$ obtained by θ_5 and θ_6, whose limit t_0 is in $[0, 1]$ because $[0, 1]$ is closed by θ_6. The final computations use the convergence of $\big(t_{n_k}\big)_{k\in\mathbb{N}}$ and the sequential definition of continuity θ_4 for γ and f, which yield the desired contradiction to step 1. We note that the use of τ_3 and θ_4 is based on the sequence characterisation of continuity, hence tightly connected to one of the usual ways continuity is dealt with in analysis. These characterisations may be generalised to metric spaces, but not to general topological spaces, where a sequence-based characterisation is not available.

A variant of $P_1^{\Leftarrow}$ is due to van Rooij and Schikhof (1982, p. 53): Choose $(x_n)_{n\in\mathbb{N}}$ convergent to $x_0 \in I$ and contained in some interval $[a, b] \subseteq I$, then $\big(f(x_n)\big)_{n\in\mathbb{N}}$ is bounded (because $\Gamma_{f|[a,b]}$ is compact, which could be shown with the technology that surjective continuous images of compact to Hausdorff spaces are closed, i.e., a level 2 structuralist argument). It follows that $\alpha \coloneqq \limsup_{n\to\infty} f(x_n) = \lim_{k\to\infty} f\big(x_{n_k}\big)$ for some subsequence; hence $\lim_{k\to\infty} \Big(x_{n_k}, f\big(x_{n_k}\big)\Big) = (x_0, \alpha) \in \Gamma_{f|[a,b]}$ and $\alpha = f(x_0)$ (similarly for $\beta = \liminf_{n\to\infty} f(x_n)$). It can thus be concluded that $\lim_{n\to\infty} f(x_n)$ exists and is equal to $f(x_0)$.

Proof 2 ($P_2^{\Leftarrow}$) (Ross, 2013, pp. 182–183):

1. Assume that f is not continuous at some $x_0 \in I$. Then, there is an $\varepsilon > 0$ and a sequence $(x_n)_{n\in\mathbb{N}}$ in an interval $[a, b] \subseteq I$ such that $\lim_{n\to\infty} x_n = x_0$ and $|f(x_n) - f(x_0)| > \varepsilon$ for all $n \in \mathbb{N}$.
2. There is a path $\gamma\colon [0, 1] \to \Gamma_f$ with $v = f \circ u$, $\gamma(0) = \big(a, f(a)\big)$ and $\gamma(1) = \big(b, f(b)\big)$.
3. For any $z \in [a, b]$ there is a $t \in [0, 1]$ such that $u(t) = z$; thus $\big(z, f(z)\big) = \Big(u(t), f\big(u(t)\big)\Big) = \gamma(t)$ and $\Gamma_{f|[a,b]} \subseteq \mathrm{im}(\gamma)$.
4. f satisfies the IVP on $[a, b]$.
5. Without loss of generality, and potentially by replacing $(x_n)_{n\in\mathbb{N}}$ with a subsequence, assume that $f(x_n) > f(x_0) + \varepsilon$ for all $n \in \mathbb{N}$.
6. By 4., there is a sequence $(y_n)_{n\in\mathbb{N}}$ in $\mathbb{R}$ such that y_n is between x_0 and x_n and $f(y_n) = f(x_0) + \varepsilon$ for all $n \in \mathbb{N}$.
7. The sequence $\Big(\big(y_n, f(y_n)\big)\Big)_{n\in\mathbb{N}}$ satisfies $\lim_{n\in\mathbb{N}} \big(y_n, f(y_n)\big) = (x_0, f(x_0) + \varepsilon)$.
8. There is a sequence $(t_n)_{n\in\mathbb{N}}$ such that $\gamma(t_n) = \big(y_n, f(y_n)\big)$ for all $n \in \mathbb{N}$.
9. There is a subsequence $\big(t_{n_k}\big)_{k\in\mathbb{N}}$ of $(t_n)_{n\in\mathbb{N}}$ with limit $t_0 \in [0, 1]$ such that $\gamma(t_0) = \lim_{k\to\infty} \gamma\big(t_{n_k}\big) = \lim_{k\to\infty} \Big(y_{n_k}, f\big(y_{n_k}\big)\Big) = (x_0, f(x_0) + \varepsilon) \notin \Gamma_f$; contradicting 3 (hence, f is cont.).

As in $P_1^{\Leftarrow}$, τ_3, θ_1, and θ_4 are used to initialise the numbers x_0, ε, the interval $[a, b]$, the sequence $(x_n)_{n\in\mathbb{N}}$, and the path $\gamma = (u, v)$ between $\big(a, f(a)\big), \big(b, f(b)\big) \in \Gamma_f$. Throughout, θ_2 connects the continuity of γ to the continuity of the coordinate functions u and v. θ_7 (and θ_8) can be applied to u to show that $\Gamma_{f|[a,b]} \subseteq \mathrm{im}(f)$ (step 3; Ross, 2013, p. 182). Then, applying θ_7 to $v = f \circ u$ allows to conclude the IVP θ_8 for f. The construction of $(x_n)_{n\in\mathbb{N}}$ is based on step 1 (i.e., on θ_4) and $(y_n)_{n\in\mathbb{N}}$

on step 4. The construction of the preimages $(t_n)_{n\in\mathbb{N}}$ of $(y_n)_{n\in\mathbb{N}}$ and the convergent subsequence $(t_{n_k})_{k\in\mathbb{N}}$ is similar to $P_1^{\Leftarrow}$ and backed with θ_5 and θ_6. As in $P_1^{\Leftarrow}$, the computation of the limit $\lim_{k\to\infty} f(y_{n_k}) = f(x_0) + \varepsilon$ yields the desired contradiction to step 3 because $\gamma([0,1]) \subseteq \Gamma_f$.

Both proofs make use of level 1 pre-structuralist praxeologies, since the technique τ_3 is a check of the definition of continuity. Here, no level 2 (pre-)structuralist arguments of the form that a certain property of a graph of a function implies continuity is used; hence, the argumentation stays at level 1. Moreover, the arguments are strongly locally backed with real analysis. Also note that Ross' (2013) proof of $t^{\Leftarrow}$ is in a sense a more complicated version of JOJO's (2020) proof by adding the arguments about the sequence $(y_n)_{n\in\mathbb{N}}$. Since the (dis-)continuity of maps between metric spaces can be characterised in terms of sequences, the proofs here also work from the more abstract perspective of metric space topology. Indeed, and a bit surprising, metric space topology is developed in the chapter where Ross (2013) discusses the proposition from t, but he does not mention structural results nor metric space terminology in its proof.

Conclusion

The task t points to a school-related basic idea about continuous functions. The equivalence may be understood as an exactification using calculus and analysis concepts. Our analysis revealed that the task allows for different proofs, taking into account different techniques and technologies. Our novel methodological approach showed that the proofs point to structuralist aspects in different ways. This holds for the mobilisation of the two levels of pre-structuralist praxeologies, but also with regards to embedding the task in courses that transition to metric space or general topology. This is valuable for calculus education since a proof comparison, potentially made explicit to students, reveals how the techniques and technologies may be enacted in multiple ways and contexts. Our approach serves as a first step to analyse corresponding praxeologies. We would also like to refer the reader to Hausberger et al. (these proceedings) for an analysis of the task t through the lens of *external didactic transposition* (i.e., the process of transforming scholarly knowledge into knowledge to be taught).

A consequence for teaching is that students may be aided in making the transition from more local to more general arguments and in attending to structures by comparing techniques and technologies in proofs presented to or demanded from them. We addressed this issue with a proposition that students are likely familiar with from calculus, whose intuitive statement had to be made rigorous carefully by choosing a suitable topological property. We hypothesise that the analysed task may therefore contribute to students' development of an appropriate image of modern mathematics, particularly at the crossroads from calculus to analysis and further to (metric space) topology. Whether it is more beneficial to give the equivalence as a task to the students or to deal with it and its proofs in a lecture depends of course on respective institutional conditions. The aim of subsequent research is to examine student solutions to the task t in relation to their institutional context and how they proceed to focus on structures or use (pre-)structuralist praxeologies.

Measurement, Inverse Proportions, and Integration by Substitution

Andrew Izsák

Tufts University, Department of Education, Medford, MA, United States; Andrew.Izsak@tufts.edu

Interpreting definite integrals and their notation as summations of small amounts of a target quantity (Adding Up Pieces) is especially productive for applied problems. This report develops a new justification for integration by substitution based on Adding Up Pieces that makes three contributions. First, whereas past research on integration has rarely foregrounded explicit, quantitative meanings for multiplication, the analysis presented here is based on connections between multiplication and coordinated measurement with two units. Second, the analysis uses coordinated measurement to explain how, across diverse situations, small amounts of a target quantity can be understood as products represented by rectangular areas. This supports reasoning about Riemann sums as approximations for definite integrals. Finally, the analysis provides a new justification for integration by substitution that relies on rectangular areas and inversely proportional relationships.

Keywords: Calculus, Multiplication, Measurement, Integration.

Introduction

A growing body of research has reported on students' interpretation and construction of integrals, especially when solving problems in physics and other domains outside of pure mathematics (e.g., Jones & Ely, 2023; Nguyen & Rebello, 2011; Oehrtman & Simmons, 2023). Integration by substitution, or u-substitution, plays a central role in many applications yet, as Jones and Fonbuena (2024) pointed out, mathematics and science education research has largely overlooked this central topic.

In traditional calculus instruction, integration by substitution is often introduced as the "reversed chain rule," which in the case definite integrals can be expressed with the following equation: $\int_a^b f'\big(g(x)\big)\, g'(x)\, dx = \int_{g(a)}^{g(b)} f'(u)\, du$. (A more general statement holds when f is simply continuous.) Typically, students are presented with an integral whose form fits the left-hand side of the equation. Their task is to identify the functions f', g, and g' that afford transformation to the right-hand side of the equation, which then has an integrand that one (hopefully) knows how to integrate. A common justification for this transformation includes replacing $g(x)$ with u and $g'(x)\, dx$ with du, a justification that can be understood simply in terms of manipulating symbols.

This theoretical report presents a mathematical analysis that foregrounds reasoning with quantities to develop a new justification for integration by substitution. The analysis makes three contributions. First, it builds upon recent advances connecting multiplication and measurement of quantities to explain how rectangular areas can be used to model products across a wide range of situations that arise in physics and other domains. Second, the focus on rectangular areas challenges some recently articulated reservations about interpreting definite integrals as "areas under curves." Third, the new justification foregrounds rectangular areas and inversely proportional relationships and, thus, focuses on the Riemann sums used to approximate definite integrals. Finally, the analysis suggests a new

instructional pathway into integration by substitution that is based on reasoning with quantities and that may be accessible to students.

The rest of this report is organized into four sections. The first section provides an analysis of multiplication with quantities that lays the foundation for interpreting definite integrals as "areas under curves." The second section explains how a focus on quantitative meanings for multiplication contributes to research on integration. The third section builds directly on the first and presents the justification for integration by substitution based on rectangular areas and inversely proportional relationships. The fourth section provides examples of written work in which students construct explanations like the one developed across the first three sections of the report.

Multiplication with Quantities and Coordinated Measurement

Thompson (1994, p. 184) articulated the following definition of a quantity when introducing his theory of quantitative reasoning: A quantity consists of "an object, a quality of the object, an appropriate unit or dimension, and a process by which to assign a numerical value to the quality". This definition implies that numbers are outcomes of measurement: They express how many units, or how much of a unit, exhaust the extent of the "quality" in question. We often use the term "multiplication" to refer to this fusion of number and measurement—for instance, we might say that a taller building is "three times" the height of a shorter building when what we mean is that three of short height exhaust the tall height. In such cases, measurement, numbers, and multiplicative language are intertwined. This meaning for multiplication, based on measurement with a *single* unit, is insufficient for understanding how Riemann sums approximate definite integrals.

In contrast to using multiplicative language with a single measurement unit, Izsák and Beckmann (e.g., Beckmann & Izsák, 2015; Izsák & Beckmann, 2019) have explicated a meaning for multiplication based on measurement with *two* units they term base units and groups units. Figure 1 shows an equation where N, M, and P are outcomes of measurement, as discussed above. The product amount is measured simultaneously in base units and in group units: P base units and M group units are measures of the same product amount. N expresses the measure of 1 group unit in terms of base units. Izsák and Beckmann have referred to this perspective as the coordinated measurement meaning for multiplication, and they have argued that it works with positive real numbers, ties together diverse situations using a single quantitative structure, and challenges the field to rethink several established results, including results about classification of problem situations in which one typically multiplies or divides (e.g., Vergnaud, 1983).

N	•	M	=	P
How many base units make one group unit?		How many group units make one product amount?		How many base units make one product amount?

Figure 1: A coordinated measurement meaning for multiplication (Izsák & Beckmann, 2019, p. 91)

In preparation for interpreting integrals as areas under curves, I highlight Vergnaud's (1983) seminal approach to classification of problem situations. He analyzed mathematical structures for multiplying with quantities and distinguished two primary subtypes. *Isomorphism-of-measure-spaces* (I-o-M)

situations are ones where the multiplicative structure "consists of a simple direct proportion between two measure spaces, M_1 and M_2" (1983, p. 129). Here the direct proportion is often viewed as a rate of change. *Product-of-measure-spaces* situations (P-o-M) are "the Cartesian composition of two measure spaces, M_1 and M_2, into a third, M_3" (1983, p. 134).

Figure 2 shows one example of an I-o-M situation and one example of a P-o-M situation. Examination of the units attached to each number helps differentiate the two classes. In the I-o-M situation, one factor is expressed as a rate (miles per hour in Figure 2a) and the units that form that rate are also the units for the second factor (hours) and for the product (miles). In the P-o-M situation, none of the terms is expressed in rate units, and the units for each factor (Newtons and meters in Figure 2b) are independent of one another. Different patterns of units on factors and products raises as a question whether a single quantitative meaning for multiplication can be used across different situations or whether more than one quantitative meaning is required.

3 miles/hour • 7 hours = 21 miles (a)

3 Newtons • 7 meters = 21 Newton-meters (b)

Figure 2: Illustrating Vergnaud's (1983) classification. (a) An I-o-M situation. (b) A P-o-M situation.

Izsák and Beckmann (e.g., Beckmann & Izsák, 2015; Izsák & Beckmann, 2019) have argued that coordinated measurement provides a single meaning for multiplication that spans both I-o-M situations and P-o-M situations. Figure 3 shows how the coordinated measurement meaning for multiplication summarized in Figure 1, combined with rectangular areas, can fit both I-o-M and P-o-M situations. The same rectangular area represents a product amount measured both in base units (each small square represents 1 base unit) and in group units (each column represents 1 group unit). Figure 3a uses the same speed • time = distance example from Figure 2a, and Figure 3b uses the same force • distance = work example from Figure 2b. In Figure 3a, if each small square represents 1 mile (1 base unit) and each column corresponds to 1 hour (1 group unit), then the measure of one column in base units is 3, the change measured in hours is 7, and the change measured in miles is 21. In Figure 3b, if each small square represents 1 Newton-meter (1 base unit) and each column corresponds to 1 meter (1 group unit), then the measure of one column in base units is 3, the change measured in meters is 7, and the change measured in Newton-meters is 21.

The examples in Figure 3 indicate how attention to two measurement units, made explicit in the $N \bullet M = P$ equation, allows one to see parallels (i.e., there is an isomorphism) between rectangular areas and the two applied situations, one an I-o-M situation and one a P-o-M situation. This, in turn, justifies why in physics and other domains interpreting definite integrals in terms of areas can be applied both to I-o-M situations and to P-o-M situations. In the next section, I explain how explicit attention to coordinated measurement extends past research on integration.

Reasoning with Definite Integrals

Research on integration goes back to at least the 1980s but has grown considerably in the last decade (e.g., Jones & Ely, 2023). One line of research has identified alternative interpretations of integrals and their notation. Thompson and colleagues (e.g., Thompson et al., 2013) have argued that

interpretating integrals as accumulations from rates of change can facilitate reasoning about the Fundamental Theorem of Calculus. In other work, Jones (2013) found that college students can interpret the $\int_a^b f(x)\,dx$ notation as indicating addition of small pieces (Adding Up Pieces), denotating boundaries of a region in the plane, and signifying a function whose derivative is the integrand. Within this line, researchers have, at times, questioned whether the area-under-a-curve interpretation for definite integrals is sufficient for modeling physical situations (e.g., Jones & Ely, 2023; Nguyen & Rebello, 2011; Thompson et al., 2013). Moreover, there have been reports of students struggling to understand how areas can represent other types of quantities—for instance, how an area can represent a distance (Thompson et al., 2013, p. 125). As the examples in Figure 3 suggest, however, the coordinated measurement meaning for multiplication supports reasoning about rectangular areas as general products across a wide range of situations. Such a meaning could help students understand how rectangular areas—and Riemann sums—can be used to approximate definite integrals across both I-o-M and P-o-M situations. (As a side note, it is more precise to say that definite integrals can be interpreted as signed areas bounded by curves and the horizontal axis.)

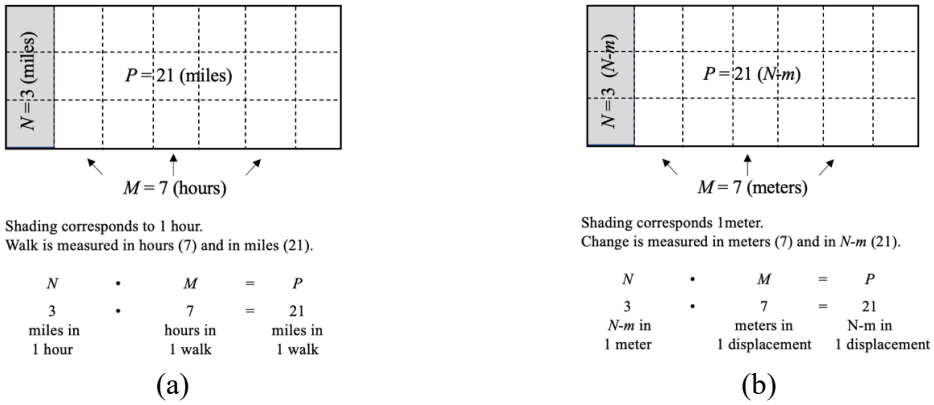

Figure 3: Coordinated measurement and area. (a) An I-o-M situation. (b) A P-o-M situation.

A second line of research on integration has decomposed reasoning about definite integrals into layers that include ones focused on local relationships (e.g., Oehrtman, & Simmons, 2023; Seeley, 2014). As one example, Oehrtman and Simmons proposed *Emergent Quantitative Models* as a tool for tracing how students' attention shifts across three scales—named the Basic, Local, and Global models—when constructing definite integrals. A Basic model relates quantities with constant values, a Local model restricts a basic model to small regions where varying quantities are approximately constant, and a Global model is a sum based on Local models. The Local model is where students would reason about products of the form $f(x) \bullet \Delta x$, but researchers have not articulated an accompanying quantitative meaning for multiplication.

Research on definite integrals summarized above has consistently highlighted the importance of reasoning about small pieces of a target quantity but, to the best of my knowledge, Jones and Fonbuena (2024) were the first to analyze such reasoning in the context of integration by substitution. They began their conceptual analysis by decomposing Adding-up-Pieces reasoning into three aspects—*partitioning* a quantity into small pieces (precursors to differentials), *determining the target quantity* in each of those small pieces (similar to the Local model mentioned above), and *summing*

the small pieces of the target quantity to get the total quantity (similar to the Global model mentioned above). Their analysis traced the consequences for each of these three aspects when one changes from one input variable to another. They described these consequences as "conversions" of the partition, integrand quantity, and interval of summation.

Similar to Oehrtman and Simmons (2023), Jones and Fonbuena (2024) did not articulate a quantitative meaning for multiplication. In the next section, I explain how multiplication understood in terms of coordinated measurement, rectangular areas, and inversely proportional relationships can be used to justify integration by substitution.

Coordinated Measurement and Integration by Substitution

Similar to the analysis of integration by substitution given by Jones and Fonbuena (2024), the analysis presented here is based on a change in the independent variable through function composition. Consider the Moving Truck situation presented below. Speed is piece-wise constant, and the above discussion of Figure 3a justifies using rectangular areas to represent distances. Think of the graph in Figure 4a as representing a Riemann sum that uses rectangular areas to show distance traveled for each segment of the trip.

Three friends are driving a moving truck from Detroit to Boston.

- *Steve takes his turn first and drives 4 hours at a steady speed of 60 miles each hour. At the end of his turn, the friends stop and rest for 1 hour.*
- *Chara takes her turn second and drives 4 hours at a steady speed of 72 miles each hour. At the end of her turn, the friends stop and rest for 1 hour.*
- *Zawadi takes her turn last and drives 4 hours at a steady speed of 54 miles each hour.*

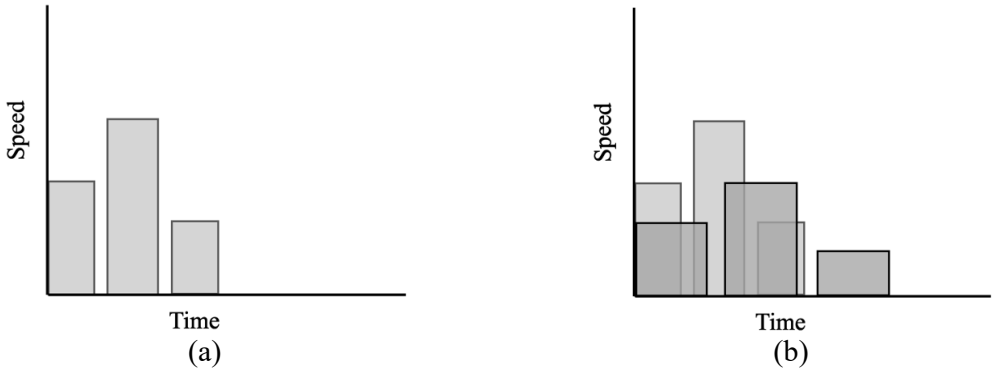

Figure 4: Moving Truck situation. (a) Time measured in hours. (b) Time measured in playlists

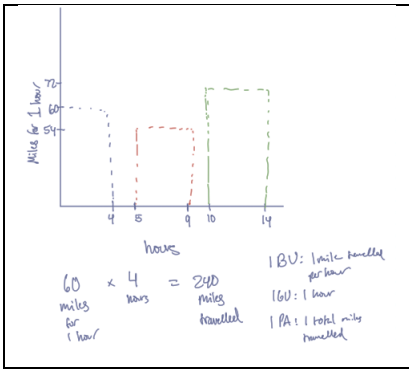
Now suppose that the three friends invent a new unit based on the time it takes to go once through a playlist that they listen to as they drive. Suppose further that 1 playlist is 2/3 of an hour. The miles driven in 1 playlist are fewer than the miles driven in 1 hour by a factor of 2/3. Thus, speeds measured in miles per playlist are 2/3 of the corresponding speeds measured in miles per hour. Simultaneously, the number of playlists it takes to measure any given duration of time is 3/2 the number of hours it takes to measure the same duration of time. Figure 4b superimposes onto Figure 4a a second graph of speeds and times for each segment of the trip based on playlists. Think of the graph in Figure 4b as representing a new Riemann sum that expresses distances when time is measured in playlists.

Notice that we have an inversely proportional relationship where shrinking in the vertical direction is offset by stretching in the horizontal direction. Thus, the total shaded areas corresponding to the two Riemann sums, and thus the distance for each segment of the trip measured in miles, is the same whether time is measured in hours or in playlists. This reasoning based a Basic model applies equally well to reasoning based on a Local model where the journey is partitioned into shorter and shorter segments.



The two equal areas in Figures 4a and 4b relate to the commonly used integration-by-substitution equation as follows. If u stands for the number of hours elapsed since the beginning of the trip, then u ranges from 0 to 14 hours. In this case, $f'(u)$ is speed in miles per hour, and we can express the total distance traveled in miles with the integral $\int_0^{14} f'(u)\,du$ (Figure 4a). Continuing, if x stands for the number of playlists elapsed since the beginning of the trip, then x ranges from 0 to 21 playlists and $g(x) = \frac{2}{3}x$ expresses the number of hours for the same duration of time. Finally, $f'\left(\frac{2}{3}x\right)\frac{2}{3}$ is speed in miles per playlist, and we can express the total distance, again in miles, with the integral $\int_0^{21} f'\left(\frac{2}{3}x\right)\frac{2}{3}\,dx$ (Figure 4b). Thus, the integration-by-substitution equation

$$\int_a^b f'\big(g(x)\big)\,g'(x)\,dx \;=\; \int_{g(a)}^{g(b)} f'(u)\,du \text{ becomes } \int_0^{21} f'\left(\frac{2}{3}x\right)\frac{2}{3}\,dx \;=\; \int_0^{14} f'(u)\,du.$$

In the above example, there is a single linear relationship between the original input variable, hours, and the new input variable, playlists. If students used a different unit of time for each segment of their journey, the same argument would work, each rectangle associated with a given duration of time measured in hours (Figure 4a) would have the same area as the corresponding rectangle with the same duration of time measured in the new unit. Thus, the Riemann sum depicted in Figure 4a would still have the same area as the transformed Riemann sum depicted in Figure 4b. The statement of integration by substitution is then plausible because the two definite integrals are approximated by the same sequence of values.

Example of Student Work

For the past few years, I have been developing a course that introduces university students to coordinated measurement and that builds paths towards integration by substitution and other core calculus topics. The students, in general, are not STEM majors, and the close examination of multiplication proves challenging but accessible. Figure 5 shows sample work for the Moving Truck produced by one student on a final exam in Fall 2023. "Nancy" and "Mary" are *N* and *M* in Figure 1.

"In this graph, one base unit would be the column of one hour to one mile traveled in that hour, while the group unit would be that column extended to the 60 miles for one hour which is the amount that Steve drives in this problem. Nancy is represented by the height of the box which is 60 miles for one hour, and Mary is represented by the width of four hours, and the product amount is the area of the rectangle that those dimensions create."

	"For the problem to be converted into playlists, I found that to find the same number of miles which is 240, I applied the 2/3 difference to be 2/3 of 60 miles per hour to be 40, which then increases the value of the group unit to be increased by a factor of 3/2 which is the inverse to then find the same Patty value."

Figure 5: An example of student work from a final exam, Fall 2023.

Discussion and Conclusion

To the best of my knowledge, the justification for integration by substitution presented above is both original and at odds with more traditional justifications. In particular, the justification presented here emphasizes why you can write an equal sign in between two numbers. In essence, the justification started with a Reimann sum for $\int_{g(a)}^{g(b)} f'(u)du$ and explained why the corresponding Riemann sum for $\int_a^b f'\big(g(x)\big)\, g'(x)dx$ gave the same number. This new justification requires reexamining several common ways of reasoning about integration. I have already discussed how the coordinated measurement meaning of multiplication supports using rectangular areas as generic models for products that span both I-o-M and P-o-M situations. In addition, the new justification consistently interprets integrands as rates. In particular, rather than associating $g'(x)$ first with dx, as is in more traditional explanations, the new justification first associates $g'(x)$ with $f'(g(x))$ and treats the entire $f'(g(x))\, g'(x)$ expression as a rate of change. This, in turn, supports consistent interpretations of integrands across related topics, including the Fundamental Theorem of Calculus. Finally, although the new analysis is not a proof, it highlights how inverse proportions, a topic from middle grades mathematics, makes the statement of integration by substitution plausible. It is not a rigorous explanation *that* the statement is true but, rather, offers a plausible explanation for *why* it is true. Furthermore, it is an explanation that students could plausibly generate.

Finally, the analysis of integration by substitution provided here extends recent research that examines ways in which students' reasoning about topics introduced in middle grades (~ ages 12-14) directly support and constrain ways they reason about calculus topics (e.g., Beckmann & Izsák, 2024; Byerley, 2019; Thompson & Harel, 2021). This emerging body of research suggests that a substantial revision to ways that topics related to multiplication are developed in earlier grades could help students be better prepared for studying calculus grounded in quantities.

Accumulation: continuity and contexts

Irena Lax[1], Dafna Elias[1], Tommy Dreyfus[1], Lia Noah-Sella[1] and Anatoli Kouropatov[2]

[2]Levinsky-Wingate College, Israel

We report on a study investigating how context affects students' understanding of accumulation and their ability to select a continuous graph for an accumulation function, given a discontinuous rate of change graph. Through quantitative and qualitative analyses, we found that extra-mathematical contexts significantly influence students' accumulative thinking.

Keywords: Integral, Accumulation, extra-mathematical context.

Theoretical Background

Integration as accumulation is at the core of understanding many ideas and applications. The accumulation function has the potential to serve as a model for various situations in continuous real-life processes, and vice versa, continuous real-life processes may demonstrate accumulation.

According to Thompson and Silverman (2008), in order to hold a well-structured understanding of the accumulation function, students need to coordinate three variables simultaneously: the value of x that changes, the value of the integrand f that changes accordingly, and the value of the quantity accumulated up to x, which derives from these changes of x and f and which changes according to both. Hence, one of the difficulties in understanding accumulation function arises from understanding accumulation as a function which depends on another function. Students typically encounter such a complex covariation for the first time when approaching accumulation.

Constructing the integral concept based on the idea of accumulation has been shown to be beneficial (Carlson et al., 2003; Kouropatov, 2016). Kouropatov (2016) built and researched a teaching unit for the integral concept based on approximation and accumulation; he concluded that this approach clarified the connection between integration and differentiation for the students and allowed them to realize the mathematical meaning of the integral.

Although the concept of accumulation is familiar to students from everyday life, they have difficulty grasping the 'bits' accumulating (Thompson & Silverman, 2008). Thompson (2013) argues that a significant reason for this is a lack of reference to meaning in teaching and research. Considering this, it has been suggested to teach integration with an approach that places the concept of accumulation at the center (Kouropatov & Dreyfus, 2013).

The effect of extra-mathematical context (EMC) on problem-solving has been widely studied in various subjects, for example, computer programming (Leinonen et al., 2021), algebra (Bottge, 1999) and proportional thinking (Lawton, 1993). Research in mathematics and science education reveals that it is difficult for students to apply their mathematical knowledge in different contexts (Delice & Roper, 2006) as the context requires an additional layer of the meaning to variables in the mathematical expression in order to be applied in the science context (Dray & Manogue, 2005), and particularly in integration problems (Alves et al., 2019; Jones, 2015).

Accumulation specifically has been found to be a concept which may be taught through EMC. Carlson et al. (2003) developed curricular materials aiming to promote students' understandings and reasoning abilities regarding the fundamental theorem of calculus, including tasks given in an EMC. The results showed that most students developed a strong understanding of the aspects regarding accumulation. Falach (2023) has defined the notion of accumulative thinking and investigated its development in a pool filling context.

In the study presented here, we examine students' facility of expressing ideas related to accumulation in different intra- and extra mathematical contexts. We ask: In what contexts do students think of accumulation and express their accumulative thinking and what role does the context have in the process?

Tasks

This study is part of a larger project, in which we examine students' personal meanings for basic concepts of calculus. As part of the project, we developed various tasks, including one in which students are presented with a split-domain rate of change function, constant and positive in each subdomain, and are then asked about its accumulation function (see Figure 1 and below). The task was designed so that there is no need for technical work, but rather for understanding that if you know how fast a quantity is changing at every moment, you can know how much of that quantity has accumulated at every moment (Thompson et al., 2019). The quantity accumulates continuously, and because of the positive rate of change, the accumulation function is monotonously increasing.

For examining the role of context, we designed four parallel versions of the task, based on different intra- and extra mathematical contexts: (1) Formal; (2) Area; (3) Motion; and (4) Pool. We present (4) in detail (Figure 1).

The accompanying sketch shows the graph of the function $f(x)$, which represents the flow of water into a pool. The flow is measured in units of liters per second.
The pool was empty at the beginning.

Alona said that using these data it is possible to sketch the graph of the function $g(x) = \int_0^x f(t)dt,\ x \geq 0$, which represents the amount of water in the pool at time x.
The students discussed the meaning of her statement to them

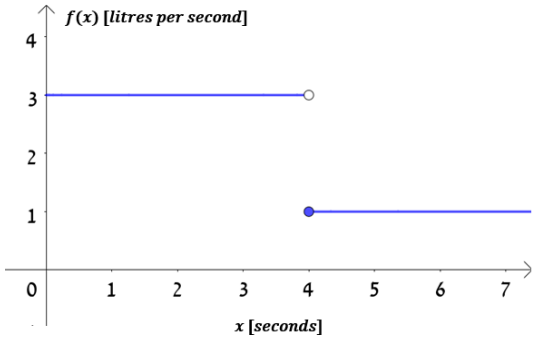

Figure 1: The pool context version of the situation in which the task is set

Table 1 demonstrates the differences between Alona's statement in the four contexts.

Table 1: Alona's statement in the four contexts

Context	$f(x)$	g(x)	Alona said that using these data it is possible to sketch the graph of
Formal	Function	Integral of $f(x)$	the function $g(x) = \int_0^x f(t)dt$, $x \geq 0$.
Area	Function	The area that accumulated between the graph of $f(x)$ and the x-axis starting from $x = 0$	the function $g(x) = \int_0^x f(t)dt$, $x \geq 0$ which represents the area that accumulated between the graph of $f(x)$ and the x-axis starting from $x = 0$ up to $x = 7$
Motion	The speed of a tortoise (meters per second)	The distance the tortoise passed at time x	the function $g(x) = \int_0^x f(t)dt$, $x \geq 0$ which represents the distance the tortoise passed as a function of the time x.
Pool	The rate of flow of water into a pool (liters per second)	The amount of water accumulated in the pool at time x	the function $g(x) = \int_0^x f(t)dt$, $x \geq 0$ which represents the amount of water in the pool at time x.

In a first task students were asked to state how close different ways of thinking about accumulation are to their own. In this report, we focus on the second task which asked students to choose the graph they think represent the function $g(x) = \int_0^x f(t)dt$, $x \geq 0$, from among those in Figure 2. The graphs represent different ways to think of integration. Graph 2 suggests accumulative thinking because it is the only continuous graph.

Which of the following graphs, in your opinion, represents the function $g(x)$?

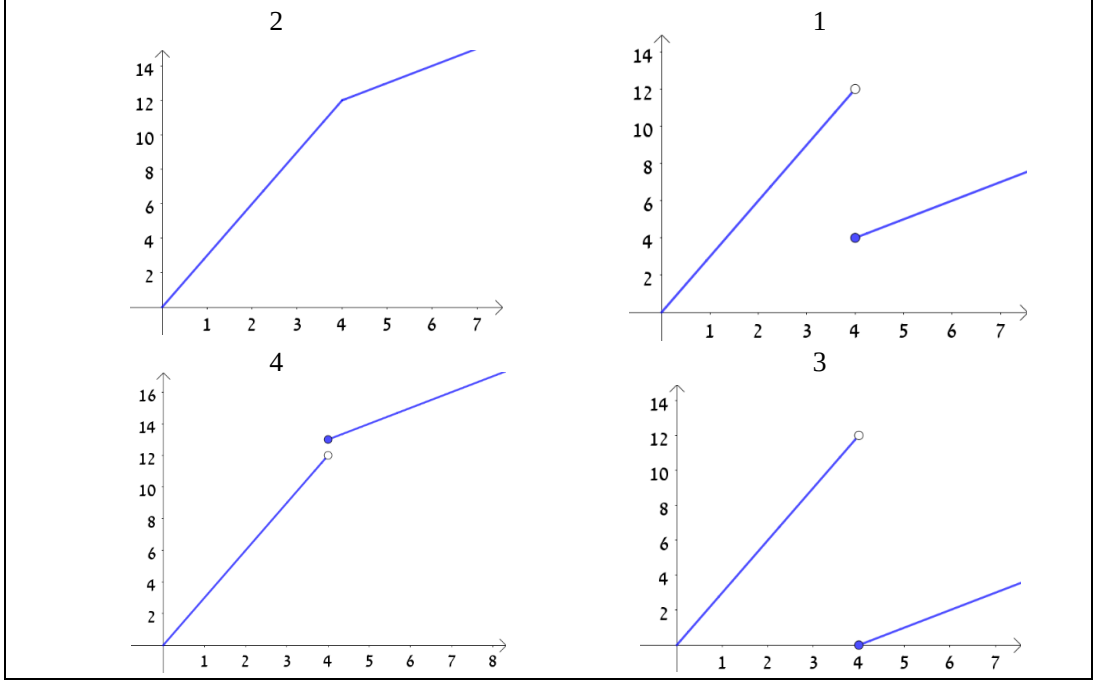

Figure 2: Proposed graph options for the function g(x)

Procedure and population

A total of 226 students from advanced track mathematics in grades 11 or 12, who had already studied integrals in school, completed a questionnaire, with approximately equal numbers in each context (see Table 2). In addition, 24 students were interviewed right after answering the questionnaire. The interviews were audio-recorded and transcribed. In the questionnaire, students were asked to mark their choice, and in the interviews, they were asked to explain their choices. In the analysis of the interviews, students' explanations were categorized by their statements, as detailed below. We report both quantitative and qualitative results from this task.

Findings

We first present some quantitative results for the 226 students who completed the questionnaire, focusing on their selection of the graph for *g(x).* Table 2 presents the percentages of students who chose each of the graphs across different contexts.

Table 2: Graph choices for g(x) across different contexts

Context / Graph Choice	Pool	Motion	Area	Formal	Total
1	12.7%	18.9%	16.4%	23.6%	17.7%
2	55.6%	45.3%	40%	18.2%	40.2%
3	6.3%	18.9%	20%	25.5%	17.3%
4	11.1%	1.8%	9.1%	14.5%	9.3%
No Answer	14.3%	15.1%	14.5%	18.2%	15.5%
N	63	53	55	55	226

We see that about 40% of all students chose Graph 2, which represents accumulative thinking, with notable differences across contexts. In the Pool context, approximately 56% of students chose the Graph 2, while in the Formal context, only about 18% did so. A difference we found particularly interesting was between the Area context (about 40%) and the Formal context (only about 18%). We found this surprising because Area is an intra-mathematical context, and so we hypothesized that the results for the Area context would be closer to that of the Formal, and not as close to that of the EMCs.

When considering EMCs, the Pool context shows a higher percentage of selections for Graph 2 than the Motion context. We turn to the qualitative results to explore how students thought about these contexts. Due to space limitations, we focus on quotes for the Pool and Formal contexts to emphasize the distinct ways students approached accumulation in each context, as reflected in their explanations.

Formal context

Of the six students interviewed, only one chose Graph 2 and explained: "Plug in each value, make a point, and connect them. Then, something continuous will come out without a hole or anything."

While expressing thoughts of continuity, the student talks about a technical algorithm of computing and plotting.

The five others chose different mistaken graphs. Their explanations included:

S1: (chose Graph 4) The function, like, f, it's not... it's not continuous, so it feels to me like... like g isn't continuous either. I'm not sure, but it seems to make more sense to me.

S2: (chose Graph 3) Because here f is not regular, g should also be irregular.

S3: (chose Graph 1) Because I think that until x equals 4, the function obviously increases, and from x = 4 it still keeps increasing, but the value at the point 4 is lower than the point, like the hole that's here. [Interviewer: "Right, but this relates to the value of f(x), which is lower?"] S3: "Yes".

S4: (couldn't choose a graph) First of all, in Graph 2. I'll go by elimination. In Graph 2, they didn't address the breakpoint at x = 4, so I kind of ruled it out.

The most common reasoning for these students was categorized as "If f has this characteristic then so should g." S1 thought of f not being continuous and thus g must also have this characteristic, S2 thought of an irregularity that must carry from f to g. S3 said that if there is a decrease in f there must be a decrease in g. S4 had the same line of logic and said that a break point for f should be addressed in g, but didn't explain further. For these students, the discontinuity in f was an obstacle they couldn't overcome. They did not demonstrate accumulative thinking but instead relied on what seems like intuitive reasoning.

Pool context

Of the six interviewees, five ultimately chose Graph 2, either immediately or after considering and ruling out the other options.

S7: Because it's the accumulation of how much water is in the pool, it's like a line that continues. And like, Graph 2 shows something continuous, like it's rising, like it keeps rising because we're not emptying it. [...] What I did connect with in 2 is that, um... like, there are two different slopes. Like, from 0 to 4 there's a certain slope, and from 4 onwards, there's a different slope. [...] Like, the faster we fill the pool, the faster the water accumulates.

S8: The function g describes the amount of water per second, […] therefore, the flow will be the slope, but the amount is not something that decreases over time. It won't decrease at the point $x = 4$, only the slope will decrease. That's why I chose Graph 2, which is the only one where there's no change in the amount of water at the point $x = 4$.

S7 and S8 chose Graph 2 and explicitly connected their choice to the concept of accumulation or the amount of water in the pool ("it's the accumulation of how much water is in the pool", "there's no change in the amount of water at the point x = 4"). This demonstrates their ability to overcome the discontinuity in f by applying accumulative thinking rooted in the Pool context. Notably, they not only selected Graph 2 based on continuity but also reasoned about the slope of the accumulation function in relation to the value of the rate of change function ("The faster we fill the pool, the faster the water accumulates"). Their explanations combine real-world intuition ("We're not emptying it,' 'There's no change in the amount of water") with mathematical concepts such as slope, rate, function, and line.

S9: I know it starts with 3x. That means until 4, it simply increases at a rate of 3 per second. So, it stops at 12, and from there the slope changes, increasing by 1 per second until it reaches 15. That's it. […] There's no jump when the flow rate per second changes.

S10: At first there's an increase of 3x, and then it just drops to an increase of, like, 1x. […] In 4, they just add water without explanation, in 3 they ignore it, and the same with 1. 2 is the only one that makes sense.

S9 and S10 also reasoned based on the continuity of the amount of water in the pool. They chose Graph 2 due to its continuity or ruled out the others because of discontinuities ("There's no jump", "they just add water without explanation"). Their reasoning combined mathematical analysis, including computations and calculations, with real-world sense.

S11 similarly reasoned that: "there wasn't a jump in the amount of water. The amount of water continued from the same point. […] Only the rate of water filling up was changed." So, all 5 students used the Pool context in their explanations, leaning on their own experience and real-life common sense.

S12 was the only interviewee in the Pool context who chose a graph different than Graph 2, stating: "The domain of the function and the domain of the primitive function should be the same domain." It seems that S12 tends to look for similarities between the graphs of functions f and g, such as ensuring they share the same domain. This choice can be attributed to an attempt at formal mathematical thinking, rather than thinking in context. She focuses on domains, possibly recalling that the domain of the derivative is contained within the domain of the function being differentiated. However, she extends this idea to 'the same domain,' not realizing that the domain of the accumulation function may be larger than that of the derivative. Thinking within the context could help avoid such misconceptions.

Discussion

In this study we asked: In what contexts do students think of accumulation and express that accumulative thinking? What role does the context have in the process? According to the quantitative results, the context had a considerable influence on students' ability to think accumulatively and to choose a continuous graph for g. The qualitative results further confirm and explain this effect. EMCs typically facilitated accumulative thinking: The continuity of the accumulation process was more evident in the Pool context, than the Motion context, and more in the Motion context than in the Area context. In the Formal version of the task, a large majority of students did not choose the accumulative graph. The interview data, where we observed students transferring properties from the f graph to the g graph with limited interpretation, reinforces the claim made by Thompson and Silverman (2008) that one of the challenges in understanding the accumulation function arises from the need to comprehend it as a function dependent on another function.

Students who did not interpret the integral as accumulation may have relied on intuitive rules (Tsamir et al., 2002). Some of these rules seemed to influence the explanations of students who chose a graph other than Graph 2. For example, we observed students (S1, S2. S12) arguing that if a function has a discontinuity, its integral (or primitive function) must also have a discontinuity. This reflects the 'No Holes' rule, which states that students often believe a function and its derivative must be defined at

the same points, meaning if there is a discontinuity in the function, there must also be a discontinuity in its derivative at the same location. Additionally, the 'More A = More B' rule, which claims that students intuitively believe if a quantity is increasing, its derivative must also increase, appeared to play a role for students who argued that if a function increases or decreases, then its integral graph should behave similarly.

On the other hand, students working within the Pool context appear to rarely rely on these intuitive rules. Instead, they often use their everyday life experience, reasoning that if you do not empty the pool and continue filling it, the graph should be continuous and rising. This suggests that real-life contexts, especially tangible ones like the Pool, may help prevent mistakes based on intuitive rules, as students draw on real-world experience rather than relying solely on intuition.

Some of the students reasoning in the Pool context combined everyday common sense with mathematical concepts such as slopes and lines, suggesting that their reasoning may create connections to their mathematical knowledge, renewing and refining their understanding of accumulation.

The results of this study emphasize the importance of context in supporting students' understanding of complex mathematical concepts, like accumulation. It could suggest that using real-world, tangible contexts helps students make meaningful connections between their everyday experiences and formal mathematics, reducing reliance on intuitive but incorrect rules.

Learning trajectory to teach double integrals with GeoGebra Applets

Maria Antonietta Lepellere

University of Udine; maria.lepellere@uniud.it

In this contribution we propose the design and use of GeoGebra Applets and homework exercises to offer, for second year Civil and Environmental engineer students, an interactive teaching method in a second course of Calculus. We give here two examples of GeoGebra Applets, on normal domain and change of variable to polar coordinates respectively, referred to specific class exercises used during a double integral' lesson. The results of two homework exercises will be compared with the same one proposed in 22/23 where no specific GeoGebra applets were proposed but the underlying idea was already present, and in 23/24 when they were introduced. The theory of multivariational reasoning to design the applets and the exercises, and to analyse the errors of the students were used.

Keywords: Multivariational reasoning theory, Homework, Teaching and learning mathematics for engineers, GeoGebra, double integrals, normal domain, polar change of coordinates.

Introduction and theoretical background

There have been several attempts to improve students' learning and the teaching of mathematics in basic and multivariable calculus through moving away from remedial classes towards teaching to increase understanding. GeoGebra is a software that allows to create different interactive applications that can be used as teaching tools in math classes. The graphics in books, as well as the pictures drawn on the blackboard, are static and require the students to possess an adequately trained imagination. Nowadays, the existence of free programs with versatile capabilities and interactive representations helps to improve the presentation of contents taught, allowing dynamic visualizations. Hohenwarter and Fuchs (2004) listed the following four uses of GeoGebra: as a tool for demonstration and visualisation; as a construction tool; as a tool for investigation and inductive discovery; and lastly, as a tool for designing and preparing teaching and learning material.

Although research on the teaching and learning of single variable calculus is a field that has attracted much research in mathematics education, the number of studies examining the teaching and learning of multivariable calculus is considerably smaller. Double integration is a fundamental concept in many engineering applications and widely used in courses across the engineering disciplines. Students should know and correctly apply integration techniques, recognise, and describe the domain of integration, and evaluate using different available strategies. Limited research has been reported that focuses on multivariable integration (Gemechu et al., 2021; Martínez-Planell & Trigueros, 2020; Alessio et al., 2022). Worsley et al. (2008) commented on students' difficulties in double integrals, which included changing the order of integration. Gemechu et al. (2021) highlighted students' lack of understanding which manifested in their difficulty in algebraically representing regions of integration. Some find difficulty when dealing with integration first with respect to y and there is no understanding that the limits of integration of the inner integral are at most functions of x and similarly for the integration with respect to y first. This process involves the description of the boundaries of subsets in $\mathbb{R}^2$ and manipulation of its equations, possibly using different coordinates (Cartesian, polar), or simply put, a broader use of 2D geometry. After working almost exclusively

with a Cartesian coordinate system to represent the plane, we would be surprised if students did not come to think of the plane and the Cartesian coordinate system as essentially equivalent. However, the plane and the Cartesian coordinate system are not equivalent, and it is important that students construct the polar coordinate system in ways related to, but not constrained by, their ways of thinking about the Cartesian coordinate system. Moore et al. (2014) also describe three types of complexity that students, future high school teachers, encountered during the construction of the polar coordinate system: understanding the measurement of the angle in radians, overcoming the input conventions output for functions in the polar coordinate system and the differentiation of the pole of the polar coordinate system from the origin of the Cartesian coordinate system.

Homework is one of students' opportunities to learn mathematics. Findings from research indicate undergraduate calculus students spend more time doing homework than they do in class (Ellis et al., 2015). Mathematicians view homework as a critical component of learning (Dorko, 2021). Moreover, students report that homework and practice exercises are important for their learning, more than other forms of instruction such as lecture. However, undergraduate mathematics education researchers have only recently begun to study student learning from homework.

Covariational reasoning is "the cognitive activities involved in coordinating two varying quantities while attending to the ways in which they change in relation to each other" (Carlson et al., 2002, p. 354). Moore et al. (2013) described how students' covariational reasoning supported them in conceiving graphs in the Cartesian coordinate system and polar coordinate system as representing invariant relationships. They have described students reasoning emergently to conceive a graph in a Cartesian coordinate system representing the same covariational relationship as a graph in the polar coordinate system despite perceptual differences in the curves. When more than two quantities are covarying, some authors speak of multivariational reasoning. Starting from the evidence that scientific phenomena often include more than two quantities and that the theoretical framework of covariational reasoning mainly focuses on two simultaneously varying quantities, Jones (2022) formally elaborated on the construct of multivariation to address the mental actions behind those "cases where more than two explicit variables relate to and change with one another" (p. 1).

The purpose of this article (continuing a work started in Lepellere, 2024), is twofold: to investigate difficulties encountered by students in solving two double integral homework exercises; to design two GeoGebra Applets one on normal domain and the other on the use of polar coordinate system to help the students to overcome these difficulties. These lend themselves to the four uses of GeoGebra mentioned by Hohenwarter and Fuchs (2004). The homework exercises and the Applets were designed considering the multivariational reasoning theory. The performance of students on two homework exercises in the academic year 22/23 will be compared with the same one given in 23/24 where the Applets were introduced and in the present one where their use were reproposed and most emphasized. The research questions are the following: 1) How did the integration of the Applets influenced the performance of the exercises proposed? 2) What were the mistakes made by the students in the homework in the three academic years? Were there any differences?

Methodology

Mathematical Analysis 2 is a second course of calculus (9 credits corresponding to 72 hours of lessons) held in the first semester of second year to Civil and Environmental Engineering students. It is preceded in the first year by Mathematical Analysis 1 (12 credits), Linear Algebra (6 credits) and Physics 1, and it is simultaneous with Rational Mechanics. The students come mainly from two different high schools: technical, especially with a focus on "construction, environment and territory" and scientific. The course was divided in three macro-sectors: differential calculus in several variables, free and constrained optimization study and implicit functions; multivariable and vector integrals; first and second order differential equations, systems of linear differential equations with simple stability studies. The students have the possibility to divide the exam into three partial tests, one for each macro-sector, but to participate is mandatory to solve several homework assignments.

During double integral lessons, in academic years 23/24 and 24/25 two GeoGebra applets were proposed, during the lesson and for the individual use at home as a test, to give students a tool to support the understanding of the concepts of normal domain and change in polar coordinate system. They were linked to two class examples, Example1 and Example2, one which required, after dividing the set into two parts, the use of normal domains, and the other required the use of the change in polar coordinates to obtain a non-rectangular domain. In 22/23 the same exercises had been proposed trying to undermine, with straight lines parallel to the axis or passing through the origin, what would later become the use of sliders in the applets. The use of applets has only made everything more dynamic. Two homework exercises, EX1 and EX2 included in a homework assignment containing 11 exercises on curvilinear and double integrals, and applications of the Gauss-Green formula) were designed to solve double integrals, the first in three different ways, thinking to normal domain with respect to x, normal domain with respect to y, change in polar coordinates, the second were expected the use of change in polar coordinates. To solve these exercises, the students were given a week, after which they had to send them us by email. The results of both exercises, for 37 students of this academic year were examined and the errors compared with the same ones proposed last year when the students were 23 and for 37 students in the academic year 22/23. For the applets and the exercises multivariational reasoning theory was considered.

The design of GeoGebra Applets

Let's look in detail the two applets (see Figure 1) linked to Example1 and Example2:

Example1. Drow the set $A = \left\{(x, y) \in \mathbb{R}^2 \mid 0 \leq \frac{x}{2} \leq y \leq 2x,\ y \leq -x + 3\right\}$ and determine its area.

The purpose of Applet1 for Example1 (https://www.geogebra.org/m/zpx5ypsv), see Figure 1a, was to show the dependence of the ordinate of the points D, E and F on the abscissa represented by the slider k and so what were the functions to take into consideration to see the set as a normal domain with respect to x and the necessity to divide the set into two parts. The "intersection" command and the slider were used to further highlight the change of the functions to take in consideration before and after the point C is crossed. The use of the slider k gives the possibility to create a multivariational track on the $x-$axis that moves simultaneously three points D and E that are in the domain of integration and F that is outside it before the intersection point C between the two straight lines is

crossed, after that the point D remains as the lower limit but the point E is replaced by the point F. Simultaneously, you could see how to express the two functions with respect to x to create the normal domains. Applet1 has the task of guiding students to understand which values follow x and which follow y based on the functions we take as the extremes of the double integral, and consequently the area (or the integral in general) we were interested to evaluate.

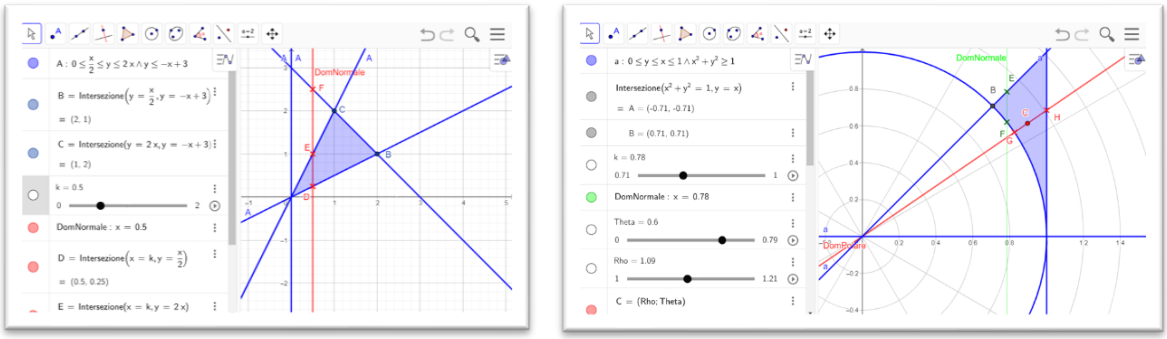

Figure 1: 1a on the left Applet1 on Normal domain, 1b on the right on Polar coordinates

Example2. Drow $A = \{(x, y) \in \mathbb{R}^2 \mid 0 \leq y \leq x \leq 1, x^2 + y^2 \geq 1\}$ and determine $\iint_A \frac{x}{x^2+y^2} dxdy$.

The purpose of Applet2 for Example2 (https://www.geogebra.org/m/uhztazbu), see Figure 1b, was to see how to represent the domain using polar change of coordinates and to compare this to the use of normal domain. Also, in this case, we wanted to reproduce, using the sliders, a multivariational experience in the classroom. The vision of the set as a normal domain is resumed as in Example1, with the slider k and the intersection points F and E and in this case the multivariations of y as a function of x too. For the use of polar change of coordinates, we have taken the advantage that GeoGebra offers to change the reference system in polar form. In this case two sliders were used, one for rho, that is the distance of any point C from the origin, and the other for $theta$, the angle that the segment OC forms with the x −axis: we have shown that if only rho varies, the point C moves along the line containing OC; if only $theta$ varies, C moves along the circumference of radius rho. If both vary, while for the intersection point G rho is always constant and equal to 1, for the point H rho depends on $theta$. We wanted students to reflect that, when polar coordinates are used, the radius depends generally on the angle, so A is transformed in a normal domain with respect to the angle and not simply into a rectangle.

The Homework exercises

To test whether the students understood the use of normal domains and the relation to the change in polar coordinates for double integrals calculation, two homework exercises, EX1 and EX2, were designed and proposed. The work done at home had sent us by email. These were within a homework assignment containing 11 exercises including double integrals, curvilinear integrals, differential forms and applications of the Gauss-Green formula. The purpose of these exercises was to guide the students in their study in preparation for the second partial test. They were part of a learning trajectory designed for a gradual acquisition of the integration techniques based on the multivariational reasoning that lies behind them. Moreover, to reflect on the mistakes made or to discover alternative

strategies to solve the exercises, the best solutions of the students were provided to everyone as correction.

EX1. Drow $A = \{(x,y) \in \mathbb{R}^2 |\, x^2 + y^2 \leq 4,\ x \geq 1\}$ and calculate in 3 different ways $\iint_A\ x\, dxdy$.

The purpose of this exercise was to push students to think about the set as a normal domain with respect to x, i.e. $A = \left\{(x,y) \in \mathbb{R}^2 |\, 1 \leq x \leq 2;\ -\sqrt{4-x^2} \leq y \leq \sqrt{4-x^2}\right\}$, a normal domain with respect to y, i.e. $A = \left\{(x,y) \in \mathbb{R}^2 |\, -\sqrt{3} \leq y \leq \sqrt{3};\ 1 \leq x \leq \sqrt{4-y^2}\right\}$, and a change in polar coordinates i.e. $A = \left\{(\rho,\vartheta) \in \mathbb{R}^2 |\, -\frac{\pi}{3} \leq \vartheta \leq \frac{\pi}{3};\ \frac{1}{\cos(\vartheta)} \leq \rho \leq 2\ \right\}$. The three requests were proposed specifically in sequence: the first more intuitive apart from having to recognize that by explicating y as a function of x two values were obtained but, having already proposed this example when the implicit functions were introduced, no great difficulties were expected, furthermore the variability values of x were easily recognizable graphically too; the second instead required to find first the intersections between the circumference and the straight line $x = 1$ to have the limitations of y and then see the limitations of x between 1 and what is obtained by explicating x from the equation of the circumference $x^2 + y^2 = 4$; the last required the use of the change of polar coordinates and therefore it was necessary both to calculate the angle obtained by the two intersection points, calculated previously, and to transform the line $x = 1$ and the circumference into polar coordinates, so the set A becomes a normal domain with respect to the angle. The three requests could be thought of as achieving three levels of multivariational reasoning.

EX2. Drow $A = \left\{(x,y) \in \mathbb{R}^2 |\, x^2 + y^2 \leq 2y,\ x^2 + y^2 \leq 2\sqrt{3}\, x\right\}$, calculate $\iint_A\ x\sqrt{x^2+y^2}\, dxdy$.

In this case the presence of $\sqrt{x^2+y^2}$ in the integrating function, and the characteristic of A as intersection of two circles, had to suggest the use of the change in polar coordinates. The latter required to find the intersection points, $O = (0,0)$ and $P = \left(\frac{\sqrt{3}}{2}, \frac{3}{2}\right)$, between the two circumferences and the respective angle $\frac{\pi}{3}$ that the segment OP formed with the $x-$axis. In this case however it was necessary to realize that the dependence of the radius on the angle undergoes a change after $\frac{\pi}{3}$ was crossed dividing the set into two normal domains with respect to the angle, i.e. $A_1 = \left\{(\rho,\vartheta) \in \mathbb{R}^2 |\, 0 \leq \vartheta \leq \frac{\pi}{3};\ 0 \leq \rho \leq 2\sin(\vartheta)\ \right\}$ and $A_2 = \left\{(\rho,\vartheta) \in \mathbb{R}^2 |\, \frac{\pi}{3} \leq \vartheta \leq \frac{\pi}{2};\ 0 \leq \rho \leq 2\sqrt{3}\cos(\vartheta)\ \right\}$. Also, in this case, different levels of multivariational reasoning were required to obtain the result. We observe that using normal domains for EX2 it was not easy to solve the single integral.

The results

Let's analyse the results of EX1 and EX2 of the intermediate test in the academic years 22/23, 23/24 and 24/25. Let's start with EX1, the Table 1. shows, in the second column the percentage of those who tried to carry out the exercise considering the set as a normal domain with respect to x or with respect to y, with change in polar coordinates in the third and finally in the last column with correct use of all three methods. The percentage of those who made mistakes compared to the number of students who solved it is shown in brackets.

EX1	Normal to x or y	Polar coordinates	3 methods

22/23	89% (21%)	34% (38%)	3%
23/24	87% (15%)	48% (36%)	9%
24/25	92% (6%)	59% (23%)	32%

Table 1: Results of EX1

Let's immediately highlight that the change in polar coordinates was less immediate for students, but the choice has grown over the academic years. Between the choice of seeing the domain normal with respect to x or with respect to y, the first was more immediate. In 22/23 three students solved correctly with respect to x but not with respect to y, which did not happen in the two subsequent academic years this means that a higher level of multivariation reasoning was reached. Moreover, it was noted that this academic year, compared to the last, the second method had a greater choice. The use of the polar coordinate had a substantial increase, as did the number of those who performed the exercise correctly in all three methods, moreover the number of errors has decreased for both methods.

Let's look at the types of errors. For the use of normal domains with respect to x: in 22/23, apart from one student who considered a quarter of a circle as the domain, not taking into account the request that $x \geq 1$, the other two were not able to correctly explain y as a function of x; in 23/24, apart from one student who exchanged the order of integration, obtaining a function as result (the fact that the exercise was asked to be solved in different ways confused her, moreover, in the case of normal domain with respect to y, the order of the integrals was correct she only made a mistake in the limitations for y considered between -2 and 2), the other transformed the domain into a rectangle but he didn't try with normal domain with respect to y and with change in polar coordinates; in 24/25, both students who made mistakes transformed the set into a rectangle, but they had the same problem with the change of variables in polar coordinates. Regarding the use of normal domain with respect to y, in all three years the errors were in finding the limitations for y: in 22/23 between -1 and 1 and between 0 and $\frac{\sqrt{3}}{2}$ that are further from the correct solution; in 23/24 between -2 and 2 and between $-\sqrt{2}$ and $\sqrt{2}$ and in 24/25 between -2 and 2, perhaps due to a distraction since the limitations of the normal domain with respect to x of the two students who made mistakes were correctly found. It can therefore be observed that those who carried out the exercise using normal domains with respect to y achieved, for what was observed previously, greater awareness of multivariational reasoning. Finally, as regards the use of the change in polar coordinates, the common error in all three academic years was to transform the set into a rectangle but while in 22/23 this error was also committed by those who had correctly carried out the exercise in the other two methods in 23/24 and 24/25 it was committed only by those who had correctly solved the exercise only as a normal domain with respect to x this means that their level of multivariational reasoning was too low to be able to recognise the variation of rho from $theta$.

Regarding the results of EX2 in the three academic years 22/23, 23/24 and 24/25, there were respectively 59%, 70% and 81% the percentage of those who tried to do the exercise and therefore increased over the years. They set it correctly respectively for 23%, 22% and 33% but, in 22/23, 18% used normal domains and did not reach the result, in 23/24 there was only one student who tried to use normal domains but, realizing that the calculation of the single integral became too difficult, so

tried to use the change in polar coordinates. This year only three students tried to use normal domains with respect to x dividing the set into three parts and only one student, using the change in polar coordinates, transformed the set into a rectangle, all the others found it difficult to understand the variations of the angle but correctly find the dependence of rho on $theta$. There was therefore a progressive improvement of student performance over the years, but we must say that these exercises were given immediately after the explanation of the topic of double integrals and the Gauss-Green formula, and the students had only one week to hand in a long assignment containing 11 exercises.

Discussion and conclusions

Understanding double integrals is fundamental also because triple and surface integrals are based on them. The transformation of a set into a normal domain requires a student's multivariational capacity since they must be able to associate to a quantity that varies, two other quantities and not only one as they were used to do in Mathematical Analysis 1 and in secondary school, moreover this independent variable is not necessarily x. The difficulty in changing to polar coordinates within the resolution of a double integral is generally twofold: in the passage between the two reference systems and in recognizing that the result is in general a normal domain. This last part is the most delicate, for our experience there are no problems for our students to transform a part of a circumference centred in the origin into a rectangle. Furthermore, students are not generally used to dealing with inequalities when more than one variable comes into play, even more if the variables in question were not adequately explored in the past as the polar one. Two GeoGebra applets were proposed to guide students to understand these delicate passages. With their inclusion the results, over the years, were undoubtedly better. Their use helped students to reflect on what functions to consider for normal domains and what happens when the angle and radius vary simultaneously in the polar change of coordinates, increasing their multivariational reasoning. However, some difficulties remain. About homework exercises, compared to EX1, EX2 proved to be more suitable for testing the ability to correctly use the change in polar coordinates in the calculation of double integrals. Moreover, when was given the possibility of avoiding the use of change in polar coordinates, in the academic year 22/23 more than in 23/24 and 24/25 students did so. This study on one hand confirms the difficulties in calculating double integrals already known in literature, giving a different interpretative key, on the other hand the use of GeoGebra applets and homework go in the direction of improvement the delivery of teaching at university level of multivariable calculus courses.

The low number of students of this research does not allow us to generalise the results obtained but they are a starting point for future improvements of teaching tools and of in-depth research. In the future we will try to propose a questionnaire before the homework to guide the reflection of what the applets want to represent; an explanation in class is not always enough. We would also like to increase the use of applets and homework exercises and to study the impact they have on the partial test.

Student understanding of double and triple integrals in rectangular coordinates

Rafael Martínez-Planell[1], Vahid Borji[2] and Maria Trigueros[3]

[1]University of Puerto Rico at Mayaguez; rmplanell@gmail.com

[2]Charles University, Faculty of Mathematics and Physics, Prague, Czech Republic

We apply Action-Process-Object-Schema (APOS) theory to study student understanding of integrals of continuous functions over general regions using rectangular coordinates. The notion of schema is used to model students' constructions. We propose a simple model (genetic decomposition) consisting of three schema component structures and three relations between these components. The model was tested with semi-structured interviews with eleven students who had just finished a multivariable calculus course. The findings of our study can be used to improve the model and design activities to help students better understand double and triple integrals in rectangular coordinates. Findings show that it can be challenging for students to go from the case of finite Riemann sums over a rectangle to the infinite context of double and triple integrals over general regions. We documented different specific constructions where students can benefit from instructional support.

Keywords: Calculus, integration, multivariable functions, APOS.

Introduction and literature review

In the past twenty years, much work has been done on student understanding of multivariable functions, as discussed in the survey by Martínez-Planell and Trigueros (2021). They show that most of this research has dealt with the formal and geometric properties of two-variable functions and with the differential calculus of these functions. However, research on students' understanding of integral calculus lags. This study aims to contribute to addressing this gap.

Among the relatively scarce literature on multivariable integral calculus, one finds studies by Bašić and Milin Šipuš (2022), Borji et al. (2024), Henriquez (2006), Jones and Dorko (2015), Khemane et al. (2023), McGee and Martínez-Planell (2014), and Martínez-Planell and Trigueros (2020). The literature on integral calculus of one-variable functions is plentiful. Of particular interest is the study of Sealey (2014), who proposed a framework to consider students' understanding of the topic. Although conceived thinking about one-variable functions, Sealey's framework can be extended to the context of double and triple integrals, as shown by Martínez-Planell and Trigueros (2020) and Borji et al. (2024) in two research cycles. The present study builds on these two previous research cycles where students' understanding of double integrals of a continuous function over a rectangle was studied. In the first cycle (Martínez-Planell & Trigueros, 2020), a model (genetic decomposition) of how students may construct their understanding of Riemann sums was proposed and tested with student interviews. As a result of the study, the model was revised, and activities were designed to help students do the proposed construction, using the layers of Sealey (2014) and the semiotic chain of McGee and Martínez-Planell (2014). In the second research cycle (Borji et al., 2024), the authors showed that most students who worked on the research-based activities resulting from the first cycle

could successfully perform the proposed constructions of finite Riemann sums over a rectangle. The present study extends those previous research cycles by going from finite Riemann sums in rectangles to considering students' understanding of double and triple integrals in general regions.

Theoretical framework

We use Action-Process-Object-Schema (APOS) theory (Arnon et al., 2014). Since the APO portion of the theory is well-known, we will only describe the Schema portion of the theory, which is what we will use. In APOS, a Schema is a coherent collection (component structures) of Actions, Processes, Objects, and other previously constructed Schemas dealing with a specific mathematical notion. The Schema is coherent in the sense that its different components are interrelated in such a way that the individual can decide when a problem situation falls within the scope of the schema.

This definition suggests that to model Schemas, one may list their component structures and describe the relations between the components that students may construct to understand the mathematical notion. Schemas are dynamic structures constantly under construction as students' mathematical horizons expand. To discuss their evolution, the Intra-, Inter-, Trans- triad of Piaget and García (1983) is interpreted as stages of Schema development in APOS. In order to classify a Schema development into one of those three stages, the notion of types of relations between Schema components has shown to be helpful. This is innovative since this notion was only recently introduced by Trigueros (2019). A *correspondence* relation is established out of habit or repetition, but the student cannot justify it. It can result from repeatedly seeing two components used in tandem or from superficial comparisons of similarities between components. A *transformation* relation groups different components, with perhaps one of them being used to justify or explain the relation between the others. The relation is used normatively in a given problem situation, although not necessarily so across different problem situations. A *conservation* relation is used normatively and fluently across different problem situations, appearing whenever advantageous. Properties in one structure are conserved or translated to properties in other structures so that the structures seem to be interchangeably used.

A Schema is said to be at the Intra- stage of development when its components are isolated or mainly related by correspondence relations. At the Inter- stage of development, groupings of different components and transformation relations start to appear. It is at the Trans- stage of development when conservation relations interrelate most components. A Schema can appear to be in transition from one to another stage of development. A genetic decomposition (GD) for a schema is a model of a Schema given as a list of component structures, a description of relations between components, and a description of how the Schema may evolve. A GD is neither unique nor meant to describe the best way a student may learn a particular notion. It is only an initial hypothesis that must be tested with student interviews and rejected or revised based on the findings. This study contributes to the development of APOS theory since not many studies centre on the Schema portion of the theory.

Genetic decomposition for double and triple integrals

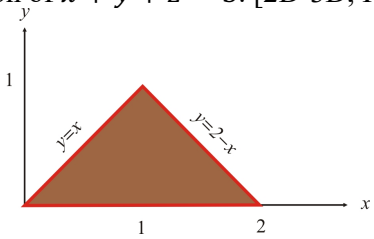
We propose a GD consisting of three components:

- Three-dimensional space (3D) as a Schema with points, fundamental planes, cylinders, and equations as Objects

- Two-dimensional space (2D) as a Schema with points, lines, curves, and the intersection of curves as Processes or Objects
- Riemann sums (RS) as a Schema including Processes for the geometric or contextual meaning of the factors of a typical term of a Riemann sum, partitions, Riemann sums and general regions of integration, integrals as limits of Riemann sums, and differential elements as "small" or "infinitesimal" rectangles or rectangular prisms as Processes or Objects

We consider the following three relations:

- 2D-3D: This relation is used to distinguish "floor" and "ceiling" (for double integrals in rectangular coordinates, the "floor" is the region of integration, and the "ceiling" is the integrand in algebraic or graphical representation; in the case of triple integrals in rectangular coordinates, the region of integration is that of the two outside integrals, the "floor" corresponds to the lower limit of the inner integral and the "ceiling" to the upper limit of the inner integral.) This relation only entails having the mental model of these surfaces and their role; it does not include the specific constructions needed to set up or give a detailed interpretation of the limits of integration in iterated integrals.
- RS-2D: Given a 2D region of integration (double integrals) in rectangular coordinates, this relation is used to do the conversions necessary to establish the limits of integration of the double integral or the limits of integration of the two outer integrals in a triple integral, and in treatments to verify that the limits of integration make algebraic sense. When establishing limits of integration, it is used to relate rectangles (may be thought of as infinitesimal rectangles) for Riemann sums to a given 2D region of integration and determine their orientation (horizontal or vertical), or equivalently, used to determine the order of integration.
- RS-3D: Given a 3D region of integration for a triple integral in rectangular coordinates or given an iterated triple integral, this relation is used to do the conversions necessary to establish the inner limits of integration or to establish or interpret the integrand in a triple integral; it is also used to relate rectangular prisms (may be infinitesimal prisms that may be imagined as line segments) to a given 3D region of integration and determine their orientation (parallel to x, y, or z axes) or determine the variable corresponding to the inner integral. For convenience and for the purpose of data analysis, we kept separate track of the representation or interpretation of the volume element $dxdydz$ (even as a memorized fact) or those corresponding to other orders of integration.



Our research questions are: What instructional implications can we find if we use the proposed GD to model students' understanding of integration? How can the GD be refined?

Method

Eleven of 21 engineering students taking an introductory multivariable calculus course at a mid-tier university in Iran were chosen by their professor (one of the researchers) and agreed to participate in the study. They were chosen based on their test average and course participation, so three were above average, five were average, and three were below average. This was done in order to obtain a wide range of different observations. The students participated in approximately one-hour-long semi-structured interviews one week after the semester ended.

During the semester, students worked on research-based activities designed to address the observations in Martínez-Planell and Trigueros (2020). The activities are described in Borji et al. (2024) and were successful in helping students construct finite Riemann sums over rectangles. Also, most students showed intuition of the limit of Riemann sums of a continuous non-negative function over a rectangle as the volume under the graph and over the rectangle. The present study considers the context of setting up iterated integrals on a general region. The course consisted of two 90-minute sessions per week. When dealing with a rectangular domain *R*, the course textbook (Stewart, 2010) motivates the double integral by first considering a continuous non-negative function *f* defined on a rectangle and the problem of finding volume under the graph and over the rectangle. After introducing a partition and suitable notation, it *defines* such a volume as $V = \lim_{m,n\to\infty} \sum_{i=1}^{m} \sum_{j=1}^{n} f\left(x_{ij}^{*}, y_{ij}^{*}\right)\Delta A$, and then generalizes to functions that are not necessarily positive by defining $\iint_R f(x,y)dA$ as the above limit when it exists. After a brief instructor's presentation of these ideas, students were assigned tasks consistent with the textbook's presentation. The tasks were designed based on the study by Martínez-Planell and Trigueros (2020). In the tasks, students interpret a product of the form $f(a,b)\Delta x\Delta y$ as the volume of a rectangular prism in space. Additionally, when forming a partition of the rectangle *R* and the corresponding Riemann sum, they interpret this sum geometrically as the sum of the volumes of the corresponding rectangular prisms. Then, they express the double integral of f over the rectangle as the limit of these Riemann sums. The tasks did not explore setting up iterated integrals over general regions. An interview instrument with 17 questions was designed. For the sake of this short report, we only show two. Following each question, we include the relations it was meant to test in brackets.

1. Establish (but do not compute) an iterated double integral to find the volume of the solid that occupies all space over the region of the *xy* plane given by the figure below and under the graph of $x + y + z = 3$. [2D-3D, RS-2D or RS-3D]

2. What does the term *dxdydz* that appears in triple integrals in rectangular coordinates mean to you? Can you interpret it geometrically? [RS-3D]

The data was first analysed by introducing codes grounded on mathematical observations as they arose from the data. Then, on a second pass, the relations in the GD and the types of relations were used as codes. The initial codes supplement the ones based on the GD. A third pass on the data was needed to distinguish between transformation and conservation relations and classify students according to the Schema development stages of the Intra-, Inter-, and Trans-triad. Two researchers independently analysed the data, which all researchers then discussed until a consensus was reached.

Results

Tables 1 and 2 show that no student constructed a Trans- stage Schema and show relations in the GD that students need support to construct, particularly 2D-3D and RS-2D.

Table 1: Number of students at the different stages of Schema development

	Intra	Inter	Trans
Number of students/11	6/11	5/11	0/11

Table 2: Number of students constructing transformation or conservation relation

	RS-2D	RS-3D	2D-3D
Number of students/11	5/11	7/11	6/11

We now consider students' results in more detail. No student constructed an integration Schema at the Trans- stage of development mainly because students did not interpret the symbol *dxdydz* geometrically as the volume of an infinitesimal rectangular prism or give an equivalent description in terms of limits. The code ~geoRC ("no geometric rectangular coordinates") was introduced to denote this. We found that it was used once for each of the 11 students. The code "ord" was also introduced ("seems to believe *dxdydz* is used just to give the order of integration"). It was used 15 times involving 10 of the 11 students. One can think of these two codes as giving more information about the relation RS-3D. The appearance of these codes was so prevalent that we decided to separate the interpretation of the volume element from the rest of the relation RS-3D. The following is an example of an Inter- student (Navid) who showed all the constructions in the GD except those coded as "~geoRC" and "ord." When asked to interpret geometrically *dxdydz*:

> Navid: When we have a triple integral with the term *dxdydz*, then we need to find the boundaries for *x*, then the boundaries for *y*, and finally the boundaries for *z*. From a geometrical point of view, it means to me that we are describing a space in 3D using the limitations for *x*, *y*, and *z*.

Navid's answer does not inform us about the student's personal meaning of a triple integral, as in Jones and Dorko (2014), but it does inform us of their meaning for the rectangular volume element. Further, Navid's answer has practical implications as it suggests the need to explicitly discuss volume elements in class. We also show Navid's response to Question 1:

> Navid: I should try for the direction which needs only one integral. First trying for x and then for y, umm $dxdy$ is better than $dydx$. For x I need to go from left to right, so x will be from y to $2-y$. For y I need to go from down to up umm let me find the intersection point of the two lines, umm the point is $(1,1)$. So y is from the *x*-axis to the intersection point, umm I mean y is from 0 to 1, so the volume under the plane $x+y+z=3$ and above the given region can be computed by this double integral [see Figure 1]

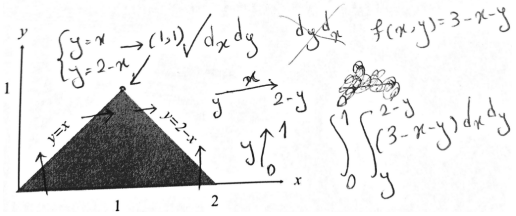


Figure 1: Navid's work on Question 1

Navid's response suggests that he had established the relation 2D-3D to distinguish "floor" and "ceiling" ("under the plane… and above the region"). Note that the explanation of the student and the arrows drawn in Figure 1 suggest that he might imagine vertical and horizontal "infinitesimal" rectangles to aid in determining the order of integration and the limits of integration. This supports the establishment of the relation RS-2D in this question. In the other interview questions, Navid consistently provided evidence of the relation RS-2D and of establishing the relation RS-3D.

Other codes we introduced to further detail RS-2D, for example, ~genx. This code stands for "no generic *x*." It means that the student seems not to imagine or use a "generic" rectangle with base *dx* when relating RS-2D (a rectangle is generic if, as you vary *x*, the corresponding rectangles fill up the region of integration and the base of the rectangles always touches the same curve below while the top of the rectangles always touches the same curve above). It was used more than once with six of the 11 students. This points to a specific difficulty in setting up limits of integration in double integrals (including the two outer integrals in a triple integral). The analogous code ~geny ("no generic *y*") was also introduced with similar results. The following example involves these and other codes and illustrates how the coding was done. In Question 1:

Samira: I divide this region into two small regions like this by drawing the line $x = 1$.
Interviewer: Why do you need to divide the region?
Samira: Because when we want to write the boundaries for *dy* from down to up we have two lines $y = x$ and $y = 2 - x$ for the upper boundary of *y*, umm but when I divide the region into two small regions then for each small region I have only one boundary line from the above.
Interviewer: Okay, write the double integral.
Samira: Since I have two regions I need to write one integral for each of them, umm for the left region I have *y* from 0 to *x* and also the boundaries for *x* are from 0 to 1. For the right region I have *y* from 0 to $2 - x$ and also *x* from 1 to 2 [right part of Figure 2].

Initially, it seemed that Samira (classified as Intra-) had established the relation RS-2D as the limits of integration were correct, and her explanation was consistent with an imagery of partitioning the region of integration and filling it up with vertical slices of base *dx* and height that goes from the lower curve $y = 0$ to the corresponding upper curve $y = x$ or $y = 2 - x$. We also note that Samira did not show having established the relation 2D-3D because the integrand was missing (see Figure 2). However, when pressed to use only one integral, Samira seemed to fall into a memorized routine that did not lead to the solution:

Interviewer: Is it possible to establish this iterated integral with only one integral?
Samira: No, because for *y* we have two different equations from above.
Interviewer: Can you establish the iterated integral *dxdy*?
Samira: If I first consider the limits for *x* I move from left to right, umm *x* is from *y* to $2 - y$, umm and for *y* we have 0 as the lower boundary and for the upper boundary we have two limitations, umm these two lines [$y = x$ and $y = 2 - x$] so we need again two double integrals.

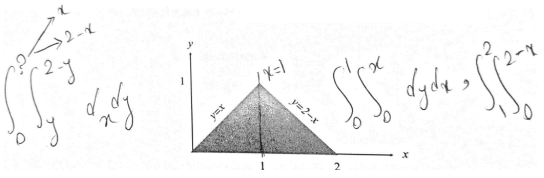

Figure 2: Samira's work on Question 1

This led us to classify the relation RS-2D in this problem as a correspondence relation and to use the code ~geny since the student seemed not to be imagining a horizontal (infinitesimal) rectangle with base *dy* stretching from the curve $y = x$ to the curve $y = 2 - x$, and filling the region as y changed from 0 to 1. We also used the code ~treat (meaning "no treatment") since a simple check of the symbolic form given as the answer (see left hand side of Figure 2) would suffice to note that the outside limits of integration should be numbers. Like in the case of Samira, the code ~treat was used 18 times with eight students, and more than once with five of those eight students.

Discussion and conclusion

Our study shows that even students who can be expected to have constructed finite Riemann sums with research-based activities can struggle when passing to the limit to consider integrals of continuous functions over general regions. One way of seeing this is by considering the understanding of volume elements. It was unexpected to us that students seemed not to have constructed a geometric mental image of volume elements of integration in triple integrals, as suggested by the results dealing with the "~geoRC" code, even after working on tasks where they drew such elements occurring in finite Riemann sums of triple integrals. This has instructional consequences since it suggests that volume elements must be explicitly discussed during instruction and in student activities.

Another contribution is the observation that many students do not undertake the simple treatment of determining if the limits of integration in double and triple integrals they have set up make algebraic sense. This observation, supported by the code "~treat," has instructional implications.

The frequent occurrence of the codes "~genx" and "~geny" and the number of students not constructing RS-2D as a transformation relation refer to the challenge of setting up double integrals. It suggests that when dealing with double integrals, or the outer two integrals of a triple integral, many students tend not to generate the imagery necessary to think of the region of integration as divided into "infinitesimal" rectangles whose base corresponds to the outer variable and that stretch from a single curve touching the base of the rectangle to another single curve touching the "top" of the rectangle. This type of imagery, aided with drawings of thin rectangles, line segments, or arrows in the 2D region of integration, can help students bridge the distance from the finite Riemann sums to the infinite integral over a general region. This supports the idea that instruction might consider going beyond the formal treatment of integration to help students construct the necessary imagery to examine and understand regions of integration prior to attempting to set up limits of integration.

The results dealing with the 2D-3D relation suggest that it might help students to develop the metaphors of "floor" and "ceiling" to think of the region of integration and the integrand in a double integral or the surfaces used to determine the inner limits of integration in a triple integral. The establishment of this relation can help students better organize the information used to determine the limits of integration. This is also supported by observations of the challenge in constructing the relation RS-3D.

In future research, we will refine the GD and use it to design and implement activities. We need to include more detail in the description of RS-2D and RS-3D so that the GD can better describe what students can do. New student data should reflect improved student understanding.

Understanding the concept of derivative through dynamic visualisations by GeoGebra

Hoang Nguyen[1] and Gilbert Greefrath[1]

[1]University of Münster, Germany; h.nguyen@uni-muenster.de, greefrath@uni-muenster.de

Many studies have investigated the challenges students face in understanding the derivative at the upper secondary level. The use of visualisations can prove beneficial in this regard. However, the studies on the effectiveness of dynamic compared to static visualisations in mathematics lessons yield contradictory results. This article thus examines the influence of dynamic versus static visualisations on the understanding of the derivative concept. Therefore, a sample size of 272 students was used to compare these two approaches in a pre-post control group design with a six-hour teaching sequence as an intervention. The results indicated that both groups exhibited an enhancement in their understanding of the derivative. However, there was a statistically significant difference in favour of the students who employed dynamic visualisations over those who used static visualisations on an understanding-oriented test about the derivative.

Keywords: derivative, understanding, dynamic visualisations, GeoGebra, static visualisations

Introduction

Calculus, and in particular the concept of derivative, has been part of upper secondary mathematics in numerous countries for over a century. In their literature review, Törner et al. (2014) found that the teaching of calculus continues to focus primarily on the development of procedural knowledge. In a study with high school and college students, Orton (1983) identified that, in principle, the formation of a derivative function works well; however difficulties tend to lie in the interpretation of the derivative as local rate of change or in the graphical understanding of the derivative (as tangent slope). In order to address the graphical comprehension difficulties, a teaching sequence for an understanding-oriented introduction of the derivative was developed in the study presented here. The sequence focuses on the use of visualisations, particularly function graphs, as a means of facilitating comprehension. Some studies have reported on the potential of dynamic visualisations to contribute to the understanding of the concept of derivative (e.g. Sari et al., 2018). Nevertheless, it remains unclear whether these can enhance understanding to a greater extent than static visualisations which can be employed with greater ease in class. This article aims to address this issue.

Theoretical Background

Students' understanding of the concept of derivative

A framework model that is still widely used today to describe an understanding of the concept of derivative was developed by Zandieh (2000) through an analysis of mathematical textbooks and discourses on the concept of derivative by mathematics educators, mathematicians and students. In order to capture the many facets of the concept, Zandieh (2000) distinguishes between the *graphical*, *verbal*, *physical* and *symbolic* representations/contexts, as well as the three layers (*ratio*, *limit* and *function*). The latter can be derived via the formal definition of the derivative at a point according to the limit of the difference quotient: "The derivative of f, f', is a *function* whose values at any point

is defined as the *limit* of a *ratio*" (Zandieh, 2000, p. 106). Table 1 presents the framework model used in this study, which includes the contexts and layers in their conception according to Zandieh (2000) and is extended by a *numeric* context based on Roundy et al. (2015). The latter allows for the formation of the derivative at a single point, circumventing the infinitesimal limit. Furthermore, the numeric context facilitates comprehension of the symbolic context.

Table 1: Framework for analyzing students' understanding of the derivative (modified after Roundy et al., 2015; Zandieh, 2000)

contexts / layers	**Graphical**	**Verbal**	**Symbolic**	**Numeric**	**Physical**
Ratio	secant slope	average rate of change	$\frac{f(x+h)-f(x)}{h}$	e.g. $\frac{f(2)-f(1)}{2-1}$	average speed
Limit	tangent slope	local rate of change	$f'(x_0) = \lim_{h\to 0}\frac{f(x_0+h)-f(x_0)}{h}$	e.g. $\frac{f(1{,}001)-f(1)}{1{,}001-1}$	instantaneous speed
Function	tangent slope at any point	local rate of change at any point	$f'(x) = \lim_{h\to 0}\frac{f(x+h)-f(x)}{h}$	limit at any point by a numeric approach	instantaneous speed at every moment

It is crucial that students are able to interpret the layers *ratio*, *limit* and *function* in different representations and utilise them in factual contexts in order to have a deep conceptual understanding of the derivative. There are a number of reasons why visualisations can be beneficial.

Learning (the derivative) with visualisations

Orton (1983) has already suggested that "graphical work is also of great importance in developing concepts of rate of change" (p. 243), since the use of the derivative in real situations happens mainly through graphs, figures and tables rather than through algebraic functional equations. A visualisation-based introduction to the derivative has the potential to facilitate comprehension of ideas such as those of decrease, increase and specific points, including extrema and inflection points, as these important properties can be readily discerned from the graph. Traditionally, visualisations employed in mathematics education have been static, such as illustrations that remain unaltered over time. However, with the increasing integration of technology in mathematics teaching and learning, dynamic visualisations are now becoming more prevalent. These are characterised by the fact that they can change when a user interacts with them. Dynamic visualisations can be generated via GeoGebra, affording students the opportunity to use the drag mode in calculus lessons, for instance, to move points or tangents along a graph or to play animations while controlling the playback speed. Furthermore, graphical, verbal and symbolic forms of representation can be linked dynamically, as well as two graphical representations – the function f and its derivative f' (Ainsworth, 1999).

A number of meta-studies have been conducted to compare the effectiveness of dynamic and static visualisations. The findings of Berney and Bétrancourt (2016) indicate an overall positive effect in favour of dynamic visualisations. However, when focusing on the eleven mathematics-specific studies, no statistically significant difference between these two kinds of visualisations could be

found. In accordance with the Cognitive Load Theory, two opposing explanations may be posited: Dynamic visualisations have the potential to increase cognitive load, for example, due to the rapid movements depicted in the animations and their transient nature. Conversely, the linking of different representations in a dynamic manner can facilitate cognitive processes (Sweller, 2020).

Tall (2009) has already emphasised the potential of computer software to make calculus concepts visible, e.g. by moving tangents along a graph f and simultaneously plotting the tangent slopes (graph f'). In a study conducted by Sari et al. (2018), a dynamic approach to introducing the derivative was investigated. The advantages of the dynamic visualisations generated via GeoGebra were observed in the construction of the derivative graph and in the integration of algebraic and geometric thinking. Fonseca and Henriques (2023) also reached similar conclusions with students who were provided with a discovery approach to the derivative via GeoGebra. Through point dragging explorations, the majority of students were able to describe the relationship between the tangent slope and the local rate of change and could apply it in several tasks.

Research question

It remains an unanswered question in the research literature whether dynamic visualisations facilitate a deeper understanding of the derivative concept. This includes, with reference to the framework in Table 1, a conceptual comprehension of the layers *ratio*, *limit* and *function* of the derivative in different contexts, the relationships between these contexts at each layer as well as the ability to solve corresponding tasks. A pilot study involving 110 students revealed no significant differences between students in the dynamic and static intervention groups with regard to their understanding of the concept of derivative. However, a discernible trend emerged in favour of the dynamic group.

Furthermore, the framework illustrated in Table 1 comprises multiple cells, which can be viewed from both a dynamic and a static perspective. In the graphical representation, the derivative at the layer *limit* is interpreted as a tangent slope. A dynamic view of the course of a graph can be obtained by observing it from a tangent moving along the graph, which represents the slope. However, the tangent slope can also be viewed in a static manner, without any movement, by zooming into the graph at a specific point. In this way, the tangent and the graph are approximately the same in a small interval. In a verbal context on the same layer, the interpretation of the derivative as a local rate of change is dynamic via the limit process of average rates of change. Alternatively, the local rate of change can be understood statically via the formal definition as the limit of the difference quotient.

Therefore, the following research question is examined in this study: To what extent does the understanding of the derivative differ in students who worked with either (1) GeoGebra-generated dynamic visualisations or (2) static visualisations after a lesson sequence on the derivative?

Methods

Sample and procedure

The study was conducted with students attending grade 11 in Germany during the school year 2023/24, between October 2023 and February 2024. To ensure a fair comparison between the dynamic and static approaches to the concept of derivative and to control for the potential influence of the teacher's personality, two groups were formed in each course, exhibiting a similar performance

level, following the administration of a pretest. One group employed dynamic visualisations throughout the six-hour teaching sequence (referred to as dynamic group), while the other group utilised static visualisations (referred to as static group). The two groups were taught in two different rooms. As illustrated in Figure 1, the teaching sequence was structured as follows: The three topics (i) interpreting the derivative as local rate of change, (ii) interpreting the derivative as tangent slope and the connection to the local rate of change, and (iii) derivative function and graphical differentiation were initially presented in a teacher-led lesson, conducted in accordance with predetermined lesson plans. Subsequently, students were required to engage in independent practice under the guidance of a research assistant. In particular, during these practice sessions, learners were tasked with completing exercises that reinforced the concepts covered in the previous lesson. This approach enabled the same teacher to hold a lesson to each group with a one-lesson delay.

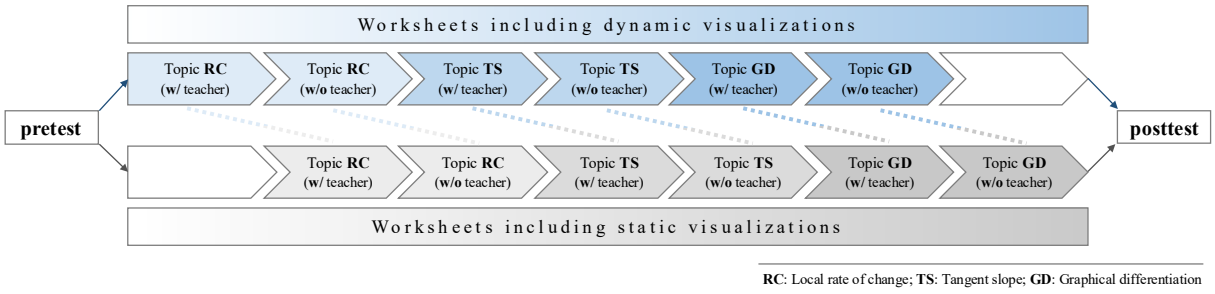

Figure 1: Design of the study

The data presented herewith pertain exclusively to students who were present for a minimum of half of the intervention period and completed both the pre- and posttest. This resulted in a total sample size of 272 students, of whom 140 were assigned to the dynamic group (80 female) and 132 to the static group (72 female).

Material

A folder containing all the requisite worksheets for the six-lesson sequence was provided to each student. The dynamic group employed visualisations created via GeoGebra, which offered a variety of interaction options (e.g. drag mode for moving points or tangents), accessible through QR codes included in the materials. In contrast, the static group completed tasks that were largely similar to those of the dynamic group, but with different instructions. They worked with a folder including static visualisations made from screenshots of the dynamic versions (see Figure 2). All tasks could be solved with the help of either dynamic or static visualisations, thereby circumventing the necessity for manual calculation of terms such as difference quotients.

In designing the lesson sequence for both groups, particular attention was paid to comparability. Castro-Alonso et al. (2016) identified biases in studies comparing dynamic and static visualisations. In order to minimise these biases as much as possible, we ensured that both types of visualisation were comparable in terms of attractiveness, variety, medium, size and realism. However, we were unable to address the issue of interactivity, given that this is an inherent feature of the dynamic visualisations used in this study.

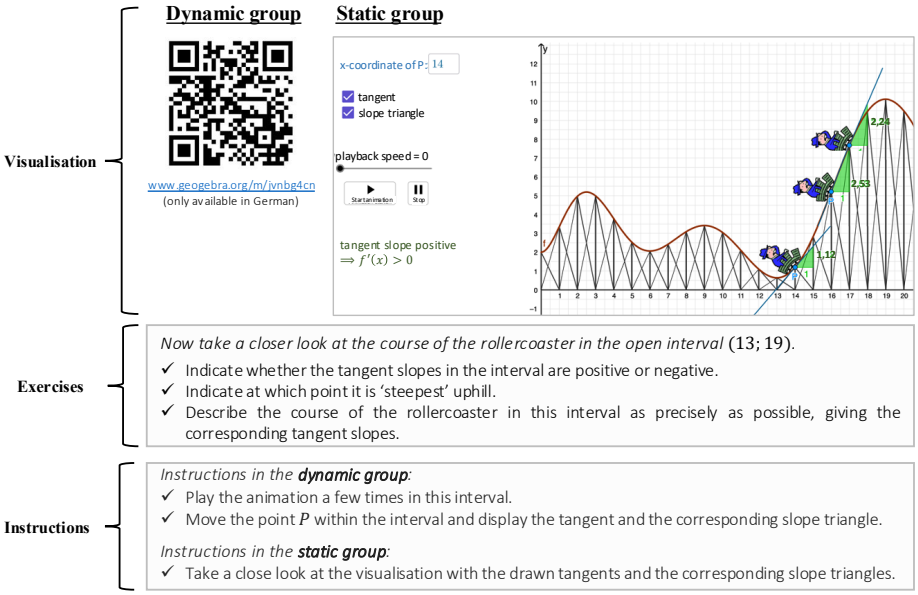

Figure 2: Example of a dynamic and a static visualisation, corresponding exercises and instructions

Understanding-oriented test on the derivative

To measure students' understanding of the concept of derivative, we used a total of 41 items. We tried to include as many layers and contexts as possible based on the modified model created by Roundy et al. (2015) and Zandieh (2000). Figure 3 shows that example 1 can be assigned to the tangent slope, while example 2 covers the layer *limit* in the verbal (and numeric) representation. In all the items used, fewer procedural skills such as determining the derivative of a function according to the derivative rules were tested; instead, the tasks focused on conceptual skills that require an understanding of the concept of derivative according to the framework in Table 1.

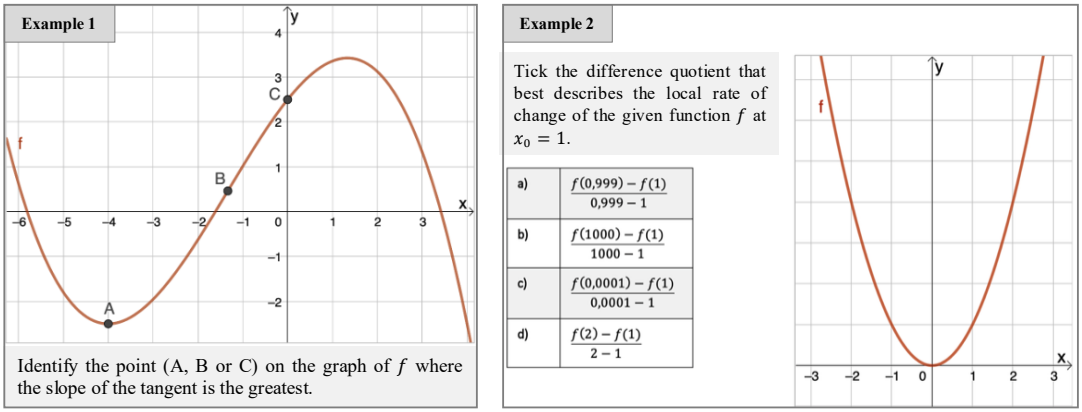

Figure 3: Sample items in the understanding-oriented pre- and posttest

At each measuring point, test booklets were developed comprising 27 items, each linked with eight anchor items. In the pretest (MP 1), a greater number of items was included that pertained to the layer *ratio*, with the objective of preventing demotivation during the testing process. In contrast, the posttest (MP 2) saw a reduction in the proportion of items related to the layer *ratio* and a shift towards

a greater focus on the layer *function*. The online questionnaire platform SoSciSurvey was employed for data processing. Subsequently, the data collected at both measuring points were scaled using a one-parameter IRT Rasch model. Overall, it demonstrated satisfactory fit values: The weighted mean squares of the individual items fall within the interval $[0.82; 1.18]$ and the item-total correlations range from 0.24 to 0.60. Furthermore, the test exhibits a WLE reliability of 0.82, which is sufficient for group comparisons. The statistical analysis was carried out using the program JASP.

Results

As illustrated in Figure 4, the descriptive statistics indicate that, on average, both groups have similar person parameters at the initial measuring point (MP 1). The dynamic group exhibited a mean of -0.44 logit with a standard deviation of 0.93 logit, while the static group demonstrated a mean of -0.45 logit ($\sigma = 0.89$). The non-significant t-test indicates that no statistically significant difference between the students in both groups at MP 1 could be found ($t(270) = 0.11, p = 0.91$). Therefore, the two groups were comparable and subsequently underwent an intervention with either dynamic or static visualisations. It can be determined that the students in the dynamic group exhibited an average increase of 1.02 logit in person parameters at the second measuring time (MP 2), reaching a value of 0.58 logit ($\sigma = 1.25$). In contrast, the static group demonstrated a smaller average increase of 0.76 logit, resulting in a value of 0.31 logit ($\sigma = 1.14$). It was thus observed that there was an overall increase in understanding the derivative in both groups.

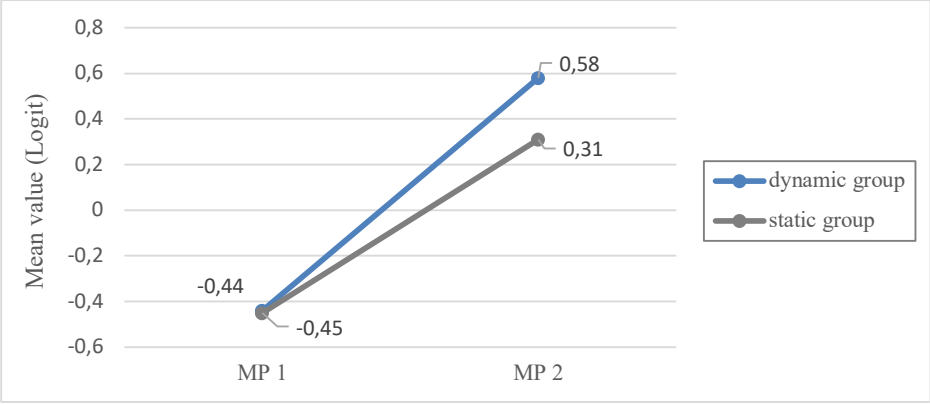

Figure 4: Graphical representation of the mean values (logit) of the two groups

To determine the influence on the independent variable posttest performance by the dependent variable group membership (dynamic or static group) while simultaneously controlling for pretest performance, we chose a multiple linear regression as a static analysis method. To do this, we used the equation $posttest = b_0 + b_1 \cdot pretest + b_2 \cdot group$, where the dynamic group was coded as 0 and the static group as 1.

Table 2: Coefficients of the regression model predicting students' posttest performance (at MP 2)

	b	SE	ß	p	R^2 (adj.)
Pretest (MP 1)	0.852	0.06	0.64	< 0.001	0.427 (0.423)
Group	-0.265	0.11	-0.11	0.02	

The coefficients of the multiple linear regression are presented in Table 2. When controlling for prior knowledge (MP 1), group membership is a significant predictor with a small effect size for the results at MP 2. This indicates that working with dynamic visualisations has at least a small advantage over working with static visualisations. Overall, the regression model explains approximately 43% of the variance in the results of the posttest.

Discussion and outlook

By more than doubling the number of participants compared to the pilot study and revising the materials, the original tendency in favour of the dynamic group was confirmed with a significant result in this study. The potential of dynamic visualisations according to Sari et al. (2018) and Fonseca and Henriques (2023) could also be supported with the results of this study. In regard to Cognitive Load Theory (Sweller, 2020), it can be assumed that the use of dynamic visualisations serves to reduce the cognitive load experienced by learners as a consequence of the interactivity and dynamic linking of content, which facilitates the learning and understanding of the derivative.

Nevertheless, the observed effect was found to be relatively minor. As previously discussed in the theory section, some facets of the framework model for understanding the derivative, as proposed by Roundy et al. (2015) and Zandieh (2000), can be viewed from both a static and a dynamic perspective. This includes the interpretation of the derivative as either a tangent slope or a local rate of change. The results of the quantitative study presented here do not provide information on the specific points during the teaching sequence at which dynamic visualisations have a clear advantage over static ones, nor do they indicate to what extent learning processes differ between students of both groups. It is conceivable that a combination of both forms of visualisation may lead to a deeper understanding of the derivative, as the layers can be handled flexibly in different representations from a dynamic and static perspective. Depending on the task, a dynamic or static view of the derivative may be advantageous. Moreover, further analysis is required to elucidate reasons behind the greater increase in understanding the derivative achieved by the dynamic group as a result of the intervention. The preliminary results indicate that the frequent use of the input field and the drag mode (e.g. moving points and tangents) by students in the dynamic group has a favourable impact on the observed development in understanding the derivative as measured in the pre- and posttest.

In conclusion, the findings of the study are exclusively limited to the influence of dynamic and static visualisations on the domain of derivatives. It is as yet unclear whether these findings can be generalised to other content areas, such as geometry. It may be hypothesised that the integral could also benefit from dynamic visualisations in calculus lessons due to the proximity of the content to the derivative. This is due to the fact that the concept of the integral, either through the accumulation of product sums or through the area, can be visualised particularly effectively. It should be noted, however, that the graphical approach to the derivative is not the only possibility. For example, Roundy et al. (2014) emphasise the physical context in which the derivative concept is applied in measurement experiments, while Tall (2009) describes an approach based on human embodiment, whereby gestures and hand movements can be used to determine the dynamically changing slopes of function graphs.

Meanings of integrals and their compartmentalization: a case study

Lia Noah-Sella[1], Tommy Dreyfus[1] and Anatoli Kouropatov[2]

[1]Tel-Aviv University, Tel-Aviv, Israel; lianoahsella@gmail.com

[2]Levinsky-Wingate College, Israel

The many meanings of integral calculus can result in students experiencing compartmentalization of knowledge. In this case study, we examine the interplay between meanings of integral held by a graduate student in mathematics education, after taking a calculus course focusing on the notions of rate of change and accumulation. To do this, we used a task-based interview designed to elicit a conflict between antiderivative and accumulation. We suggest a novel approach to analysing knowledge compartmentalization, exposing the connections that exist and the connections that are lacking between these two meanings of integral held by the student.

Keywords: Integral, Accumulation, Antiderivative, Compartmentalization, Meaning.

Introduction

In calculus, we often use 'integral' as an umbrella term subsuming definite integral (with numerical bounds), indefinite integral and accumulation function. While these are all integrals, they are mathematically connected yet distinct. It is therefore important to investigate how students relate to these integrals, what connections and distinctions they form between them, and whether they can identify when each is relevant.

In the Israeli high-school curriculum, up until recently, integrals were conceptualized as either antiderivative or as area-under-a-curve. In recent years, a new curriculum has been introduced, that also includes conceptualizing integral as accumulation (Dreyfus et al., 2021). This raises the question – how do students relate accumulation to their previously held conceptualizations? In this study, we focused on antiderivative and accumulation, and investigated the connections made between them. To investigate these connections, we used Thompson's framework for meaning (Thompson et al., 2024), in combination with compartmentalization of knowledge (Mandl et al., 1993; Shiakalli & Gagatsis, 2006; Vinner & Dreyfus, 1989).

Theoretical Background

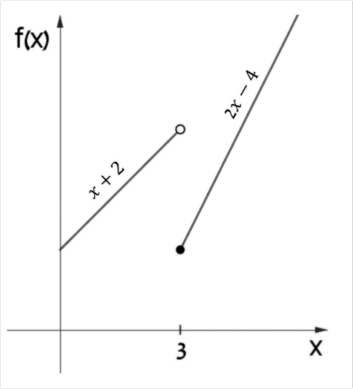
Calculus is often regarded as a barrier in higher education, with many students experiencing difficulties. In particular, the notion of integral presents students with many challenges (e.g., Thompson & Harel, 2021). One challenge is that there are several different conceptualizations of integral, each appropriate in different circumstances. For example, Jones (2015) found that though conceptualizations of integral as area or antiderivative are less productive for contextualized integrals than Riemann sum-based conceptualizations, US college students draw on them more frequently. Thompson et al. (2019) developed a course that conceptualizes integral as accumulation to help students develop a dynamic conception of functions, quantities and change, that centres around the fundamental theorem of calculus.

Though there exists empirical research on compartmentalization (e.g., Hausberger et al., 2021; Shiakalli & Gagatsis, 2006), a single accepted definition of the term does not exist. Mandl et al. (1993) refer to three types of compartmentalization: when a learner's previously held beliefs are not in accordance with the formal scientific knowledge that the learner acquired; when different closely interconnected concepts are stored separately, and not viewed as parts of the more complex network that makes up the problem structure; and when learners ignore knowledge from everyday experiences and deem it irrelevant to the scientific situation they face.

On the other hand, Shiakalli & Gagatsis (2006) consider learners' mathematical knowledge regarding an object as compartmentalized if the learners identify two different representations of the object as two different mathematical objects. This can result in learners struggling to transition between different representations.

Lastly, Vinner and Dreyfus (1989) define compartmentalization as a phenomenon in which a learner has two different, potentially conflicting schemes in their cognitive structure, and certain situations stimulate one scheme, while other situations stimulate the other. These schemes can even be in contradiction with one another and can result in inconsistent or incoherent learner behaviour. This can result in learners possessing relevant knowledge but not perceiving it as relevant, or in learners using two different strategies to solve the same problem getting contradicting outcomes, but without cognitive conflict arising. In other words, using schemes that are cognitively disconnected results in outcomes that are cognitively disconnected, and so, even if the outcomes are mathematically contradictory, they will not be cognitively contradictory, and will not result in cognitive conflict.

Thompson et al. (2024) builds on the theories of Piaget to define meaning-in-the-moment as the space of implications existing at the moment of understanding. In other words, a person's personal meaning is what comes to their mind in a situation, as well as what could be implied, i.e., what could easily come to mind next. The implicative nature of meaning offers a lens through which to look at personal connections between different notions. Thus, it is a suitable framework for investigating compartmentalization as well. We therefore suggest defining compartmentalization as a cognitive state where actions, operations, images, schemes or meanings that might be expected to imply one another do not. This definition is compatible with previously observed behaviours described above: if different representations do not imply one another, the learner will struggle in transitioning between them; if relevant knowledge is not easily implied by the situation, it will not be deemed relevant; if different schemes are both implied by the situation but do not imply one another, a learner using both might get contradicting outcomes, without experiencing conflict. Using a framework that accounts for all behaviours could afford a more nuanced examination of the phenomenon, and potentially expose new such behaviours.



Methods

In this research we conducted an intrinsic case study (Creswell & Poth, 2018), by conducting a task-based interview with Alma, a graduate student in mathematics education, taking an analysis course centred around ideas of rate of change and accumulation. These notions were only recently introduced into Israeli high school curriculum, to be taught alongside the already established notions of antiderivative and area (Dreyfus et al., 2021). Hence, they were new to the students taking the course.

Alma was one of three students interviewed on this task; the students were chosen because they had high achievements in the course, and were thus more likely to have developed connections between their previous conceptions of integral, and accumulation. Due to space limitations, in this paper we focus only on Alma, who presented an interesting example of compartmentalization. The interview was recorded and transcribed. We also recorded all of Alma's writing and sketching.

In the task, Alma was given a non-continuous piecewise linear function. She was requested to graph the derivative of the given function, and then graph the accumulation function of that derivative [Figure 1]. Since the accumulation function $g(x)$ differs from the given function $f(x)$, this task is designed to induce conflict between conceptualizations of integral as antiderivative and as

The given graph describes the function $f(x)$ whose domain is $x \geq 0$.

a. Sketch the graph of the function $h(x) = f'(x)$.

b. Sketch the graph of the function $g(x) = \int_0^x f'(t)dt$.

Figure 1: The task

accumulation. The given function has a derivative for $[0,3)$ and $(3,\infty)$, and the derivative has no antiderivative in the original domain $[0,\infty)$, since an antiderivative function cannot be well-defined at $x = 3$. However, the accumulation function in the domain $[0,\infty)$ exists and is different from $f(x)$. In the interviews we focused on two differences between $f(x)$ and $g(x)$. First, $f(0) \neq g(0)$. Second, $f(x)$ has a discontinuity at $x = 3$ wheras $g(x)$ is continuous throughout.

We analysed the data in accordance with Thompson et al.'s definition of personal (in-the-moment) meaning (2024), looking for the implications brought to Alma's mind, how 'easily' they are brought to her mind, and what potential 'triggers' brought them to her mind. Due to the implicative nature of meaning, to identify Alma's personal meanings we paid attention to her distinct language, i.e., terms and phrases first brought up and used by her and thus indicative of her own implications. Ergo, we interpreted all mathematical terms and notations she used, particularly those used initially, intuitively, immediately; those that are unique. Since meaning is related to scheme, we examined Alma's claims and justifications, i.e., how she used the implied terms and notations to make sense of the

mathematics. We used this to expose the connections between the mathematical notions that comprise the meaning and possibly elucidate the structure of the scheme.

Thompson et al. (2024) refer to the space of implications as what is easily brought to mind. We interpret 'easily' as a scale – some implications are more easily brought to mind than others. We use several criteria to determine this. First, if an implication is recurring, if it is repeated at several points throughout the interview, then it is presumably more easily implied than an implication that occurs sparsely. Second, what is brought up immediately is likely more easily implied than what is brought up afterwards. Moreover, notions that require interviewer involvement to arise are less easily implied by the task than those that arise without intervention. Additionally, notions that are only brought up after the interviewee "gets stuck", deems their current scheme unhelpful, or encounters a cognitive conflict are even less easily implied than the previous ones.

As stated, we also paid attention to the possible 'triggers' that brought each notion to mind. These can be mathematical triggers, i.e., a mathematical notation or notion brings to mind another notion, a scheme, a claim etc. 'Triggers' can also be external, e.g., a social norm, a recent previous experience. To determine the possible 'triggers' we asked ourselves several questions: Which mathematical stimuli appeared just before the implication arose? What was the goal of the reasoning in which the implication appeared? In reference to which question\given\statement did the implication appear?

Findings

Alma has high achievements in the course, but low confidence. She began the interview exclaiming that she does not like analysis, and upon reading the task added "oh, you just killed me". Though she displayed a lack of confidence, Alma sketched an appropriate graph for the derivative [Figure 2], however she did not clearly address $x = 3$. Her sketch of $f'(x)$ was accompanied by consideration of linearly increasing functions, and ratios. The term 'Rate of Change' was not mentioned.

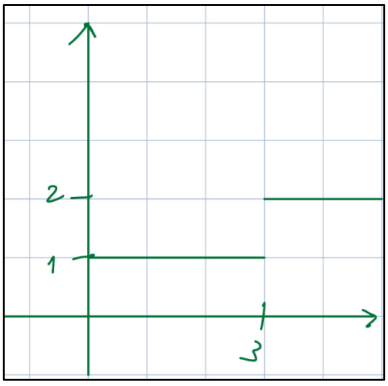


Figure 2: Alma's sketch of f'(x)

As Alma read the second part of the question, where she was asked to graph the accumulation function, her initial response was "I don't know how to do this. Sorry". However, she immediately followed with the statement "I mean, I want to say that it's this" while pointing at the graph of $f(x)$. This is indicative of Alma's implication for integral as antiderivative, though she struggles to elaborate, and upon prompting by the interviewer only adds: "simply because this is the connection between f' and h, the integral of … this is the connection between h and the integral of h."

From Alma's use of qualifiers in her statement – "I want to say that", it appears that this is her own most salient implication for integral. Further probing by the interviewer revealed what was holding Alma back:

> Alma: Look, if you asked me this a month and a half ago [before the analysis course started], I would just tell you it's that.
> Interviewer: Okay.
> Alma: It's just that because of [the professor] (sighs and laughs) we can't use the word integral. Just kidding, it's not forbidden, but we just like have to explain it in different terms.

Thus, we learn that Alma's immediate (presumably stable) implication for integral is "the opposite of derivative", and using the word integral is expressing this notion. Alma had also been exposed to conceptions of integral as accumulation in the course, however she struggled to connect these conceptions with the meaning she already possessed. This is further evident by her statement: "… what I want is to go back to this function ($f'(x)$ and to integrate it. Like, not to integrate it, to …". In this statement she references two different actions, one of which is integrating a function, and the other she does not name, but states it is not integration. The statement was made immediately after referencing the course, and immediately before reasoning that she expected the integral to start from (0,0). Since she justified this expectation by claiming that "at zero it doesn't have an accumulation yet", it appears that the second action referenced was accumulation.

Ergo, Alma seems to have difficulty in conceptualizing integral as accumulation. It appears that while accumulation is brought to her mind when reasoning about integrals, it is 'less easily' brought to mind than antiderivative, to the point where several times in the interview she even distinguished verbally between 'integral' and 'accumulation'. While accumulation was brought to her mind during the task, it appears that the trigger was in large part the context of the interview as part of the course.

As Alma attempted to reason using accumulation, she developed a cognitive conflict between her accumulation reasoning and her antiderivative reasoning. This is due to $f(0) = 2$ while $g(0) = 0$. Alma reasoned that at $x = 0$ the accumulation function should equal zero, since "… at $x = 0$ it doesn't have an accumulation yet". However, her antiderivative reasoning suggested to her that $g(x)$ and $f(x)$ should be one and the same, as previously observed.

> Alma: Why do I want to start from zero? (9 second silence) Look, the graph here is given from $x = 0$, right? So that means that if I want to check the accumulation of this function, then at zero it doesn't have an accumulation yet. It's the starting point of my accumulation, that's why I want … that's why there is this gap that I don't understand. … conceptually I don't know how to settle it with… with the fact that when I start to sum here, because like, I can draw the integral of this function without this constant (circles 2), without the 2 in the given function ($f(x)$).

Alma considered that the difference might be due to an integration constant – "what does it mean? Is it some kind of plus c? What? Don't remember, oh, it's this plus two". While she suggested an integration constant as a possible resolution to the conflict, her use of the word integral as distinct from accumulation suggests that she struggled connecting her conceptualization for integral as antiderivative with her conceptualization for integral as accumulation, even though both conceptualizations were implied.

As the interview continued, Alma proceeded to sketch a graph of $g(x)$ using accumulation considerations, starting at zero, and continuous at $x = 3$ (Figure 3). After sketching her graph, Alma gestured at the graph of $f(x)$ and exclaimed: "and then I don't know what this is". Thus, Alma still had not resolved the conflict. Moreover, Alma states "… it is almost forced upon me. I can only suppose that there's some piece of information that I don't, I don't understand all the way, and it's not here (gestures at the graph she drew)". It appears that for Alma, while both $f(x)$ and $g(x)$ are perceived as integrals of $h(x)$, $g(x)$ lacks some information that exists in $f(x)$. Ergo, this statement supports the hypothesis that for Alma there is a hierarchy between antiderivative and accumulation that favors the former. Furthermore, Alma explicitly stated: "right now there's like two types of attempts to think about things mixed in my head".

As she explained her conflict, Alma skirted around a possible resolution, however, she kept returning to the possibility of her sketches being mistaken. Interestingly, Alma first mentioned rate of change only at this point in the interview, suggesting it is less easily brought to her mind.

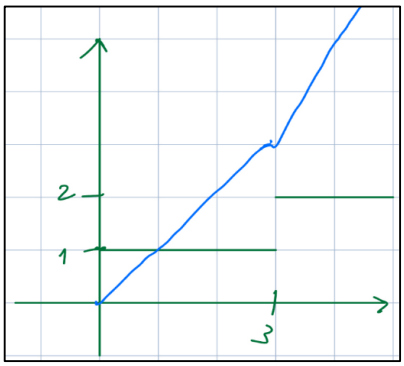

Figure 3: Alma's sketch of $g(x)$ (blue)

Alma: … And I know these constants have some role, and yes, the negative four, it moved us down, but I can't say how right now, what I drew wrong, or in the derivative itself, or maybe the derivative is drawn okay, but we know that the derivative, it actually only expresses rate of change, and there are a lot of different functions that can have the same rate of change, but something about them is different, and that thing is elusive to me right now.

To eliminate the doubt Alma displayed in the graph she drew of $g(x)$, the interviewer informed Alma that it is in fact correct. This led Alma to state:

Alma: … rate of change alone, presumably, is not enough to describe an integral. Or this is an integral and this is … I don't know. Umm … I need to think about it more.

Thus, it appears that Alma was contemplating two different solutions to her conflict. The first, that a given rate of change is not enough to 'describe an integral'. Here Alma was likely using integral in the sense of 'primitive function', closely connected with antiderivative. The second, that only one of the functions is in fact the integral of $h(x)$. Finally, she settled on the explanation that "there are two integrals here for the same rate of change". Additionally, Alma could not explain to the interviewer the difference between $\int_0^x f'(t)dt$ and $\int f'(x)dx$, claiming that to her they are the same.

What was immediately and most easily brought to Alma's mind by integrals is ideas of antiderivative and primitive function. This is in fact so salient to her, that she even struggled to explain it in terms

other than 'integral' or 'integrating'. Thus, at times she used 'integral' as synonymous with $f(x)$. Consequently, this meaning is both dominant and laconic. However, due to the course, Alma also developed another meaning – accumulation. While her accumulative reasoning might be intended to satisfy the interviewer to some extent, accumulation is brought to her mind independently, and is explicitly used in her reasoning during the task.

Though both meanings are brought to mind by '$g(x) = \int_0^x f'(t)dt$', they do not seem to be brought to mind by one another. Furthermore, Alma didn't seem to know when each meaning is relevant. Thus, Alma's reasoning with antiderivative is independent from her reasoning with accumulation, resulting in compartmentalization.

Discussion and Conclusion

In examining Alma's meanings, we found that she can employ reasoning related to both antiderivative and accumulation, however she cannot determine which is relevant in the situation. The immediacy of her use of antiderivative reasoning, and the apparent use of accumulation reasoning to satisfy the interviewer suggest a hierarchy of implications that favours antiderivative reasoning, which is the less relevant one in the given situation. This suggests compartmentalization between the two notions.

Another aspect suggesting compartmentalization is the apparent incompatibility between Alma's conceptions of antiderivative and accumulation. Though both notions were implied by the task, and both implied by 'integral', the connection Alma makes between both notions is mainly in name, and not in substance. Consequently, Alma does not recognize the requested function specifically as an accumulation function, but as an integral in a generic sense. This could also explain her struggle with referring to accumulation as integration, since she formed no meaningful connection between the meaning she held for integration prior to the course and accumulation.

We claim that though Alma experiences cognitive conflict due to her contradicting results, this behaviour still suggests compartmentalization, as the emergence of conflict is due to her tenuous and superficial connection between accumulation and antiderivative. Moreover, while she does recognize the relevant knowledge as relevant, we claim her inability to inhibit irrelevant knowledge is also a consequence of this compartmentalization. Thus, our suggested framework affords a more nuanced examination of compartmentalization, that enables the identification of more complex behaviours.

Like the students in Jones' survey (2015), Alma invokes less relevant knowledge. Our analysis of her meaning suggests the possibility that the low frequency of Riemann sum-based conceptualizations could be a result of weak connections between them and antiderivative and area conceptualizations. These results also suggest that in attending to meaning when teaching the different manifestations of integral, it is important to attend not only to the meanings we want students to develop, but also to the meanings they currently possess, and to the connections and implications we want to exist between them, otherwise students' knowledge could be compartmentalized. The approach suggested by Thompson et al. (2019), where a single notion of integral as an accumulation function is presented, could be a step in this direction; however, this is an issue for further research.

Introducing preservice mathematics teachers to multivariable functions through modelling: A study and research paths approach

Farzad Radmehr[1] and Heidi Strømskag[1]

[1]Norwegian University of Science and Technology, Trondheim; farzad.radmehr@ntnu.no

This study explores the introduction of multivariable functions to preservice mathematics teachers (PSTs) through a modelling approach grounded in the Anthropological Theory of the Didactic. Implemented within a master's course, the study employs Study and Research Paths (SRPs) to guide PSTs in constructing models that serve as tools for determining the best football player in a league. Despite limited backgrounds in calculus, PSTs developed practical knowledge of multivariable functions, using weighted sums of variables to model the system studied. Through iterative refinement and empirical reasoning, PSTs enhanced the accuracy of their models. The findings suggest that SRPs can effectively facilitate the learning of multivariable functions, even in the absence of formal mathematical techniques. Questions remain about how further integration of SRPs and mathematical modelling can enhance PSTs' abilities to develop more sophisticated mathematical models.

Keywords: Mathematical modelling, multivariable function, pre-service teacher education, study and research paths, the anthropological theory of the didactic.

Introduction

Functions play an important role in mathematics. They are initially introduced in school algebra and are prevalent in calculus, real and complex analysis, abstract algebra, and many other branches of mathematics (Dorko, 2023). While there is a vast amount of research focusing on the teaching and learning of single-variable functions, comparatively less research has been dedicated to the teaching and learning of multiple-variable functions despite their fundamental role in modelling real-world systems and their widespread applications across many STEM (Science, Technology, Engineering, and Mathematics) and social science subjects (Martínez-Planell & Trigueros, 2021). In this paper, we report on the implementation of a teaching and learning approach grounded in the Anthropological Theory of the Didactic (ATD), known as *study and research paths* (Bosch, 2018; Chevallard, 2019). This method was taught and used in a master's course in a teacher education programme to introduce preservice mathematics teachers (PSTs) to multivariable functions and to the role variables and parameters play in modelling real-world systems. Our approach is relatively different from what has been proposed for introducing multivariable functions to university students and what can be found in traditional calculus textbooks, where vectors and the geometry of space are first introduced to students (e.g., Stewart et al., 2021). The strategy proposed here does not require comprehensive knowledge of single-variable calculus or visual representations of functions. As such, it can help PSTs and other university students with limited background in calculus to develop at least some partial knowledge of multivariable functions and their utility in solving real-world problems. The research question addressed in this paper is: *What knowledge about multivariable functions and their utility do preservice teachers without a rigorous background in calculus develop through study and research paths focused on modelling of a real-world system?*

Teaching and learning of multivariable functions

Previous research highlights that students' understanding of single-variable functions influences their understanding of multivariable functions, such as through their understanding of covariational reasoning from single-variable functions (e.g., Weber & Thompson, 2014). When generalising knowledge about functions from single-variable to multivariable cases, several considerations must be addressed, including the transformation in the nature of input, output, dependent and independent variables, as well as the domain and range (Dorko, 2023). For instance, while an x-value from a set A is an input for $y = f(x)$, an ordered pair (x, y) from a set $A \times B$ is an input for $z = f(x, y)$. Studies on student learning of multivariable functions highlight challenges such as difficulties in identifying domains and ranges, graphing, and reasoning with free variables, which hinder their ability to apply these functions in real-world settings (Borji et al., 2022; Dorko, 2023). Several teaching strategies have been suggested to enhance knowledge of multivariable functions. These include investigating the *global* behaviour of a two-variable function, fixing one variable at a time to analyse two-variable functions, using a function machine to generalise the concept from single to multivariable cases, and explicitly clarifying the roles of variables in different contexts (Martínez-Planell & Trigueros, 2021; Kabael, 2011). Furthermore, to address language-related issues in learning multivariable functions, the consistent use of embodied language is suggested: "move to the front-back instead of x increases-decreases, right-left instead of y increases-decreases, [and] up-down, instead of z increases-decreases" (Martínez-Planell & Trigueros, 2021, p. 698).

Theoretical tools from the ATD: Modelling and Study and Research Paths

In the ATD, two basic notions are "system" and "model" (Strømskag & Chevallard, 2022). A system $\mathcal{S}$ is any entity that operates according to its own laws. Given a system $\mathcal{S}$, a system $\mathcal{S}'$ is considered a model of $\mathcal{S}$ if studying $\mathcal{S}'$ allows us to answer specific questions about $\mathcal{S}$. Chevallard (1989) presents the original framework for modelling within the ATD, breaking the process down into three key stages that remain foundational today: *system definition*, which involves identifying the system and specifying the relevant variables and parameters in relation to the question being addressed; *model construction*, which entails establishing relationships between the defined variables; and *model exploration*, which involves manipulating and analysing the model to gain new knowledge about the original system. The third stage is driven by the modelling process's objectives, which might encompass solving equations, optimising functions, or exploring the model under different conditions. This framework has been further elaborated by Barquero (2023). Moreover, as discussed by Strømskag and Chevallard (2022), the relationship between systems and their algebraic models is crucial for translating complex real-world scenarios into mathematical representations. A key aspect of this translation lies in the explicit use of parameters, for example through multivariable functions, which allows for the flexible modelling of various aspects of a system. Tackling a generating question Q within the ATD means inquiring into Q, where the inquiry can develop along different study and research paths (SRPs) (Bosch, 2018). A notable characteristic of an SRP is the creation of what is known as a *didactic milieu*, which consists of the tools collected primarily by the students for studying Q. This milieu comprises existing answers, derived questions, works of different types (e.g., theories, reports, and historical studies), and datasets. In an SRP, there is a dialectic between *study* (consultation of existing works) and *research* (creation of elements for an answer to Q that are not

available in the existing works). The path of an inquiry may be illustrated by a directed graph along with a table containing the elements of the milieu used to generate an answer to Q (Strømskag, 2024).

Methods

This paper reports from a case study conducted at a Norwegian public university, involving SRPs carried out by PSTs enrolled in a master's course as part of a teacher education programme for Grades 5–10. Prior to this inquiry, which was their first encounter with an SRP, they were introduced to some ATD notions (e.g., didactic paradigm, model and system, SRP, and praxeology), as discussed by Strømskag and Chevallard (2022) and Strømskag (2023). The PSTs had no formal teaching of multivariable functions or vector algebra. They had only studied some basic single-variable calculus in their first year of study as part of a mathematics education course designed for this group of PSTs, including two 3-hour sessions on derivatives and two on integrals, following teaching on algebraic thinking, equations, programming, and functions. In their other mathematics education courses in the second year, they were taught statistics, probability, and geometry. It is worth noting that in the Norwegian teacher education system, PSTs in teacher education programmes for Grades 5–10 do not take any pure mathematics courses; instead, mathematical content knowledge is integrated into their mathematics education courses. Aligned with the ecological dimension of modelling proposed by Barquero et al. (2013), SRPs were used in this study as a teaching method to overcome curricular constraints where multivariable functions were introduced as tools to model real-world systems. The case consists of six groups of three PSTs, with each group undertaking its own SRP that was required to qualify for their final examination. The research data comprise these elements: three reports submitted by each group while working on the modelling assignment between February to April 2024, a questionnaire completed by the PSTs after completing the SRPs, and the lecturer's reflective notes from the course. Five of the six groups gave consent to use their data in our study. This paper presents an analysis of the reports from these five groups, with excerpts from Group 1 (hereafter G1) serving as representative of the others. The topic of the generating question was chosen in consultation with the PSTs to give them more agency in their study process. Consequently, the following generating question, here denoted Q_0, and guiding prompts were presented by the lecturer:

Q_0: How would you select the best football player in a football league [of your own choice]?

- What is the system studied? [Define the system and identify its variables and parameters.]
- Create a model of this system that enables you to answer Q_0.
- What knowledge can be inferred from your model and what limitations does this model have?

(The information in square brackets is a condensed version of what was provided in the assignment.)

Results

Defining the system: Discussing types of data and informational sources

In the context of deciding who the best football player in a league is and intending to build a model to make this decision, the system would be the set of all relevant factors and variables that define and influence the performance and evaluation of football players within that league. Although this definition was not explicitly given in the PSTs' first report, they focused on finding what possible data they could use from various sources to address Q_0, such as Eurosport.no (Myhre & Fredheim,

2022), FotMob.com (n.d.), and NIFS.no (n.d.). They discussed several questions, for example "Should different positions have different criteria?", which led to identifying four positions to include in the model—goalkeeper (hereafter keeper), defender, midfielder, and striker—along with additional factors to be considered. For example, G1 explained their criteria for selecting the best keeper as follows:

> We start by looking at the number of saves and goals conceded, and the ratio between these numbers. This is because the number of goals conceded can be influenced by the quality of the defence in front of the keeper … Furthermore, we consider the ratio of penalties saved to penalties conceded … Physical attributes such as height, agility, strength, and reaction time are also important … Additionally, we use the Goals Prevented metric, which indicates the number of goals conceded compared to the number of goals the keeper was expected to concede.

Constructing a model: Mathematising and using statistics to determine parameter values

In a lecture after the first reports were submitted, the lack of mathematising was discussed, and the PSTs were encouraged to study how multivariable functions could be used to find an answer to Q_0. Two examples were presented by the lecturer: $f(x_1, x_2) = ax_1 + bx_2$ and $y_{Gk} = 8x + 4y + 0.3z$. The PSTs were also reminded about the different roles that parameters and variables play in modelling systems, as previously discussed in the course, drawing on literature (e.g., Strømskag & Chevallard, 2022). All groups then used multivariable functions in their models, reflecting on this feedback. In what follows, we examine G1's construction of a model to determine the top football player, with a focus on the mathematical elements in this process. Section titles in italics are used for clarity.

Multivariable functions: The proposed model uses linear functions to evaluate players based on various parameters. Each player's performance is assessed using a formula that combines different weighted variables relevant to their position (i.e., keeper, defender, midfielder, striker).

$$y_k = ax_1 + bx_2 - cx_3 + dx_4 + ex_5 + fx_6 + gx_7$$
$$y_d = ax_1 + bx_2 - cx_3 + dx_4 + ex_5 + fx_6 + gx_7$$
$$y_m = ax_1 + bx_2 - cx_3 + dx_4 + ex_5 + fx_6 + gx_7$$
$$y_s = ax_1 + bx_2 - cx_3 + dx_4 + ex_5 + fx_6 + gx_7$$

G1 explained that y_k, y_d, y_m, and y_s are the performance scores for keepers, defenders, midfielders, and strikers, respectively. They further clarified that the variables x_i represent different numerical aspects of a player's performance: x_1 = goals scored; x_2 = team goals; x_3 = goals conceded; x_4 = assists; x_5 = matches over 45 min played; x_6 = player average rating; and x_7 = team average points.

Variables and parameters: The variables in these functions are drawn from key performance indicators (KPIs) that are relative to each football position. The parameters a, b, c, d, e, f and g are placeholders that G1 later assigned values to, reflecting the relative importance of each KPI for different positions, aiming to model each player's contribution to their team's success. However, this notation may have been problematic, as both variables and parameters should have been position specific. For example, $y_k = a_k x_{k1} + b_k x_{k2} + c_k x_{k3} + d_k x_{k4} + e_k x_{k5} + f_k x_{k6} + g_k x_{k7}$, or, more simply, $y_k = w_{k1} x_{k1} + \ldots + w_{k7} x_{k7}$ for keepers, with similar subscripts for the other positions. Here, w_{ki} denotes the weight of the variable x_{ki}.

Use of statistics: The model heavily relies on statistical data derived from various performance metrics (e.g., FotMob.com and Nifs.no), such as goals scored, assists, and player ratings. These data are used to populate the variables in the functions, which then produce a numerical score that represents the player's overall performance.

Exploring the model: Iterative testing and parameter refinement

Model validation: After testing the model on actual players, using "Best of the Season" (TV2, n.d.), a ranking of the best players in 2023, G1 explained their process of adjusting the parameters (or weights) of the multivariable functions to best match the observed data:

> In our model, it is easier for attacking players to achieve a high score compared to defenders. We also noticed that it was particularly difficult for the keeper to score many points … Currently, player ratings have a relatively small impact, while the number of goals scored and conceded by the team had a large effect … We have not found any variables that similarly count positively for defenders and keepers, so we have decided to further adjust the parameter *c*—the number of goals conceded by the team. We also felt that the player rating had too little impact and will adjust it slightly upwards. To ensure that the number of goals scored and conceded by the team does not have as much influence, we will slightly decrease these parameters.

Two successive iterations of adjustments like this were made to the model's parameters, with each round enhancing the accuracy of the scores to better reflect a player's performance, considering the different roles and expectations associated with their positions. G1's process, as described in the above quote, is an example of "model fitting," where the goal is to find the set of parameters that minimises the difference between the predicted values generated by the model and the actual data. The parameters of G1's model were not mathematically justified (e.g., through regression analysis); instead, the model fitting was conducted through trial and error, similar to what the other groups did.

Optimisation: The final step in the model development involved tweaking the parameters to minimise biases towards certain positions and ensure that the model could fairly evaluate players across different roles on the pitch. Here is G1's resulting model:

$$y_k = 10x_1 + 0.2x_2 - 0.3x_3 + 8x_4 + 0.5x_5 + 10x_6 + 10x_7$$
$$y_d = 3x_1 + 0.3x_2 - 0.5x_3 + 3x_4 + 0.5x_5 + 10x_6 + 10x_7$$
$$y_m = 1.5x_1 + 0.4x_2 - 0.8x_3 + x_4 + 0.5x_5 + 10x_6 + 10x_7$$
$$y_s = x_1 + 0.5x_2 - 1.1x_3 + x_4 + 0.5x_5 + 10x_6 + 10x_7$$

Modelling within the SRP framework: The milieu and path of the inquiry

Given space constraints, we briefly comment on the modelling assignment as an SRP, using G1 as an example. As an overview, Figure 1 depicts the path of the modelling process, while Table 1 lists the milieu elements incorporated throughout. At the start of the modelling process, there was no existing model available to the PSTs, so the concept of "existing answers" was applied not to Q_0 but to the derived questions, Q_k. The attributes of the variables in the constructed model were determined by the derived questions that addressed players' performances. Existing answers to these questions included player statistics and ratings, which served as works for creating a dataset to test the model and refine its parameters. Notably, G1 interpreted "works" (see Table 1) as the activities they

performed, rather than as products of human creation, as defined in the ATD. On a broader level, the challenge lay in modelling a complex scenario where inherent laws are elusive and difficult to define, unlike in physical or mathematical systems. This adds an additional layer of difficulty to the modelling process, highlighting the need for further research in this area.

Discussion and conclusions

All five groups based their models on what we denote here as $y_R = \sum_{i=1}^{n} a_{Ri} x_{Ri}$, using between five and eight variables, and applied this to four different player positions, R (i.e., keeper, defender, midfielder, striker). This model provides a low-threshold introduction to multivariable functions. Regarding the notation y_R used for the dependent variable, it is particularly suitable for studying systems (as in this SRP) where there is no need to address the function as a mapping, considering

properties like continuity or operations such as differentiation and integration. In contrast, the notation $f_R(x_{R1},\cdots, x_{Rn})$ would be more effective in cases where such properties and operations are relevant. It should be recognised that the mathematical expression $a_{R1}x_{R1} + \cdots + a_{Rn}x_{Rn}$ (a weighted sum), can also be understood within the domain of linear algebra. In this context, it is interpreted as a linear combination of the variables, where the performance score for each player is represented as the scalar product of a vector of coefficients (weights) and a vector of player statistics. However, this conceptualisation was not introduced in the course since vector algebra had not been part of the secondary school curriculum for these PSTs. The PSTs developed some basic knowledge of multivariable functions through empirical, heuristic, and iterative reasoning, which reflects a practical approach to model fitting. By using trial-and-error methods, guided by intuition and domain-specific football knowledge, they iteratively adjusted the model's parameters to achieve fairness and accuracy across player positions. Although their approach lacked formal mathematical techniques like regression analysis, it effectively engaged the PSTs in hands-on problem-solving. This enabled them to explore the impact of various variables and parameters, deepening their knowledge of multivariable functions and their utility in modelling real-world systems. These findings align with Dorko (2023), who observed that students can develop meaningful knowledge of multivariable functions through practical engagement and intuitive reasoning, even without formal calculus training. This reasoning is crucial at this stage, laying the groundwork for more formal methods. In conclusion, the study suggests that PSTs without a strong calculus background can develop practical knowledge of multivariable functions through modelling, enabling them to create models where these functions serve as accessible tools for studying real-world systems through weighted sums of variables. However, while this approach has proven effective, open questions remain about how integrating SRPs with mathematical modelling can further enhance PSTs' capacities to develop and apply more complex models based on multivariable functions, particularly in scenarios that demand deeper mathematical insights and the handling of more intricate datasets.

Inconsistencies in teachers' symbolism for the gradient and the gradient function - m and $\frac{dy}{dx}$

Innocent Tasara and John Monaghan

University of Leeds, Faculty of Education, Leeds, United Kingdom; i.tasara@leeds.ac.uk

This paper aims to contribute to ongoing research that seeks to understand and improve the teaching of elementary calculus. It draws from a qualitative study investigating how mathematics teachers in English schools introduce elementary differential calculus. The study examines the commognitive constructs in the teachers' pedagogical calculus discourse. Interviews with the teachers and observation of their introductory lessons on the derivative were used to collect qualitative data, and a commognitive thematic discourse analysis was used to deconstruct the teachers' pedagogical calculus discourse on the derivative. This paper reports on some inconsistency and ambiguity with calculus symbolism found in the teachers' pedagogical calculus discourse, particularly in the transition between the gradient (for straight-line graphs) and the gradient function (for curves).

Discourse, commognitive, derivative, calculus, symbolism.

Introduction

This paper presents some findings on calculus symbolism drawn from a doctoral study on the teaching of elementary calculus. It examines the calculus symbolism in the teachers' pedagogical calculus discourse, particularly focusing on the transition from (and between) the gradient (slope) to the gradient function (derivative as a function).

The doctoral study explores how teachers of mathematics introduce differential calculus to pre-university level students (16 to 18 years) in England. As a mathematics teacher educator, the researcher observed that many student teachers' understanding of elementary calculus concepts was often disjointed and limited to algorithmic rules of differentiating functions, which they had difficulty explaining. A preliminary review of the literature revealed that Berry & Nyman (2003), who had also worked with undergraduate and postgraduate students training to become mathematics teachers over several years in the UK and the USA, described their students' understanding of calculus as "a set of loosely connected actions based on a set of algebraic rules that can be applied in restricted, often artificial, algebraic situations" (p. 482). In a study, with 29 teachers, investigating teachers' beliefs towards calculus, Eichler & Erens (2014) report that all the teachers shared a view on calculus as a set of rules for students to be memorised and used in solving routine problems. The researcher's observations about student teachers' difficulties with calculus were, certainly, not isolated.

Students' difficulties with calculus are well-established in the literature. Tall (1992a) gave an extensive summary of the challenges that students encounter in learning calculus. A decade earlier, Orton's (1983) study with 16 to 22-year-olds found that the students lacked adequate intuition or understanding of the derivative concept. More recently, a survey conducted by Park (2013) with 12 elementary calculus university students found that they did not understand the distinction between the *derivative at a point* as a constant and the *derivative* as a function. In an examination of the calculus discourse of experts as reflected in the three most popular calculus textbooks in the US, Park

(2016) also found that nearly identical symbols were used in representations for the derivative at a point and the derivative of a function.

This paper focuses on the following research question: In teaching differential calculus, what visual mediators do teachers use? It discusses the visual mediators, particularly the calculus symbolism in the teachers' pedagogical calculus discourse. It advances knowledge on the researcher's previous PME paper (Tasara, 2018) that examines the word use and narratives (Sfard, 2008) in the teachers' pedagogical calculus discourse, which found some inconsistency in the teachers' pedagogical calculus discourse in their use of calculus words. This CERME paper will show evidence of some inconsistency in the teachers' pedagogical calculus discourse in their use of calculus symbolism.

The study and this paper are informed by the commognitive framework (Sfard, 2008) that views mathematics as a form of discourse, that is, a special type of communication with specific ways of saying and doing (Sfard, 2008). Thus, the study offers an alternative research perspective (to most past studies) on researching teachers and their teaching of elementary differential calculus (mathematics) that does not focus on teacher knowledge but on the teachers' mathematical discourses, herein referred to as the teachers' pedagogical calculus discourse; the amalgam of the teachers' mathematical and didactical discourse on calculus.

According to the commognitive perspective, visual mediators and word use are the tools with which the participants of a discourse "identify the object of their talk and coordinate their communication" (Sfard, 2008, p. 145). Visual mediators could be physical visible objects or symbolic artefacts such as algebraic notation and expressions, tables, graphs, diagrams or drawings that are used to mediate instruction (Ryve et al., 2013; Sfard, 2008). Sfard (2008) further asserts that visual mediators are an integral part of the act of communication in literate mathematics discourse. Indeed, visual mediators are an integral part of the teachers' pedagogical calculus discourse. Sfard (2015) describes symbolic artefacts as referring to numerals, algebraic expressions and graphs, and that they serve as "representations of impalpable mathematics objects" (p. 132).

Methods

Researching the teachers' calculus discourse requires examining their communicative activity, i.e. the teachers' forms of saying and doing in teaching calculus (Sfard, 2008). Therefore, a qualitative approach was adopted, in which interviews with seven different teachers of mathematics and observations of their introductory lessons on the derivative were used to generate qualitative data on the teachers' pedagogical calculus discourse. Although the methodology of my research was informed by the commognitive framework, analysing the huge amounts of qualitative data needed a systematic approach, i.e. thematic analysis (Braun & Clarke, 2006). By focusing on the commognitive constructs of word use, visual mediators, narratives and routines (Sfard, 2008) in the teachers' calculus discourse and following the process of thematic analysis, the study was able to analyse 'how and when' teachers used literate calculus words and calculus symbolism. Braun & Clarke (2006, p. 12) assert that thematic analysis (at the latent level) involves identifying and examining the "underlying ideas, assumptions, and conceptualisations [of the commognitive framework] – and ideologies - that are theorised as shaping or informing the semantic content of the data". Data analysis

followed the process of thematic analysis, in which the coding, defining and naming of overarching themes was informed by the epistemological assumptions and the four constructs of the commognitive framework. Hence, the process of thematic analysis was effectively combined with the theory of commognition to form the *commognitive thematic discourse analysis*, as a creative new application of the commognitive theory and thematic analysis.

Findings

Five out of the seven lessons observed displayed evidence of some inconsistencies and ambiguity with calculus symbolism (and word use) for or between the gradient for a straight line and the gradient function. For the purposes of this paper, exemplar excerpts from the lesson observation (LO) data transcripts, T4LO and T2LO, of two participant teachers, T4 and T2, respectively, are presented and discussed as examples that illustrate evidence of the inconsistencies in the transition from the derivative as a constant to the derivative as a function in introducing the concept of the derivative.

Observations from T4LO

In the lesson T4LO, the teacher used the function $y = x^2$ and a sketch diagram of the graph of $y = x^2$, see Figure 7.1 and Figure 7.2 below. [T4LO]:

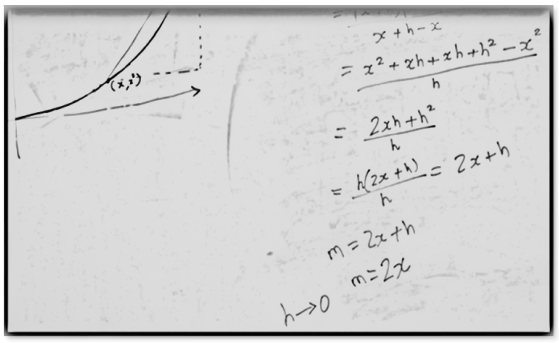

Figure 7.1 The gradient of secant through (x, x^2) and $[(x+h), (x+h)^2]$

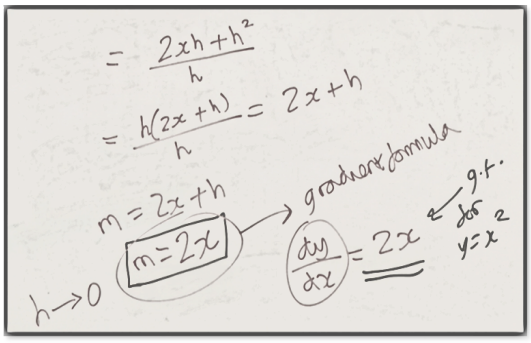

Figure 7.2 From m (gradient) to $\frac{dy}{dx}$ (gradient function)

Figures 7.1 and 7.2 capture the stage when the lesson had moved away from numerical coordinates to general points $(x, x^2)$and $[(x+h), (x+h)^2]$. Before this stage, the lesson had progressed from computing the gradient of a chord, by using two given points, (x_1, y_1) and (x_2, y_2) with specific numerical coordinates on the graph. The teacher used the formula $m = \frac{(y_2-y_1)}{(x_2-x_1)}$ for computing the gradients of secant lines (chords). The figures show the algebraic computation for the gradient of a secant line passing through the general points (x, x^2) and $[(x+h), (x+h)^2]$, which are substituted into the formula $m = \frac{(y_2-y_1)}{(x_2-x_1)}$, i.e. the algebraic manipulations and simplification of the quotient $m = \frac{((x+h)^2-x^2)}{((x+h)-x)}$ culminating into $m = 2x$.

Below is an excerpt from the lesson in which the teacher is explaining Figures 7.1 and 7.2. [T4LO]:

192 Teacher Okay. Time to think again guys. The gradient we found is that the gradient is equal to $2x + h$. Same, same question as last time. What happens as *h* gets

		closer to 0? What happens is, in other words, what happens as this point gets close, close to the original, the original point as *h* gets close to 0? What is the gradient of that line? [*Teacher pointing to the secant on the sketch diagram for the graph of* $y = 2x$]
193	Student	$2x$
194	Teacher	Yeah. $m = 2x$. Okay, because as *h* approaches 0, *h* becomes 0 and we're just left with $m = 2x$. Now that looks a bit weird because we've now got a gradient that isn't just a number, okay? What's gone on there? Why have we, usually in GCSE we get $m = 1$ or $m = 3$? Why have we got a bit of algebra for our gradient?
202	Teacher	That's right because this is a general formula for the gradient. This could tell us about the gradient at any point we want. It's not just *m* = 10. The gradient's not just 10, is it? Because Gxxx said right at the start of the lesson the gradient changes. This is a *general formula for the gradient at any point,* okay? Now we've got a name for that. We call it the gradient, we call this, we call this the *gradient formula*, okay. And we've got a special…we've got some *special notation* for it. Instead of saying $m = 2x$ we write $\frac{dy}{dx} = 2x$ and this is called the *gradient formula*, okay. So $\frac{dy}{dx} = 2x$, that's the gradient, that's the gradient formula for which curve?
203	Student	$y = x^2$
204	Teacher	$y = x^2$. This is always gonna be the gradient formula for the line $y = x^2$, okay, and that's it. That's differentiation, finding the gradient formula.

The symbolic mediator $h \to 0$ in Figure 7.2 depicts that as *h* approaches zero, the gradient $m = 2x$. Note the two signifiers in the teacher's utterance [192], "as *h* gets closer to 0" and "as this point gets close, close to the original", both describe $h \to 0$ (as *h* approaches *0*) without no mention the limit or explanation of the limit definition of the derivative. Based on Figure 7.2 the teacher introduces the derivative of the function $y = x^2$ as "$m = 2x$ is the gradient formula" and "$\frac{dy}{dx} = 2x$ is the gradient function". Here, it can be construed that these two utterances imply that $m = \frac{dy}{dx}$. Also, note that $\frac{dy}{dx}$ is introduced as "some special notation" [202] that is used instead of the m, the latter which is symbolism for slope (gradient). The teacher's utterance here, suggests that $\frac{dy}{dx}$ is the same as m, only that it is a special or different notation for the same object.

What is not done here, could be more important, a substantiation of the difference between $\frac{dy}{dx}$ and m. Consider these two utterances: (i) "We call it the *gradient*, we call this, we call this the *gradient formula*, okay" [202], and (ii) "So $\frac{dy}{dx} = 2x$, that's the *gradient*, that's the *gradient formula* for which curve?" [202]. Note that in both utterances the teacher gives $\frac{dy}{dx}$ two names, i.e. he calls $\frac{dy}{dx}$ *gradien*t and *gradient formula*. See how this is depicted in Figure 7.2. The teacher writes $\frac{dy}{dx} = 2x$ and $m = 2x$, and both are labelled as *gradient function*. The $\frac{dy}{dx}$ calculus symbolism was, thus introduced and subsequently adopted by the class. There were no questions from the students nor further explanation from the teacher about this new symbolism, $\frac{dy}{dx}$.

Observations from T2LO

In contrast to T4LO (and all the other lessons), in which the introduction to differentiation was built on the function y = x^2, T2LO used the function y = $x^2 - x - 6$, instead. Figure 7.3 is a snapshot from the lesson showing the algebraic computation for the gradient of a secant line through the general points $[(x), (x^2 - x - 6)]$ and $[(x + h), (x + h)^2 - (x + h) - 6]$. This was the procedure used to estimate the slope of the tangent to the graph of the function $y = x^2 - x - 6$ at the point $[(x), (x^2 - x - 6)]$. Like in T4LO, the teacher in T2LO used the gradient quotient $\frac{(y_2 - y_1)}{(x_2 - x_1)}$ to compute the gradient estimation for the tangent at $[(x), (x^2 - x - 6)]$. [T2LO]:

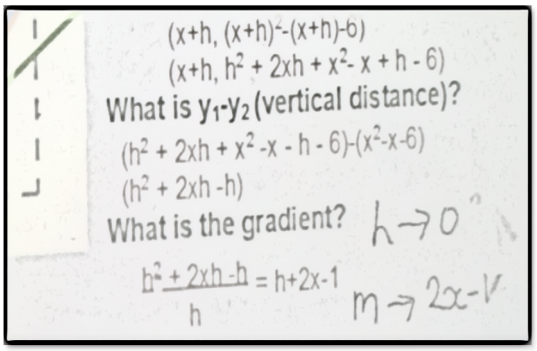

Figure 7.3 The gradient of a secant line

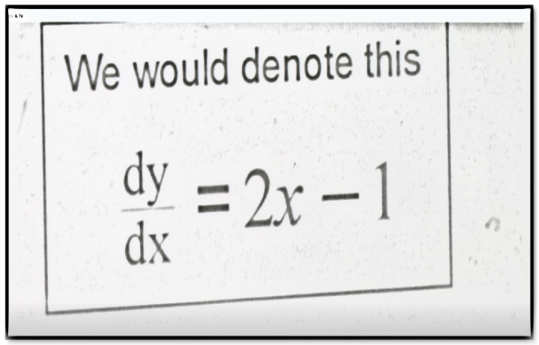

Figure 7.4 The gradient function of $y = x^2 - x - 6$

Below is an excerpt from T2LO about Figures 7.3 and 7.4. [T2LO]:

373	Teacher	We know as h gets smaller and smaller it goes to 0. So, then our gradient function, let's call it m for now, for the sake of *it will go to* $2x - 1$ [*my italics*]. … We found out the gradient function for this [*Teacher pointing to the function*]. … I thought it was nice to finish off with something like this [*Teacher displays Figure 7.4*] because I know you've seen this before. We think about the distances there [*Teacher pointing to the graph of the function*], being like $\frac{dy}{dx}$. Then we denote it like that [*Teacher pointing to Figure 7.4*].
374	Student	So, was the gradient $2x - 1$?
375	Teacher	The gradient function was $2x - 1$, yeah, for any point x.

Here, like in T4LO we see the introduction of new keywords, 'gradient function' and new symbolism, $\frac{dy}{dx}$. However, when a student describes $2x - 1$ as the *gradient* [374], the teacher immediately corrects the student with the endorsed narrative '*gradient function … for any point* x' [375], thus, reinforcing that $\frac{dy}{dx} = 2x - 1$ is the *gradient function* (not gradient, as in T4LO) for $y = x^2 - x - 6$. Like in T4LO, the $\frac{dy}{dx}$ symbolism was not adequately substantiated, apart from what is displayed in Figure 7.4, showing that $\frac{dy}{dx} = 2x - 1$. Neither were there any questions from the students about the meaning of $\frac{dy}{dx}$ symbolism.

Similar to T4LO, the symbolic mediators $h \to 0$ and m are used in T2LO, and m is used to denote the gradient function. Note that unlike in T4LO (where the teacher writes $h \to 0$, $m = 2x$), in

T2LO the teacher does not use the $=$ sign but writes $m \rightarrow 2x - 1$, instead (See Figure 7.3). T2 explains "as h gets smaller and smaller it goes to 0" and the mediator m (gradient function) is described as "… *it will go to* $2x - 1$" [373], which is consistent with the symbolism displayed in Figure 7.3.

Discussion

In teaching differential calculus, algebraic symbolic artefacts are an important aspect of visual mediation, and so are graphical mediators. In line with Sfard's (2008) argument for the multiplicity of visual realisations, and consistent with Tall (1992a) who argues for versatile transitions between representations in the teaching of calculus, the teachers used combinations of, and constant shifts between numerical, algebraic and graphical mediators in substantiating and constructing the definition of the derivative.

The evidence above shows that the teachers used the symbol m to signify gradient functions. The pupils at this stage (post-16) would be familiar with the symbol m as a signifier for gradient (slope). Yes, the parameter m is typically used to denote the slope (gradient) of a straight line (Styers et al., 2020) and it comes from the formula $y = mx + c$ for any linear functions (Stump, 1999). By describing $\frac{dy}{dx}$ simply as "some special notation" [T4LO; 202] that is used instead of the m, it implies that $\frac{dy}{dx}$ and m are mediators signifying the same object. Such use of m to signify the gradient function was common in other lessons too, e.g. in T2LO, m is used to mediate the gradient function, $2x - 1$. Teachers in this study used the parameter m, which is usually used to signify the slope of a straight line, to signify the gradient function. These findings are consistent with Park's (2016) analysis of the calculus discourse of experts on the derivative as reflected in the three most popular calculus textbooks in the US.

> The realisations of both the derivative at a point and the derivative of a function were mediated with nearly identical symbols suggesting a possible difficulty with understanding the difference between them. (Park, 2016, p. 417)

The findings also show evidence of ambiguity and inconsistency with calculus symbolism. The mediator $\frac{dy}{dx}$ was explained simply as "some special notation" in T4LO and "We denote it like that" in T2LO. There is a lack of adequate substantiation of the mediator $\frac{dy}{dx}$, e.g. what it means, where it comes from or whether it is a fraction. Furthermore, the evidence shows inconsistencies between the teachers' substantiation of the mediator $h \rightarrow 0$. As $h \rightarrow 0, m = 2x$ in T4LO, whereas in T2LO we see this: as $h \rightarrow 0, m \rightarrow 2x - 1$. It is important to point out that these two visual symbolic mediators ($=$ and $\rightarrow$) signify different discursive objects and that they convey different meanings. Thus, there is ambiguity here, around the concept of limit for the derivative: Does it go to … or does it equal to …? In literate calculus discourse, as $h \rightarrow 0, m(for\ \frac{dy}{d\,x}) \rightarrow 2x$, the limit. The symbolic artefacts that teachers use matter because they fulfil the role of visual mediators and serve as "representations of impalpable mathematical objects" (Sfard, 2015, p. 132). They (symbolic artefacts) are an integral part of the thinking and communication process in mathematical discourse (Sfard, 2008).

Learning and doing mathematics means becoming capable of participating in the literate discourse (Sfard, 2008). The research found evidence of some didactical ambiguity with some calculus symbolism in the teachers' pedagogical calculus discourse on the derivative. It is vitally important that the calculus symbolism teachers use in introducing the derivative is substantiated explicitly to facilitate students' induction into, and participation in, literate calculus discourse. Besides, past studies have shown that moving from and between the derivative at a given point on a curve, to the derivative as a function is not simple for students (e.g. Park, 2013). This research found evidence of teachers using both m and $\frac{dy}{dx}$ to signify the gradient function, thus, using the same signifier for the derivative at a point and for the derivative as a function. Park (2013) found students also describing 'the derivative as a tangent line', which suggests that the students "considered the 'derivative' as a point-specific object but also a (linear) function defined on an interval" (p. 624). Therefore, how differential calculus symbolism is introduced matters if students are to become capable of participating in literate calculus discourse.

Conclusion

The commognitive framework provided an analytical perspective for examining and explaining how teachers construct and substantiate the notion of a derivative and a derivative function in introducing differential calculus. On the face of it, these findings suggest that ambiguity and inconsistency with calculus symbolism in the teachers' calculus pedagogical discourse could be a factor behind some of the students' difficulties with calculus. The teachers in this study may or may not have difficulty understanding the difference between m and $\frac{dy}{dx}$. However, the evidence suggests that their students could potentially have difficulties understanding the difference between these two symbolic artefacts and their applications. For constructing and substantiating the definition of the derivative, teachers should pay close attention to calculus symbolism and explicitly explain the difference in application between the mediators $\frac{dy}{dx}$ and m. Symbolic mediation brings "generative power" (Sfard, 2008, p. 159) to the discourse and offers a "powerful manipulative ability" (Tall, 1992b, p. 9). However, calculus symbolism can be a source of some difficulties with calculus, for both teachers and students, alike. Nevertheless, teachers should seek to substantiate explicitly the symbolic mediators in their calculus discourse and do so consistently with literate mathematics discourse.

Understanding and Basic Mental Models of the concept of derivative

Hans-Georg Weigand[1], Gilbert Greefrath[2], Reinhard Oldenburg[3], Hans Stefan Siller[1] and Volker Ulm[4]

[1]University of Würzburg, Germany, hans-georg.weigand@uni-wuerzburg.de; [2]University of Münster, Germany; [3]University of Augsburg, Germany; [4]University of Bayreuth, Germany

An empirical study with 501 university students of mathematics, mainly at the beginning of their studies, investigated the relation between the understanding—concentrated in basic mental models (BMMs)—of the derivative and the capability of solving derivative problems. The results show that the BMM of tangent slope is of central importance, it is much less for the local rate of change, while the local linearization plays no role. The study emphasizes the meaning of BMMs for successfully solving problems related to the concept of derivative.

Keywords: Basic Mental Model, concept understanding, concept image, derivative, tangent slope, rate of change, local linearity.

The understanding of the concept of the derivative is a central goal of the teaching of calculus. In the following, we refer to Basic Mental Models (BMMs) as a core part of the "concept image" and the framework of Zandieh (2000) concerning this understanding of this concept.

Concept definition – concept image

The relation *concept image – concept definition* has been studied in many different contexts since the early 1980s (Tall a. Vinner, 1981). "Concept definition (is) a form of words used to specify that concept" and "Concept image describes the total cognitive structure that is associated with the concept […]. It is built up over the years through experiences of all kinds, changing as the individual meets new stimuli and matures" (Tall & Vinner, 1981, p. 152).

This relation has been studied für many different concepts, for example, numbers, functions or limits. A problem concerning this framework is that the *concept definition* is very narrow, mainly concentrated on the definitions(s) of the concept, while the *concept image* is a too extensive concept. This calls for a possibility to have a concentrated core of a concept concerning the *concept image*.

Basic Mental Models of the concept of derivative

The concept of Basic Mental Model (BMM, in German: Grundvorstellung) has been well established in German-speaking didactics of mathematics for many years (vom Hofe & Blum, 2016). A BMM of a mathematical concept is a content-related interpretation that gives meaning to this concept, providing relations to meaningful contexts (see Greefrath et al., 2016). BMMs of mathematical concepts can be considered within the theoretical framework of *Concept Image–Concept Definition* (Tall & Vinner, 1981). They are parts or subsets of the *Concept Image* of a mathematical concept. While *Concept Image* refers to all individual mental images identified with the concept, BMMs are the *core* or *central components* of these images. *Normative BMMs* are derived from didactic analysis of mathematical concepts, *individual BMMs* are specific BMMs in a student's mind.

Based on didactical analyses, Greefrath et al. (2023) identified four BMMs of the first derivative of a function at a point (Table 2) and validated them in a comprehensive empirical study.

Table 2: Basic Mental Models of the first derivative of a function at a point (Greefrath et al., 2016)

BMM of the local rate of change (RC)	A varying quantity is considered. The derivative is the local rate of change of this quantity. If the quantity changes with time, the derivative has the meaning of an instantaneous velocity or speed.
BMM of the tangent slope (TS)	The graph of a function in a coordinate system is considered. The derivative is the slope of the tangent to the graph at a point. The development of this BMM is closely related to the development of the concept of a tangent to a graph.
BMM of the local linearity (LL)	If you "zoom in" more and more on the graph of a function at a point of interest, the graph locally appears more and more as a straight line. The derivative is the slope of this straight line. Software for dynamic mathematics with the possibility of zooming in on the screen is particularly useful for developing this BMM.
BMM of the amplification factor (AF)	A quantity y is dependent on another quantity x. The derivative indicates how strongly small changes in the quantity x affect the dependent quantity y. ($\Delta y \approx m \cdot \Delta x$)

Understanding the concept of derivative

BMMs are an important element for understanding and applying a concept. However, understanding a concept is much more than knowing one or some BMMs of the concept. There are many ways to describe the concept of *understanding*. Skemp (1976) distinguishes between instrumental and relational understanding. Another distinction is that in *conceptual knowledge*—about the properties of a concept, relationships between different properties and relationships to other concepts—and *procedural knowledge* – knowing how to solve equations, how to calculate limits or derivatives of functions (Hurrel, 2021). Zandieh (2000) proposed a comprehensive theoretical framework for analysing students' understanding of the concept of derivative. She distinguishes *multiple representations of the derivative* on the one hand, and on the other she considers the *derivative as a ratio, a limit and a function* (Table 1). The framework is developed for school mathematics, however, it might also be used for the university level (Feudel & Biehler, 2021). There are also some follow-up developments concerning this framework (for example, Radmehr & Turgut, 2024)

Table 1: Zandieh's framework for understanding the derivative

	Graphical	**Verbal**	**Symbolic**	**Physical**
Ratio	Slope of the secant line	Average rate of change	Difference quotient	Average velocity
Limit	Slope of the tangent line or slope of the curve under magnification	Instantaneous rate of change	Limit of the difference quotient	Instantaneous velocity
Function	Graph of the derivative function	Instantaneous rate of change as a function	Derivative as a function	Velocity as a function of time

Each column of this framework can be seen as an element of the concept image or/and of a BMM of the concept of derivative. We are interested in the understanding of the concept of derivative in a point of a function and in the relation between the function and its derivative function. This means, we refer to the limit and the function row of Table 1. The BMMs of the derivative are a part of the concept image and specify it in the sense of a core image or core perception.

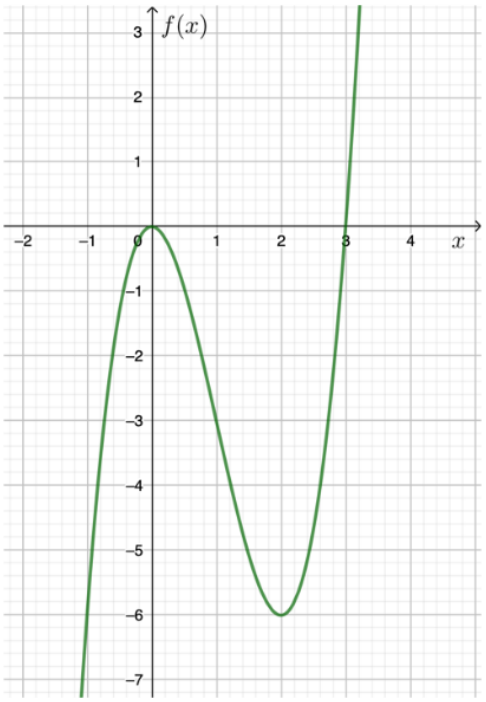
Research questions

Our hypothesis is that BMMs are helpful–and maybe essential–for solving problems. In the following, firstly, we are interested how students solve mathematical derivative problems. Secondly, we want to quantify the relation between students' capability to solving problems and their BMMs. We are interested in the following research questions:

1. To what extend are students able to solve derivative problems?
2. What is the relation between students' capability to solve derivative problems and their BMMs?

Methods

A test with two groups of problems was developed. In the capability–test, mathematics students had to answer questions concerning the concept of derivative. In the following BMM–test, the students were classified with regard to their individual BMMs. The test is designed for university students of mathematics at the beginning of their teacher training courses or undergraduate courses in scientific disciplines like computer science, physics, chemistry or biology. A total of 501 students took part in the study. They were recruited in mathematics preparatory courses of teacher training programs (all school types) at four different German universities.



Problem Group 1: Capability–Test

Seven tasks were developed that relate to the first derivative of a real function at a specific point or in an interval of the domain of definition or to the entire derivative function. According to the classification scheme by Zandieh (2000) (cf. Table 1), the tasks refer to different representations – *Graphical*: relationship between graph and first derivative; *Verbal*: verbal descriptions of properties of the derivative; *Symbolic*: interpretation of a statement on the symbolic level; *Physical*: interpretation of an environmental situation.

Two types of tasks were used. For type 1 (tasks 1 to 4), three suggested solutions were given for each task, for which the student had to decide whether the statement given in each case was correct or incorrect.

Problem 1.1

The adjacent figure shows the graph of a real polynomial function f of third degree. Mark whether the following statements regarding the derivative function f' are true or false.

	true	false
All the values of the function f' are negative in the interval]0; 2[.		
The function f' is strictly monotonically increasing in the interval]0; 2[.		
The function f' has a local minimum at the position $x = 0$.		

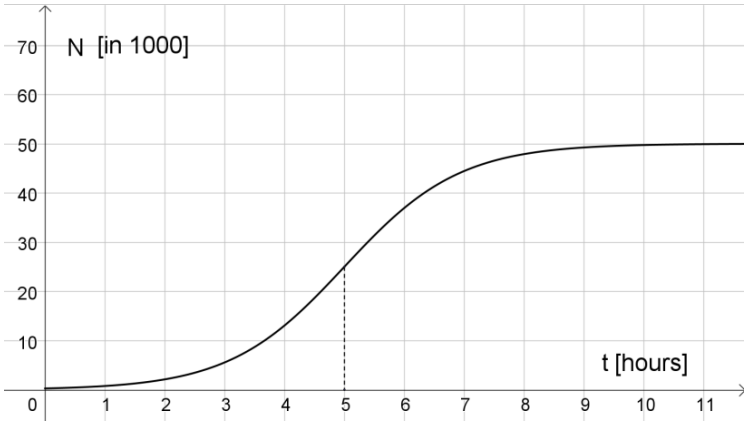
Problem 1.2

The function values $f(t)$ give the outside temperature measured at time t. Mark which interpretation of the expression

$$\lim_{t \to t_o} \frac{f(t) - f(t_o)}{t - t_o}$$

is correct or incorrect.

	true	false
The expression indicates how the temperature changes between t_o and t.		
The expression indicates how the temperature changes at the time t_o.		
The expression indicates how high the temperature is at the time t_o.		



To reduce the guessing probability, a problem is only considered as correct if all subtasks are correct, otherwise, it is wrong (guessing probability 12.5 %).

Problem Group 2: BMM-Test

In Greefrath et al. (2021, 2023), a test was developed and tested to assess BMMs for university students of mathematics. The basic idea of this test is to present the students problems with argumentations that suggest certain BMMs. For each item, students are asked to mark on a five-point Likert scale from (– –) to (+ +) to indicate the extent to which the answer corresponds to their own thinking. The complete test consists of 13 tasks, eight items were selected for the test used here. Moreover, we skipped the BMM AF because it is not yet emphasized in high school and is useful only for quite limited kinds of problems. Students should be able to work on tasks with different BMMs and looking at problems from different perspectives. Therefore, test contexts were chosen that are conceivable with all BMMs. An example of the BMM–test is the following item:

Problem 2.1

The figure below shows the number of bacteria N in a nutrient solution as a function of the time t (in hours).

The special meaning of the time $t = 5$ can be explained in different ways.

	– –	–	o	+	+ +
If you zoom in on the graph, it appears like a straight line at every point. This has the greatest gradient for $t = 5$.					
The slope of the tangent to the graph is greatest at $t = 5$.					
The number of bacteria changes most rapidly at the time $t = 5$.					

Evaluation method

Homogeneity was checked with Cronbach's alpha. Correlations of sum scores were measured with Pearson's correlation coefficient. Linear regression was used in the analysis of dependencies. All calculations were carried out with the statistical program R.

Results

Capability of the Derivative

The mean values and standard deviations of the capability-test are shown in Table 3. Cronbach's α for problem 2 to 4 indicate good homogeneity, whereas these for problem 1 are more heterogeneous. For problems 5 to 7 exactly one answer is correct, determining Cronbach's alpha is not possible.

Tab. 3: Means and standard deviations of the capability–test

	Mean value	**Standard deviation**	**Cronbach α**
Task 1	0.24	0.43	0.26
Task 2	0.61	0.49	0.62
Task 3	0.28	0.45	0.60
Task 4	0.61	0.49	0.69
Task 5	0.62	0.49	–

Task 6	0.66	0.48	–
Task 7	0.84	0.37	–
Average	0.55	0.24	0.62

Overall, the capability to solve problems is not unidimensional. The value for Cronbach's alpha is 0.62. Especially the problems with a given graph (2, 4, 5, 7) are solved better on average than the others.

Basic Mental Models

Table 4 shows the mean values and standard deviations as well as Cronbach's alpha of the sum scores for TS, RC and LL. We confirmed the results in Greefrath et al. (2023), that a three-dimensional model for the BMMs fits quite well.

Table 4: Mean and standard deviations for the TS, RC and LL

	TS	RC	LL
Mean value	0.81	0.62	0.57
Standard deviation	0.20	0.21	0.22
Cronbach's alpha	0.86	0.79	0.82

Relation between Problem-solving capability and BMMs

All correlations – except the correlation of capability and LL – are (even highly) significantly different from 0. This shows that TS and RC are associated with capability of solving derivative problems, whereas it is weak for LL (see Table 5).

Table 5: Correlation matrix

	Problem-solving capability	TS	RC	LL
Problem-solving capability	1.00	0.32	0.17	0.05
TS	0.32**	1.00	0.29**	0.30**
RC	0.17**	0.29**	1.00	0.31**
LL	0.05	0.30**	0.31**	1.00

Discussion

The Capability-test covers many aspects of the two higher levels Limit and Function of Zandieh's (2000) framework, as well as all graphical, verbal, symbolic and physical representations. Furthermore, the test shows different levels of difficulty – mean values of 0.24 to 0.84 – with the items in the first column of the framework having higher solution rates than the items without graphical representation. In the test, more procedural aspects of knowledge such as understanding the derivation rules were not taken into account.

In the students' BMMs, the tangent slope is most prominent, while rate of change and local linearization occur much less frequently. Particularly in view of the stronger emphasis on modelling skills in school analysis (in curricula and textbooks, less in actual teaching), one might have expected a stronger emphasis on the local rate of change. The basic idea of local linearity plays a rather subordinate role. Presumably, typical learning processes in mathematics lessons play a central role here, in which the tangent concept is supported above all by the predominance of intra-mathematical problems. The repeatedly demanded view of the derivative as a local rate of change is probably not yet sufficiently developed due to too few modelling examples.

The ranking of the basic concepts tangent slope, local rate of change and local linearization does not change if only students with high or low problem-solving capabilities are considered. In the sub-group of students with lower problem solving abilities, the preference for the BMM tangent slope is much lower than in the high achieving group. but the other BMMs are even lower. Hence, even in this subgroup the BMM tangent slope is the best predictor of at least limited success. However, it can be assumed that BMMs are useful for increasing the capability to solve derivative problems and consequently the understanding of the concept of derivative (according to vom Hofe and Blum, 2016).

Furthermore, the results of a linear regression show that the tangent slope can predict the ability to solve derivative problems with a relatively high weight (again, especially for the items where a graph is given), this is the case for the rate of change to a lesser but also significant extent, while the concept of local linearization does not play any role.

Limitations

In terms of subject selection, this test clearly selects students by limiting them to mathematics students. However, this at least allows the assumption that the capability test would be worse with a non-subject-specific test group, for example, students from social studies.

Furthermore, it must be taken into account that the capability-test only consists of 7 questions and the BMM-test is based on self-reporting by the students. Developing a test which determines the "actual BMMs", is a research problem for the future.

Conclusion

The result of this study shows that the BMM of tangent slope is of highest priority for the solving of derivative problems. This justifies the special importance of the graphical representation, which is also prominently emphasized in Zandieh's framework. The rather low correlations between BMMs and the problem-solving capabilities shows that these are different categories, but they are not independent, as highly significant correlations exist. It still needs to be clarified what significance the different BMMs have for certain content areas and problems. This can provide indications how and when BMMs should be developed in school mathematics. Bednorz et al. (2023) have proposed a learning path for this purpose. Based on the results of this study, it can be assumed that the BMMs RC and LL are more difficult to teach and require well thought-out special strategies. However, the local rate of change is important in the school context, especially in relation to application tasks, and local linearization is important on university mathematics level. This means that the development of

all BMMs is important for the broad and global understanding of a concept, as they show different perspectives and offer different ways of using and working with the concept.

TWG 26: Mathematics in the Context of STEM Education

Introduction to the papers and posters of TWG26: 'Mathematics in the context of STEM education'

Michelle Stephan[1] and Nelleke Den Braber[2]

[1]University of North Carolina at Charlotte, College of Education, USA; mstepha1@charlotte.edu

[2]NHL Stenden University of Applied Sciences, Leeuwarden, The Netherlands

TWG26 met for the fifth time in Bolzano, at CERME14 to continue the work started at CERME11. Since our inception in 2019, our research interests have shifted from characterizing the nature of mathematical modeling, teacher preparation, and rigorous research methodologies in STEM to creating frameworks for interdisciplinary teaching, teacher and student STEM competencies, and STEM assessment. At CERME14, 16 papers and six posters were submitted. Among them 11 papers and four posters were presented, involving authors from nine different nationalities (Denmark, Germany, Italy, Greece, Portugal, Spain, Austria, Turkey, and USA). The papers and posters were grouped under four themes, (i) *The Nature of STEM* (two papers), (ii) *Student Learning in STEM* (four papers), (iii) *Working with Teachers in STEM* (three papers, four posters), and (iv) *AI in STEM* (two papers). Most of the presented research was about the role of mathematics in inter- and transdisciplinary STEM teaching and learning environments. Only one paper included Arts (STEAM), yet most of the posters did. The ideas and issues in the papers and posters will be presented under these four themes.

The Nature of STEM

The first paper by Spreitzer et al. investigated the presence and nature of mathematical activities within integrated STEM lessons as part of a nationwide school experiment in Austrian lower secondary education. Semi-structured interviews were conducted with 11 experienced teachers to examine what mathematics is integrated into the activities, how students respond to them, and which activities are considered unsuitable for STEM lessons. Findings indicate that activities such as measurement, construction, and modelling are frequently integrated, while practices like reasoning and justification are less common and perceived as challenging to implement. Mathematics was predominantly viewed as a means to an end rather than a learning objective in itself. Nonetheless, some teachers actively sought to broaden the role of mathematics showing the potential for mathematics in STEM.

The second study by Larsen and Svendsen focused on interdisciplinary STEM assessment, as part of the LabSTEM project in Danish secondary education. Drawing on the Anthropological Theory of the Didactic (ATD), the researchers analyzed student presentations to determine how mathematical tasks, techniques, and theoretical justifications were incorporated. The findings revealed that while students frequently applied mathematical techniques such as regression analysis and modelling using GeoGebra, theoretical components were often omitted or insufficiently explained. Integration of mathematics with scientific disciplines varied across groups, with some demonstrating coherent connections and others struggling to relate mathematical models to biological or chemical processes. The study highlights the need for clearer guidance in STEM assessment design to ensure that both practical and theoretical mathematical knowledge is addressed.

Student Learning in STEM

There were three papers presented that involved research associated with student learning. The papers had very little in common regarding the STEM topic being explored but all studies investigated student reasoning. Altindas et al. conducted a study that explored how university *life science* majors reason about graphs representing a STEM context. Researchers conducted semi-structured interviews with 16 students to learn how they reason about the graph of a logarithmic function depicting a titration curve. Students were asked to describe how the PH changes as a base solution is added at a constant rate. Researchers analyzed how students "chunked" the graph into particular sections and what those chunks revealed about the nature of the PH change. They found that students' reasoning with the chunked graph varied from surface level mathematics and science descriptions (e.g., describing the shape of the graph as increasing) to deep, intrinsic use (e.g., explaining how the PH changes at the inflection point of the logarithmic function). They concluded by suggesting that where students anchor their experiences (mathematics or science) may influence how they anchor their reasoning, on the mathematics or scientific characteristics of the titration graph.

Erbasan and Boston conducted a single case study of a 5th-grade student's computational thinking skills while participating in a STEM activity called the *Moonbase*, developed by LEGO®. Computational thinking has been identified as essential reasoning of all STEM disciplines. While no shared definition exists, they defined the main components of computational thinking as 1) decomposition, 2) pattern recognition, 3) algorithmic thinking, 4) abstraction, 5) generalization, 6) debugging, and 7) problem solving. The authors examined the components of computational thinking that emerged as the student built a robot to use hypothetically on the base of the moon and program it to move about the surface collecting "modules" to make it easier for astronauts to complete their tasks. The researchers found that the student engaged in debugging, decomposition, and pattern recognition, showing that this particular STEM activity has the potential to support some of the components of computational thinking.

Finally, Klaas et al. examined whether high school students' reason mathematically as they try to solve complex real-world problems constructed by employees at a local business, as well as to identify effective means of supporting their problem solving. Students selected from a palette of problems posed by workers at the business and are assigned a university student mentor and an employee to provide support. One of the most critical stages of the two-year challenge is the problem-solving stage in which the mentors provide students with an integrated problem-solving model (e.g., problem solving from chemistry and computer science). The researchers conjectured that an integrated problem-solving model, as opposed to mathematical problem-solving alone, may support students to create less superficial solutions to the authentic STEM challenges. In this paper, they compared problem solving in mathematics and computer science with chemistry to determine overlapping components that may be useful for students in the future. They found aspects of Polya's problem solving approach within each of the other STEM disciplines such as "devising a plan" but they are implemented slightly differently (e.g., in mathematics devising a plan, in computer science devising an algorithm). Nevertheless, the authors found enough overlap that they will continue to explore comparisons with other STEM disciplines so that they can implement this more general STEM problem solving approach with students.

Working with Teachers in STEM

This section included four papers: two studies focused on professional development through collaboration among STE(A)M teachers, one study on supporting teachers in primary education, and one study on teacher competences in STEM education. Additionally, there were four posters that fell into this category and were presented during our mini-poster session on the third day of the TWG.

The study by Adesso et al. investigated how STEAM teachers, working in teams, approached the solution of a real-world problem in different ways. As part of an Italian summer school training, 45 STEAM teachers engaged in activities such as building an electric network on a breadboard, leading to the discovery of the Fibonacci sequence. The researchers used the concept of disciplinary borders to explore interdisciplinarity and Habermas's construct of rationality to understand communication across disciplines. Data were collected through video recordings of group discussions and final interviews. The results revealed how teachers navigated disciplinary boundaries through epistemic, teleological, and communicative rationalities, with dialogue playing a key role in mediating and transforming understanding. The study highlights how interdisciplinary collaboration fosters professional development by enabling teachers to integrate diverse perspectives and co-construct knowledge at the borders of their disciplines.

The study by Bogiatzi et al. was part of an international programme and focused on professional development sessions involving Greek teachers (six mathematics and two science teachers). The aim was to explore the meanings teachers attribute to inquiry in STEM and how these evolve through collaborative dialogue. Using grounded theory, the researchers analyzed transcripts from teacher meetings to identify emerging meanings of inquiry, supported by theoretical constructs of dialogical moves and argumentation. The findings revealed diverse epistemological and didactical interpretations of inquiry, including tensions between mathematical and scientific inquiry, challenges in integrating digital tools, and concerns about student engagement. While some teachers prioritized disciplinary goals, others attempted integration, often facing practical constraints. The study underscores the complexity of implementing integrated inquiry-based STEM teaching and the value of structured dialogue in supporting teacher learning.

The study by Bennet and Rutchi explored how primary school teachers interpret and value a framework for integrated STEM education, focusing on four elaborated methods of integrating mathematics into science instruction. Conducted in a single school district in western United States, the mixed methods case study involved 24 primary teachers who completed a survey assessing their understanding, comfort, and perceived importance of each integration method. While most teachers recognized the value of integrated STEM and expressed confidence in applying three of the four elaborations, the construct "Accentuate Interdisciplinary Constructs" (AIC) revealed a notable discrepancy. Despite acknowledging its relevance for student learning, teachers rated AIC as least important for classroom integration, suggesting a gap between theoretical appreciation and practical implementation. The findings highlight how limited content knowledge, rigid lesson structures, and beliefs about student readiness may hinder deeper interdisciplinary teaching. This study underscores the need for targeted professional development that addresses both pedagogical and epistemological challenges in STEM integration, particularly in primary education contexts.

The fourth study by Stoffels investigated how mathematics teachers engaged in the MINTco@NRW project perceive and prioritize key competency areas required for mentoring students in authentic, interdisciplinary STEM learning environments. Using a multiple case study approach, six teachers from North Rhine-Westphalia participated in semi-structured interviews, reflecting on a competency model developed to support their mentoring roles. Teachers were asked to rank eight competency areas and discuss their relevance both within the project and in regular classroom teaching. Findings reveal considerable variation in how teachers prioritized competencies such as communication, project-based learning, and digital competence, with no clear consensus across cases. While most teachers found the model adequate, the ranking process highlighted tensions between theoretical importance and practical application. Teachers also noted that several competencies, particularly authentic problem-solving and digital literacy, are transferable to everyday teaching, though implementation is often constrained by institutional factors. The study underscores the complexity of teacher competencies in integrated STEM contexts and suggests that professional development should be tailored to individual needs and teaching environments.

All four posters were in this category as well. Berciano et al. shared a qualitative case study that explored the presence of mathematical process standards in three STEAM projects implemented in Basque secondary schools. The researchers analyzed teacher interviews and project activities to identify how mathematical processes—such as reasoning, representation, and communication—were integrated. While teachers did not explicitly prioritize mathematical processes during project design, several emerged organically through student activities. The findings suggest that mathematics often plays an instrumental role in STEAM contexts and highlights the need for more intentional integration of mathematical competencies in interdisciplinary project planning.

The poster by Costa et al. outlined the development of a STEAM lesson plan focused on water conservation and Sustainable Development Goals, created within the Erasmus+ ProSTEAM project. Using design research methodology, the plan was iteratively developed and tested across five cycles involving university experts and primary school teachers from multiple European countries. The plan included hands-on mathematical tasks to quantify water usage and promote sustainable habits. Teachers who implemented the plan in professional development programmes in Portugal and Lithuania reported high relevance to curricula and strong student engagement, supporting the value of integrated STEAM approaches in primary education.

The poster by Ortiz-Laso et al presented a study which explored how pre-service mathematics teachers identify school-relevant mathematical content in a real-world carpentry video sourced from Instagram. Fifteen Spanish pre-service teachers analyzed a video demonstrating how to divide a wooden plank into three equal parts using a geometric technique. While most participants correctly described the carpenter's method, only half recognized Thales' theorem as the underlying mathematical principle. The study highlights a gap between disciplinary knowledge and the ability to connect it with practical applications. The authors argued for the inclusion of real-world tasks, such as social media content, in teacher education to strengthen contextual understanding and support the implementation of integrated STEM education.

The last poster by Silvestri presented findings from the Erasmus+ STEAM-Connect project, which involved secondary mathematics teachers from five European countries in designing interdisciplinary STEAM activities. The study focused on the role of horizontal (teacher–teacher) and vertical (teacher–researcher) connections in shaping the design process. Through interviews and qualitative analysis, the authors found that teachers who engaged in both types of collaboration demonstrated greater evolution in their understanding and implementation of interdisciplinarity. Representations of interdisciplinarity ranged from metaphorical (e.g., a cooking pot) to structural (e.g., concept maps). The findings suggest that sustained collaboration fosters meta-disciplinary awareness and supports the development of meaningful STEAM practices.

AI in STEM

There were two papers on this theme presented. Both research projects involved exploring issues around the use of artificial intelligence (AI) and mathematics. Fock et al. argued that mathematics instruction should emphasize STEM contexts with a focus on education for sustainable development (ESD). STEM challenges require problems that promote high cognitive engagement and utilize meaningful contexts, yet most problems found in the literature are procedural and therefore must be altered. ChatGPT seems to be a potential alternative source for creating STEM and ESD tasks, so the authors designed a study to understand how mathematics pre-service teachers modified STEM problems generated by ChatGPT. They found that when PSTs intentionally modified a ChatGPT-generated STEM task, the cognitive demand indeed was higher. However, when PSTs did not intentionally modify the task, the cognitive demand only slightly raised in quality, showing that PSTs may still need to learn how to assess tasks' cognitive demand.

The second paper presented by Stenkilde et al. explored how research bias, particularly gender bias, can be incorporated into mathematics instruction for lower secondary grades. In particular, they attempt to address a pervasive STEM challenge: how to integrate STEM ideas (AI in this case) into Danish mathematics classrooms in such a way that teachers adhere to the mathematics standards they are obligated to teach. To explore such possibilities, they analyzed the content and interviewed the author of one particular research article that explains how to model algorithmic bias, in this case, modeling gender bias in ChatGPT's algorithm. Using the KOM-framework, they investigated the modeling competencies involved in determining algorithmic bias and found that these modeling competencies could indeed be replicated in lower secondary classes, albeit in less sophisticated forms (e.g., since students are not familiar with Python, they would need to calculate gender bias manually). Consequently, Stenkilde et al. concluded that it is possible to integrate AI and computational thinking through modeling competencies in lower secondary schools without taking time away from teaching mathematics standards.

Conclusions

We end this introduction by reflecting on the conversations generated by the paper and poster presentations, sharing the new insights and questions that arose as well as next steps of the Thematic Working Group. First, we articulated the ways in which research in the STEM TWG is distinct from other research at CERME. While science, engineering, and technology serve as contexts for mathematics problems, STEM education research focuses mainly on the *integration* across these four

disciplines. Special attention is given to the role of mathematics in this integration, whether it is merely instrumentally used in the service of the other disciplines or if it can also be developed as the primary content. A focus on the integration or interdisciplinary nature of STEM necessitates collaboration and coordination of practices across disciplines. Second, teaching and learning STEM ideas is new territory for researchers, teachers and students alike. There is very little STEM research to guide teachers who are already charged with designing, implementing and assessing STEM lessons and competencies and no consensus on the best way to design or define STEM learning. STEM researchers have some work to do; creating frameworks for designing STEM lessons, outlining STEM competencies for students and teachers, creating analytic tools to analyse students' STEM learning, determining sound methods for assessing those STEM competencies and providing research-based professional development for teachers is essential.

STEAM Teachers in TEAM shape their professional development at the border of disciplines

Maria Giuseppina Adesso[1], Roberto Capone[2] and Oriana Fiore[3]

This paper presents the idea of the border as a semiotic cross-cultural space to characterize interdisciplinarity in mathematics education exploring the intersections between mathematics and other disciplines, fostering meaningful communication between them. Using artifacts such as springs and networks we have investigated how STEAM teachers, working in team, approach in different manners the solution of a real problem discovering the Fibonacci sequence. We show how is it possible to interpret interdisciplinarity as a comparison between rationalities. Our arguments are framed by De Luca Picione and Valsiner's idea of the border as a metaphor and Habermas's construct of rationality. Results reveal the way the connections between the disciplines emerge and develop at the border.

Keywords: Interdisciplinarity, STEAM Education, border, Fibonacci, semiotic.

Introduction and Rationale

This paper presents the idea of the border as a semiotic cross-cultural space (Capone & Faggiano, 2024) to improve the STEAM teacher's professional development exploring the intersections between Science, Technology, Engineering, and Mathematics, mainly focusing on Mathematics and Physics, fostering meaningful communication between them. The starting point of this study is the premise that interdisciplinary teaching enables educators to integrate the knowledge and perspectives of various disciplines, thereby addressing the challenges of a complex society more effectively (Morin, 2001). However, it is common to argue that mathematics relies on the hypothetical-deductive method, while physics uses the experimental-inductive method, as if the two approaches to knowledge were mutually exclusive. In reality, this sharp distinction has been questioned by Jahnke (1978) and Winter (1983), who argued that the division between 'intuitive' and 'deductive' reasoning is flawed. They asserted that mathematical proof should not be viewed as a departure from observation and measurement but rather as a tool that guides the intelligent exploration of phenomena. Hanna and Jahnke (2002) examined the relationship between physics and mathematical proof by using concepts from physics to model a mathematical problem. Moreover, in recent decades, the role of technology has become essential for improving the teaching and learning of Mathematics and Physics (Artigue, 2010). After all, it is increasingly common to hear that an approach to teaching mathematics through engineering techniques enhances students' skills and stimulates interest in the subject (Pepin et al., 2021). Finally, art can often serve as an engaging tool for effective lessons. To support the previous assertions, an experiment was conducted with approximately 45 Italian STEAM teachers: an interdisciplinary training including Mathematics, Physics, Technology, Engineering, Art, was organized (Capone, 2022). Teachers were involved in the discovering of a Mathematical object,

starting from/including STEAM (mainly Physics labs activities) experiments. The involved teachers have different scientific backgrounds (they are physicists, Mathematicians, Engineers), and each one has its own teaching experience, in different contexts. In what sense is the proposed activity a STEAM activity? This interdisciplinary activity involves Science (S) for the concepts, computation and measurements of resistance, springs, etc.; Technology (T) for the use of the breadboard and the simulation software; Engineering (E) for the hands-on activities of constructing the springs system and the electrical networks using the breadboard; Art (A) is involved for all the connections with golden ratio in art; Mathematics (M) is, of course, used for studying the relationships between physical quantities and the discovery of the golden ratio.

The idea of interdisciplinarity and the metaphor of the border

Referring to Klein's (1990) definition of interdisciplinarity, this text explores disciplinary borders as dynamic, semiotic tools that shape human psychological development. Viewed through a psychological lens, borders facilitate the construction of meaning via classification, categorization, and interpretation, influencing human cognition and behavior. In this semiotic context, borders create a symbolic field where meaning is organized and transformed through cultural processes. De Luca Picione and Valsiner (2022) introduced the Generalized Semiotic Functions of Borders model, which operates along eight dynamic tension continuums. These continuums, with opposing forces, co-define and interact, reflecting the complexity and evolving nature of borders in shaping meaning and development: 1) Distinction: within a homogeneous and undifferentiated field, the border makes a possible difference, thus producing singularities (De Luca Picione & Valsiner, 2017). 2) Differentiation: the border helps to build the sense of identity starting from the difference with otherness. 3) Separation: the border acts ambivalently because it serves to connect and to create a bond. In a homogeneous and undifferentiated field, it is only possible to link something through a preliminary operation of separation. 4) Containment: the border allows for the creation of a frame within which it is possible to give sense and value to experience. This function makes it clear that borders are semiotic operators that generate meaning. 5) Protection: the border always acts as a function of protection, realizing a filter function from environmental/social perturbations. 6) Mediation: the border acts as a structure of mediation against the immediacy of action and reactive forms. 7) Transformation: the border acts as a function of connection, exchange, information, filtering and shock absorption. Borders are liminal zones of transformations, which make it possible to temporarily suspend too rigid distinctions and classifications, allowing fusion, merging, mixing and chaos. 8) Regulation: the operation of regulation makes possible to orient a system and its actions towards the future. In mathematics education, interdisciplinary collaboration relies on borders as semiotic spaces that both separate and connect disciplines. Borders highlight differences between disciplinary cultures while enabling their interaction. To fully understand interdisciplinarity, borders must be enriched with pragmatic and semiotic aspects, framing mathematics education as a mediation between diverse rationalities.

Habermas's construct of rationality

How could we understand and interpret the way the communication between disciplines can take place and how context contributes to construct meaning? In this attempt, we refer to pragmatic

linguistics and, in particular, to Habermas' Communicative rationality. According to Habermas (1981), the adjective rational can be attributed to a person who carries out a discursive activity intending to account for his choices according to criteria of validity. Rationality consists of three interrelated components: epistemic rationality (an opinion is rational when it is possible to justify it in a given context.), teleological rationality (one acts rationally when one acts according to a purpose by implementing intentionally chosen means), and communicative rationality (you aim to make the interlocutor share your communication content by choosing effective means of communication). The purpose of showing the same activity according to different rationalities is to create an understanding between the disciplines. Comparing different points of view leads to affirming all points of view as acts of truth through communicative interaction. Communication is a social action oriented towards understanding, sharing meanings concerning the world between the speakers involved, and sharing a lifeworld. In this paper, the Generalized Semiotic Functions of Borders model is used as a theoretical lens to characterize the border between disciplines. Habermas's construct of rationality is used to understand how interdisciplinarity is achieved through the communicative act that allows us to accept the other's point of view, which becomes part of our knowledge. We posed the following research question: how can the construct of rationality (adapted from linguistic pragmatics) give us a key to understanding educational activities crossing the border between STEAM disciplines?

Participants and Methods

To answer our research question, we have designed and implemented an interdisciplinary teaching activity (Adesso et al., 2024) based on the following principles: allow teachers' work in a fixed disciplinary contest; foster the crossing of disciplinary borders; promote debate between teachers, in circle time and after in plenary, that can be meaningful to connect the different activities and build up to recognize the other's point of view as a possible alternative to one's own point of view and not in opposition to it; recognize that there are different ways to the solution of a problem. The experiment was conducted during a summer training school for teachers, in which 45 participated in an interdisciplinary workshop, titled: 'From the Physical Phenomenon to the Mathematical Model or Vice Versa? Springs, Electrical Networks, and Fibonacci.' The workshop was led by one mathematics education researcher and two physics education researchers. The whole activity lasted four hours in a one-day meeting. The teachers were divided into three groups of seven (Groups 1,2,3) and three groups of eight (Groups 4,5,6), each including mathematicians, physicians, engineers, biologists, etc. The various steps of the lab activities were interspersed with group discussion moments. The research methodology is qualitative conducted with observational-interpretive techniques. The instruments used were the recording of the dialogues of the teachers engaged in the various working groups and a final brainstorming through an interview in which each group reported on their experience. The interview was videotaped. The video and pictures have been selected and coded, so that each group of multimedia files in each step of the activities is associated with a specific semiotic function of borders. Moreover, the dialogues have been organized in order to evidence the three rationalities. Specifically, in the final report each group summarized the role of each teacher in the group itself and how rationality evolved from epistemic to communicative ones. During the observation, the researchers tried to glean what elements emerged during the group activity according to the categorization of boundary processes (Valsiner) and rationales (Habermas). At the end of the

activities, there was a sharing session between the groups: a representative from each group communicated how the work evolved. We provided the teachers with a problem situation, along with worksheets, and each group could organize the activity according to the epistemology they felt closest to.

Activities

The activities have been divided into several steps. Teachers were involved in the equivalent resistance calculation of an infinite two-dimensional electrical network. In this step, they built a system of resistances using a breadboard, electrical resistances of the same value, jumps, and an ohmmeter.

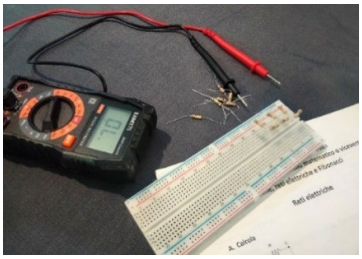

Figure 1: Teachers build an infinitive network of resistance using a breadboard

The teachers built a network using a breadboard in such a way that two resistors in series form an elementary cell, to which resistors are alternately added in parallel and then in series. As they added the resistors, they measured and calculated the equivalent resistance and record the results in a table.

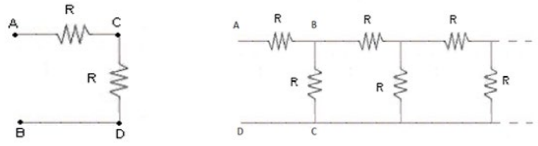

Figure 2: Single cell of an infinitive network of resistance

This experimental activity corresponds to the theoretical framework described below. As shown in figure 2, starting from a single cell of equivalent resistance 2R, adding to this a second elementary cell, we obtain an equivalent resistance equal to 5/3R. Adding cells to the starting one, we obtain the series of equivalent resistances between A and B, for each new added cell: $\frac{13}{8}R; \frac{34}{21}R;\ \frac{89}{55}R$; ... If we now consider the succession consisting of the numerator and denominator elements of these fractions, the numerator occupies the even place and the denominator the odd place: 1,2,3,5,8,13,21,34,55,89,... which we recognize as a Fibonacci succession whose generic term is $a_{2n+1} = a_{2n} + a_{2n-1}$

having denoted n as the number of cells. The equivalent resistance of a network with n cells will be $R_{eq} = \frac{a_{2n}}{a_{2n-1}}R$. For n $\rightarrow \infty$ this ratio tends to the golden number 1.618..., therefore, the equivalent resistance of an infinite one-dimensional network of resistors is: $R_{eq} = 1{,}618\ldots . R$. During the second step, teachers cross from the practice by using electric resistances to that by using the elastic springs, i.e. from the electricity to the mechanics. We still work within the Physics, but at the border

between two of its areas.

Figure 3: Some cells of an infinitive network of springs

Parallel resistor connection corresponds to a series of springs and vice versa, so it is possible to compute the equivalent elasticity constant of a cell of springs (see Fig.3), thus obtaining the following terms: $2K, \frac{5}{3}K, \frac{13}{8}K$ ...

The division between the generic term a_{2n} and the previous term a_{2n-1} is: $K_{eq} = \frac{a_{2n}}{a_{2n-1}} K$. For n $\rightarrow$ ∞ this ratio tends to the golden number 1.618… The teachers built a system of springs with the geometry in Fig.3, using springs with the same spring constant, a dynamometer, and some mechanical rods. Also in this system, the teachers experimentally re-discovered the Fibonacci sequence, thus approximating the gold number, considering a system of springs analog to the system of resistance. At the conclusion of the activity, the connections between the golden number and some artworks from ancient Greece to the Renaissance were highlighted, so as to show students in the classroom an interdisciplinary activity in which, starting with experiments in the Physics lab (S) and using technology (T) to build appropriate artifacts (E), they could discover the presence of Mathematics in art (A) as well.

Discussion and results

The exploration of interdisciplinary collaboration among STEAM teachers in this study sheds light on how the construct of rationality (adapted from linguistic pragmatics) can give us a key to understanding educational activities crossing the border among disciplines. The three rationalities identified by Habermas: epistemic, teleological, and communicative emerged during the activities. Epistemic Rationality was evident when teachers engaged in discussions centered around the nature of knowledge within their respective disciplines. For instance, in the various groups, we noticed how some teachers approached the problem by first solving it numerically. Others approached it by neatly arranging the resistors on the breadboard in series and parallel, measuring the equivalent resistance step by step. In doing so, they worked by applying the specific epistemology and methodological approach of a particular discipline.

Here we show protocols about the video-recorded summary dialogue, held by one teacher per group (named by the number of the group to which they belong).

Teacher 1: In our group, some have worked a lot on the practical part of building the network. Some have calculated the results through physical laws, and someone has started working directly on it from a mathematical point of view.

From the perspective of border processes, three functions emerged: distinction, differentiation, and separation. Moreover, some remained within their disciplinary borders, a sort of comfort zone. In this, we recognized the bordering process called protection. Distinction refers to the initial recognition

and articulation of the unique identity and borders of each discipline. This recognition is critical because it ensures that each discipline retains its core identity and does not become diluted in the collaborative process. For instance, in the experiment described, the mathematics teachers emphasize the abstract, formula-based approach (e.g., Ohm's Law), while the Physics teachers rely on physical experimentation and measurement. A clear distinction between these approaches allows participants to bring valuable, discipline-specific insights to the table. Separation helps ensure that interdisciplinary collaboration does not collapse into a single homogeneous process but respects the differences that make each field valuable. In the context of the STEAM experiment, engineers measure directly, mathematicians calculate, and physicists experiment. By maintaining this separation in the early stages, teachers can approach the problem from their disciplinary strengths, ultimately contributing to the collective understanding. Containment refers to the ability of each discipline to hold and sustain its own knowledge structures, while also interacting with other disciplines. Even as teachers in this experiment engage in cross-disciplinary discussions, each group retains the capacity to function within its own disciplinary framework. The physicists continue experimenting with resistances, while the mathematicians proceed with calculations, both contained within their disciplinary paradigms, yet open to integrating findings from each other. Protection is the safeguarding of disciplinary methodologies and epistemologies during interdisciplinary engagement. It ensures that as different disciplines interact, none is compromised or diminished by the other. In the experiment, protection manifests when, for example, the mathematical rigor of Fibonacci calculations is preserved even as the concepts are applied in physical contexts like resistances and springs. The dialogue protects the methodological rigor of mathematics while enabling its application in physics. During the problem-solving activities that involved the construction of circuits and mechanical systems, teleological rationality became prominent. Teachers discussed the goals of the tasks, the intended outcomes, and the practical steps needed to achieve them. Here, the dialogue shifted to a more action-oriented, goal-directed form of reasoning. Throughout the process, communicative rationality played a crucial role in mediating between the epistemic and teleological aspects. It was through dialogue that teachers were able to negotiate their different rationalities, seeking mutual understanding and consensus. For example, when a disagreement arose about the application of the Fibonacci sequence in a physical context, the teachers engaged in a communicative process to reconcile their differing perspectives, thus allowing the border between Mathematics and Physics to be crossed and redefined (mediated by the use of technologies)

> Teacher 2: We have tried, by comparing ourselves, to put together different approaches so from the mathematical point of view and from the physical point of view and also go to look for that regularity and how to go about finding results in the various approaches also discovering some interesting things in the regularity clearly given by the Fibonacci succession. We have found some difficulties in the measurements depending on the instruments with compared to the precision of the mathematics, but finally we agreed.

The border, as a dynamic space, encompasses several dimensions that are activated through dialogue: differentiation, mediation, and transformation. In the early stages of the dialogues, the borders between disciplines were clearly marked by distinct epistemic rationalities. Each teacher's contributions reflected the unique knowledge structures and methodologies of their discipline, thereby highlighting the differentiation inherent in interdisciplinary collaboration.

Teacher 3: In our group, since there is no physicist, the approach was to start from the abstract, from the formulas that are known to us from Ohm's laws because the formula gave us confidence in proceeding with the calculations; then some began to build, others started from the abstract to get to the concrete. The experiment confirmed the accuracy that we had done the math right.

As the dialogue unfolded, the border became a space of mediation, where the teachers' rationalities intersected. This mediation was not merely about finding common ground but involved a deeper process of negotiating the meanings and applications of concepts across disciplinary lines. For instance, the teachers collectively explored how the Fibonacci sequence could be interpreted both mathematically and physically, using communicative rationality to bridge the epistemic and teleological divides.

Teacher 4: I'm really excited about how the golden ratio came out of our experiments. It wasn't something we had planned, but it was a natural find.

Teacher 5: Agree. This type of interdisciplinary approach is valuable because it allows you to explore and discover in a natural way, without preconceptions. It's a powerful way to teach not only Math, but also the scientific method.

The final dimension, the transformation, occurred as a result of the successful mediation of rationalities. The border was no longer a barrier but a site of transformation where new, integrated forms of knowledge emerged. The teachers' understanding of the Fibonacci sequence, for instance, was transformed as they collectively recontextualized it within the framework of physical systems. This transformation reflects the evolving nature of the border, as it is continuously reshaped by the dialogues that take place within it.

Teacher 6: And it also demonstrates the importance of dialogue between us as teachers. Without this collaboration, we might never have arrived at this discovery.

Regulation refers to the way disciplines negotiate rules, norms, and practices when collaborating across borders. This dimension ensures that interdisciplinary work is structured and guided by mutually agreed-upon frameworks or standards. Regulation helps in managing the interactions between disciplines to avoid confusion or conflict and ensures that the collaborative process remains coherent and productive. During the STEAM activity, regulation occurs in the structured steps of the experiment, such as dividing the teachers into groups and guiding them through the stages of building circuits and discussing their findings. These structured interactions regulate the collaboration, so that all participants follow a shared process while contributing their disciplinary perspectives.

Conclusions

The aim of the workshop was to create a homogeneous and undifferentiated environment aimed at discovering the golden number. Immediately the boundaries between disciplines emerged through the processes of distinction, differentiation and separation. Singularities emerged that made it possible to distinguish the disciplines which appeared differentiated according to the different approach that the teachers adopted. Then it came out how the disciplines, despite the singularities, communicated with each other. The results that emerged from this experimentation can be looked in a twofold aspect: from the point of view of STEAM teaching and STEAM teaching research. From a teaching point of view, the activity can be a stimulus to experiment in class and see if the same border functions emerge. From the point of view of research, we provided a key to interpretation through two theoretical

frameworks in order to characterize what happens at the boundary between disciplines, and to interpret the actions of the teachers during the experimentation. In conclusion, this study provides a framework for understanding interdisciplinarity in STEAM education through the metaphor of the border as a semiotic cross-cultural space. The collaborative processes observed among the participating teachers highlight the potential for professional development that transcends disciplinary borders, fostering a deeper, more integrated understanding of complex phenomena. This research contributes to a more nuanced understanding of how teachers can work together to build their professional development at the borders of their disciplines.

GRAPHICAL reasoning: Students' ways of chunking a logistic function graph representing a titration

Nigar Altindis[1] Kathleen Bowe[2] and Melissa Aikens[2]

The University of Alabama[1], Assistant Professor of Mathematics Education, USA, naltindis@ua.edu

University of New Hampshire[2] , USA

We report students' graphical reasoning approaches to a logistic function graph depicting a titration curve. We conducted semi-structured interviews with 16 students, who were tasked to "explain the relationship between the pH of the solution and the amount of base added" modeled by a logistic function. Retrospective analysis showed several chunking approaches: (1) chunking based on graphical trends (e.g., "linear" (8 out of 16); (2) chunking based on the increasing and decreasing rate of change (4 out of 16); and (3) chunking based on the pH scale (4 out of 16). We discuss students' interpretations of surface-level or intrinsic properties of mathematical concepts or chemical ideas. We conclude with implications to help students move from viewing graphs as disconnected chunks to seeing them as continuous models of scientific phenomena.

Keywords: Graphical interpretation, titration experiment, chunking, reasoning.

Introduction

Representations of mathematical concepts, including symbols, graphs, and tables, are used as tools for communicating and making sense of mathematical ideas (Altindis, 2021;Dreyfus, 2002). Scientific disciplines employ similar representations to model and communicate about the phenomena under consideration. In this work, we focus on graphical representation. Students approach graph interpretation by drawing upon prior knowledge and experience. Their approach depends on familiarity with the context and mathematical properties of the graph, prior experiences related to the graph's context or its shape(s), and their ability to conceptualize and focus on the variables presented on the graph axes. We explore "students' graphical reasoning", which we define as their approach(es) to obtain meaning from a graph; more specifically, the cognitive activities involved in extracting information about represented data, finding trends and relationships in that data, and extrapolating or making inferences based on the data (Curcio, 1987; Glazer, 2011).

Visual chunking

Visual chunking refers to a process of breaking down visual information in representations into meaningful segments or "chunks" to facilitate understanding and interpretation. Visual chunking is predicated on structural regularities, where the patterns or groups are not arbitrary but rather derived from recurrent or significant structural features (Stieff et al., 2020; Talanquer, 2022). This facilitates the compression of substantial quantities of information into manageable chunks, allowing individuals to overcome the restricted capacity of working memory, thereby enhancing

both comprehension and cognitive retention (Thalmann et al., 2019; NRC, 1999). Experts encode meaningful groups of features or patterns in representations as "chunks" which activate relevant concepts or cognitive activities that facilitate interpretation and use of a representation (Carpenter & Shah 1998; Stieff et al., 2020). Frequent exposure to visual representations as part of gaining expertise in a particular domain supports the automatic and tacit recognition and interpretation of visual features (Cartrette & Bodner, 2010; Connor et al., 2021; Domin et al., 2008; Stieff et al., 2020). Novice and inexperienced students, on the other hand, may employ spatial chunking, a strategy that generates chunks by considering the spatial closeness of individual units to one another (Stieff et al., 2020). This approach may or may not correspond to expert chunking, as it may not be informed by appropriate domain knowledge. For novices, first interpretations of representations are often based on the most salient and easily processed features. They may retrieve knowledge based solely on surface similarities or recent experiences or elevate the importance of the most salient features during reasoning (Shah & Oppenheimer, 2008).

Graphical reasoning

Reasoning through a graphical task involves a series of cognitive activities, starting with extraction of information and progressing through construction of a sequence of meanings to generate claims and conclusions (Curcio, 1987; Glazer, 2011; Lithner, 2008; Thompson et al., 2024). Visually chunking the graphical information into smaller, more manageable chunks based on prior knowledge and experiences is a common first step for novices and experts alike (Rodriguez & Jones, 2024; Talanquer, 2022). A viewer may then make a claim about the chunks, either in isolation or as connected chunks, by utilizing whatever scientific or mathematics knowledge they activated. If the supporting arguments are situated into intrinsic properties of math, based on scientific principles, or both, then the argument is likely to be valid, and the reasoning could be classified as productive; if the argument is based on surface-level math, science, or both, then such reasoning is likely unproductive (Lithner, 2008).

Study purpose

We situate this study within the framework of Steffe and Thompson's (2000) definition of "students' mathematics." We employ the term "students' graphical reasoning" to describe the various ways in which students understand, interact with, and reason through graphical representations and the outcomes of these processes. Understanding how students visually chunk graphical representations and then use those chunks to draw conclusions about the represented phenomenon is a critical step in understanding "students' graphical reasoning". Only by recognizing the visual patterns and intuitive, mathematical or scientific ideas that guide students' graphical reasoning approaches can instructors develop strategies to support the development of sophisticated graphical reasoning. This study therefore asks the following: What chunking strategies are employed by STEM students when interpreting a logistic function that illustrates a chemistry titration experiment curve, and how is their interpretation related to intrinsic properties of math or chemical phenomena?

Method

This study is part of a larger study conducted at a research-intensive university in the northeastern United States. Approval was obtained from the university's Institutional Review Board (IRB), and informed consent was secured from all participants. Participants (N=16) were recruited from an introductory biology course for life science majors, an introductory chemistry course for life science and chemistry majors, and an introductory chemistry course for engineering majors. A stratified sampling approach was used: participants were contacted based on their performance (high, middle, low) on a course assignment involving proportional, covariational, and graphical reasoning (not described here). Interview data were collected via hour-long semi-structured interviews at the beginning of the academic year.

Interview Protocol

A semi-structured interview protocol was developed with input from chemistry, mathematics, and biology experts. The data presented relates to one task with a graph depicting a strong acid-strong base titration (Figure 1). Students watched a video of a titration, showing the collection of pH data as a strong base was added to an acid-containing beaker (MrGrodskiChemistry, 2020). Students were asked to describe the relationship between the pH of the solution (y-axis) and the amount of base added (x-axis). The interview was audio and video recorded. This figure was previously published in a related work (Altindis et al., 2024).

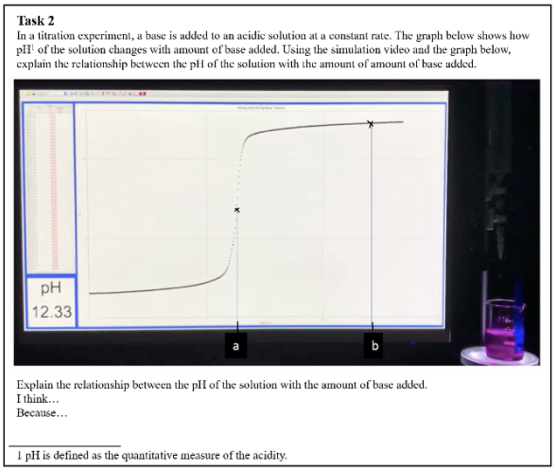

Figure 1: Titration curve task

Method of analysis

Interviews were analyzed for chunking approaches by looking for (1) how students chunked the graph, (2) their connections to underlying mathematical properties (e.g., slope, inflection points, asymptotes), and (3) their ability to construct scientifically grounded interpretations of the titration process, using a constant comparative analytical method (Corbin & Strauss, 2014). In some cases,

the chunking approach was obvious: students chunked and interpreted a specific section of the graph. In other cases, students' approach was buried in their speech and written artifacts.

Results

We identified three chunking strategies employed by students: (1) chunking based on graphical trends, (2) chunking based on the increasing and decreasing rate of change, and (3) chunking based on the pH scale and its logarithmic nature.

Chunking based on graphical trends

In the 'chunking based on graphical trends' approach, students chunked the graph into distinct segments based on observable trends in the graph's behavior. They used trend-focused language, such as describing sections of the graph as showing a "fast increase" when the slope is steep, or a "slow increase" or "flattening" when the line began to level off. Half (n=8 of 16) of the students chunked the graph into three chunks based on graphical trends (similar to Rodriguez & Jones, 2024), including Emma in the following excerpt.

> Emma: ...when the reaction started, it was pretty level and then slowly when things are added, it slowly increases and then at one point it hit a tipping point, spiked up, and then when it hits a certain level, it can't go any higher and then it starts to level out gradually.

Emma describes how the line shows that the reaction starts off steadily, then gradually rises, hits a tipping point where it spikes, and finally levels out. She attempts to justify her observations by relating them to a chemical process, stating "a certain amount of solution was added to really engage in the reaction to cause a sudden spike" which suggested "a huge change happened". While her interpretation is seemingly grounded in the experimental context, it remains at a surface level without delving into chemical entities or mathematical principles.

Students who took this approach to understand the graph often identified the most salient patterns in the line, including the initial gradual increase, a spike, and a final leveling-off. Relying on the most salient features is a common strategy for novices (Rodriguez & Jones, 2024; Talanquer, 2022).

Chunking based on changing rate of change

Four out of 16 students chunked the graph based on changing rate of change. Carson examined the graph through a mathematical lens, specifically focusing on the rate of change and its connection to the steepness of individual segments.

> Carson: ...the pH kind of slowly increased more and more until it got to a certain point. And then it kind of took off and increased a lot... with just a little bit of base and then it topped off and slowed down again. But it kept increasing the whole time that there's base being added. ...it rose with every drop whether it was increasing by a lot or a small amount of pH at a time. ...the amount of change of pH was a lot higher in the section between the tipping point [curve immediately before 'a'] and

when it slowed down compared to how much the pH change between the beginning and the tipping point. The middle section had a much higher rate of change than the beginning.

Carson's statement suggests that the pH displayed distinct patterns in different chunked sections of the graph. He highlights that the rate of pH change was notably more significant between the "tipping point" and where it begins to slow down (i.e. curve after 'a') compared to the pH change between the graph's initial point and that transition. However, Carson's emphasis on mathematics meant he overlooked chemistry-related information conveyed by the graph.

In contrast, Charlie also indicated chunks which differed in the direction and magnitude of the rate of change, but her explanation of the relationship between focused on the chemical process.

Charlie: ...the pH increases slowly until all the acid... or all the H+ ions are neutralized or turned into water and then it increases rapidly until it is very alkaline so the pH is very high…. because from the beginning the pH slowly increases and there are many H+ ions present because of the low pH. ...and then when most of the H+ ions are bound into oxygen or uh, into the water, the pH increases rapidly because the OH- concentration is increasing.

Charlie's initial description of the pH increasing slowly until neutralization, followed by a rapid increase to a high pH, indicates an understanding of key trends. She references the molecular entities represented ("H+ ions", "OH-") and their relative concentrations over the course of the titration, demonstrating an ability to connect the line behavior to the chemical process.

Chunking based on pH scale

Most students approached the pH scale as a series of numerical values without explicitly acknowledging the logarithmic nature of the scale. However, some students, like Kevin, attempted to relate their chunks to logarithmic change.

Kevin: ...as base is added... the solution rises in pH slowly. And then around 'a', abruptly increases possibly because the pH, which is 7.... And then maybe... once it gets past that point it goes a lot quicker because... the pH scale is... I don't know how to describe it. At 7 it's like a base of one, like a ten to the first. And then at 8, it's 10 times that. Then at 9, it's 10 times that again. So it keeps increasing exponentially from 7 to 0 and then from 7 to- I think 14. So I think that's why it has this really slow increase and then an abrupt increase here and then another slow increase.

Kevin seems to understand that the pH scale is nonlinear, and he tries to articulate that this is why the pH initially rises slowly, then more quickly around pH 7, and then slowly again. These words suggest that he understand the concavity of the inflection point. Kevin explains the sharp increase by suggesting that the graph's behavior reflects the exponential nature of the pH scale.

Discussion

This study explored how students reasoned through a logistic function graph depicting a titration curve, demonstrating how students' chunking approaches and connections to mathematical properties and scientific principles relate to their interpretation of a graphically-modeled phenomenon. We observed several chunking approaches, which varied depending on students' prior knowledge of mathematics and/or science. The most common approach involved chunking the graph based on trends (e.g., "linear", "exponential" (8 out of 16)). Students also chunked based on increasing and decreasing rate of change (4 of 16) and on the pH scale (4 of 16).

Students' use of mathematical properties during graphical interpretation varied from *surface-level* to *intrinsic* use. At surface-level, students relied on superficial and possibly inaccurate reasoning, such as misidentifying the logistic function as exponential or failing to recognize critical features like the changing rate of change at the inflection point. All students who chunked the graph based on trends chunked it into three chunks, anchoring their reasoning to graphical shape and employing trend-focused language (similar to Rodriguez & Jones, 2024). Relying on the explicit or salient features may have tacitly reduced cognitive load for these students, but without additional domain knowledge in mathematics (or science), their chunking approach may have limited what relationships they could find (Talanquer, 2022). Similarly, it is not granted that students will notice the (pH) log scale, so they may just focus on numerical values of pH, not recognizing the tenfold change occurring. In contrast, students who used *intrinsic* mathematical properties focused on critical properties of logistic functions, such as slope, inflection points, and asymptotes. They utilized these properties to anchor their reasoning and accurately justify interpretations but may not have connected them to the titration process (e.g. Carson's case).

Students' ability to construct scientifically grounded interpretations of the titration process also varied from *surface-level* to *deep*er use of scientific concepts. A *surface-level* explanation was disconnected from or only loosely tied to the titration phenomenon, such as chunking the graph based on the pH scale. Kevin, for example, conceived that each unit on the pH scale represents a tenfold change, but a tenfold change in what (H^+ ions) was not described. Some students tied the graph *deep*ly to the titration process, seeing behaviors and critical features of the line as representing changing concentrations of molecular entities and key chemical transition points (e.g. inflection point is the chemical equivalence point). For example, Charlie recognized the rapid change in pH represented when all initially present acidic H^+ ions were bound into water as part of the neutralization reaction. Most students' arguments were limited to surface-level use of concepts, demonstrating little integration of the experimental context and graph trends.

Conclusion

The students interviewed in this study came from introductory biology and chemistry, bringing different content knowledge, particularly in mathematics. While chunking makes it easier for students to analyze trends, relationships, or patterns within graphs, students' varied approaches demonstrate that instructors need to consider in what ways students' prior experiences may

influence how they anchor their reasoning: on the intrinsic mathematical properties of the graph, on scientific principles or features of the phenomenon represented on the graph, or on surface-level features. How students chunk may limit what kinds of inferences they can make or conclusions they can draw. A student chunking based on trends, for example, may miss that the rate of change is increasing or decreasing around an inflection point, which could have important mathematical or scientific implications depending on the context. Similarly, chunking based on mathematical properties may enable a student to accurately address tasks within a mathematical framework, but they may struggle to connect their reasoning to the experimental context.

Understanding these differing approaches can guide design of interventions that promote a holistic understanding of graphs, benefitting mathematics and science education. Students failing to move beyond surface-level graphical features or surface-level scientific concepts underscore the need for tasks that go beyond simply identifying shapes or regions of a graph. For students who rely on mathematical reasoning, tasks should include prompts that explicitly connect mathematical properties to chemical concepts. In short, instructors should encourage discussions around how meaningful features of graphs emerge, not only from the mathematical structure but also from the scientific context in which the data is situated.

Primary teachers' understandings of integrated STEM elaborations: Discrepancies between importance and practice

Cory A. Bennett[1] and Wendy Ruchti[1]

[1]Idaho State University, United States; corybennett@isu.edu

The intentional integration of science, technology, engineering and mathematics (STEM) is well understood to support student learning, especially as it relates to developing deeper conceptual learning. However, teachers' understanding of integration, and the ways in which integration can be implemented within the classroom, is not as strong. Building off a previous study (Bennett & Ruchti, 2022), for which an elaboration of Bybee's (2013) nine perspectives of STEM was proposed, this article describes primary teachers' understanding of the four specific and intentional methods in which integration in mathematics and science can be effectively implemented. This mixed methods case study, which included 24 primary teachers, only 10 of whom indicated they had some expertise in mathematics or science content, was conducted in the Intermountain-west of the United States. For the purpose of this paper, findings will focus on one elaboration as it presented a conflict between teachers' beliefs and their instructional values.

Keywords: STEM Education, Integrated Learning, Primary Grades.

Introduction

Supporting teachers in the integration of science, technology, engineering, and mathematics (STEM) in the classroom continues to be an area of much needed attention for several reasons. There continues to be no clear understanding or definition as to what STEM integration means or even what it looks like in practice (Bybee, 2013; Larsen et al., 2022). Given this lack of clarity from the research community, it is perhaps no surprise teachers struggle to effectively implement authentic, integrated STEM learning experiences (Aguilera et al., 2021). This means that in addition to being clear on operationally defining STEM, there is a need to support teachers with understanding the varied instructional approaches to STEM teaching and learning. However, all of this is predicated on teachers valuing varied instructional approaches and understanding how these approaches fit within their individual context. So, while different frameworks for integrating STEM may be valued by the larger research community, these frameworks cannot be studied to understand their effectiveness if teachers do not value them in the same way.

Review of Literature

The research field continues to grapple with a definition for STEM and thus the conceptual frameworks also vary (Roehrig et al. 2021). Although there are multiple models of integration, a common element often centres on the important role mathematics plays in supporting learning in science, either to enhance scientific content knowledge or scientific process understanding (National Research Council, 2011). The significant overlap and alignment of the Science and Engineering Practices, one dimension of the Next Generation Science Standards (NGSS Lead States, 2013), and the Standards of Mathematical Practice (National Governors Association, Center for Best Practices, & Council of Chief State School Officers, 2010) provides an area primed for integration (Bennett &

Ruchti, 2014). In addition, understanding science content often relies on an understanding of mathematics content and yet there are very few opportunities for teachers to participate in integrated STEM-related professional learning, and existing curricula are not currently designed to support teachers' effectively integrating STEM content within their day-to-day routines and instructional spaces (English, 2016). The nature of the integrations, and the scaffolding used, must be explored in more detail in order to support K-12 teachers' implementation of STEM education (Kelly & Knowles, 2016). Likewise, the integrations should be based on an understanding of exceptional pedagogical approaches from each discipline and key learning theories. This includes using integration to develop topics or content in more depth and apply content to real-world situations (NCSM: Leadership in Mathematics Education & National Council of Teachers of Mathematics, 2018). In essence, the integration of STEM content should allow for learning that extends each content area and creates a different kind of understanding.

However, the fluid and flexible nature of integrating disciplines can be challenging for classroom teachers without models of when and how this can be accomplished in the classroom. However, when teachers are able to integrate, and when they utilise a real-world contextualized application, the experience can create deeper connections and more authentic learning for students (Sandall et al., 2018). According to Moore and colleagues (2014), the role of the teacher in integrated STEM learning is to help students learn to see the abstract nuances in the content, including how to decontextualize content, before applying the learning in a variety of ways. Unfortunately, barriers exist for teachers that limit their ability to create these outcomes.

For example, teachers often lack the knowledge and/or equipment to bring integrated STEM to the classroom as well as finding the balance of developing problem-solving skills and teaching science content challenging (Dare et al., 2018). Furthermore, schedules and school structures, along with curriculum alignment, are often inflexible and therefore not conducive to quality integration (Margot & Kettler, 2019). To further complicate matters, mixed messages from experts in the field, colleagues, and school leaders about conceptions of STEM education can cause teachers to reject implementation (Aguilera et al., 2021). Dare and colleagues (2018) noted that the nature of integration, or how teachers perceived their role in making connections between multiple disciplines, was a struggle when attempting to implement integrated STEM in a science classroom. Specifically, teachers struggled to balance addressing each of the STEM disciplines, and how to move between disciplines. This means that missed opportunities for varied forms of integration can occur. In addition, teachers reported difficulty integrating mathematics into their science instruction and felt that their students were unable to do mathematics in their science classrooms; key science skills like computational thinking are often not included in their instruction (Rinke et al., 2016). For many teachers, they are often more comfortable teaching concepts separately or *adding on* to what they already teach as opposed to explicit integration (Crotty et al., 2017). Likewise, teachers often assume students will see the mathematical connections within the intended integrated lesson, rather than being explicit about the mathematics (Larsen et al., 2022); thereby making for more authentic STEM learning.

Theoretical Framework

Though conceptions of integrated STEM abound in the literature and policy documents, (Kelly & Knowles, 2016; Roehrig et al., 2021) most conceptions ultimately do not address the nature of the integrations specific to a teacher's context. That is, current frameworks often focus on broader structural aspects (Vasquez et al., 2013), curricular approaches (Roehrig et al., 2021) or traits that exemplify STEM characteristics such as being inquiry or problem based (Fan et al., 2021), whereas the framework understudy for this project focuses on the instructional techniques and pedagogical practices teachers would employ in the classroom and during the lesson to integrate STEM concepts. This study is based on Bybee's (2013) perspectives for STEM integration but incorporates an elaboration of these perspectives to better support teachers with STEM integration within their context. Specifically, these elaborations focus on four specific methods of integrating mathematics into science including 1) *Simultaneous Infusion*, 2) *Accentuate Interdisciplinary Constructs,* 3) *Temporary Shift in Discipline*, and 4) *Lateral Concept Connections* (Bennett & Ruchti, 2022). *Simultaneous Infusion* is when mathematical and scientific habits of mind and practices, such as the importance of using data and communicating ideas and understandings in STEM, are considered simultaneously during a science lesson. Likewise, *Accentuate Interdisciplinary Constructs* attends to the ways in which specific content understandings or skills from one discipline can be deliberately highlighted to support more purposeful learning. This differs from *Temporary Shift in Discipline*, which is a shift from one discipline (e.g., science) to conceptually explore a skill in another discipline (e.g., mathematics), and then a shift back to the original discipline (science) to bring new understandings to the primary science focus. Lastly, with *Lateral Concept Connections*, the focus of the learning moves from a primary science concept to a new science concept. For a more thorough description of the framework, see Bennett and Ruchti (2022). The purpose of this shift is to give students new content to reinforce a mathematical concept. When considered in light of Margot & Kettler's (2019) position that teachers are catalysts in advancing STEM talent, this study uses a constructivist epistemology to understand participants' perspectives on integrating STEM learning.

Methods

The purpose of this mixed methods case study was to understand how primary teachers understand and value an emerging Integrated STEM Elaborations framework (Bennett & Ruchti, 2022), which is built on Bybee's (2013) broader STEM integration framework. This study surveyed 24 primary teachers to understand the extent to which the four elaborations were: 1) clear to understand, 2) perceived as comfortable to implementation, 3) important for students in learning STEM, 4) instructionally important when integrating STEM content, and 5) valued in relation to the other elaborations. That is, the researchers wanted to better understand how this framework for STEM integration is understood by primary teachers to better support primary teachers with the integration of STEM content and practices. As such, the research question for this project was: How do primary teachers understand and value an emerging STEM integration framework within their context?

Participants

Participants in this study included 24 primary teachers from across one school district located in the Intermountain-west of the United States. Primary teachers were purposefully identified because they

typically teach all content areas to the same group of students, have more flexibility in their day to explore more project-based learning experiences. Of the 24 teachers in this group, ten were teachers in early childhood settings, which includes kindergarten through second grade, and the other 14 were teaching in third through fifth grade classrooms; none listed mathematics or science as a secondary area of expertise. With respect to years teaching, 12 were novice to early career teachers, with nine years of experience or less, and the other 12 had more than 10 years of experience, with seven indicating they had more than 15 years of experience. No demographic information on race, ethnicity, or gender identity were collected.

Data Collection & Analysis

Data collected included an anonymous cross-sectional survey (Creswell & Guetterman, 2019) sent to all primary teachers within the district. Respondents were given approximately one month to respond from when the initial invitation was sent out. The survey included closed-ended Likert-scale questions focusing on their understanding of the Integrated STEM Elaboration framework and open-ended questions seeking clarity on other aspects of STEM integration that should be considered. The Likert-scale items were coded numerically to allow for a descriptive analysis (Creswell & Guetterman, 2019), with less favourable beliefs coded as a 1 and stronger, more favourable beliefs coded as 5. The data were independently analysed by the research team to identify outlying or incongruous responses and to look for common themes within these incongruous responses. This included analysing responses according to specific sub-groups: 1) Number of years teaching, 2) content area emphasis, and 3) in which current grade level they taught. The research team then compared notes and re-categorized themes to appropriately capture the emergent patterns within the data set. Again, emphasis was placed on identifying outliers in the data set in order to develop additional questions for further areas of study; knowing where there are discrepancies, potential misunderstandings, or other outliers allows for more focused follow-up research.

Findings

Although there were common themes between the STEM Integration Constructs, one in particular provided data that seemed incongruous with anticipated results. That is, while the responses for *Temporary Shift in Discipline*, *Simultaneous Infusion*, and *Lateral Concept Connections* were all generally uniform and consistent between sub-groups, the data for *Accentuate Interdisciplinary Constructs* (*AIC*) was somewhat unexpected. Recall, *AIC* attends to the ways in which specific content understandings or skills from one discipline can be deliberately highlighted to support more purposeful learning. This is different from *Temporary Shift in Discipline* because the learning of one content area does not stop entirely; the teacher does not plan for a deliberate change in the content to support the overall learning goals. For example, the science content will be better understood because of conceptual understandings in the mathematics that are used, discussed, and highlighted during the science exploration.

Table 1: Percent of responses for greatest importance for sub-groups

	Simultaneous Infusion	Accentuate Interdisciplinary Constructs	Lateral Concept Connections	Temporary Shift in Discipline
Percentage for greatest importance (n=24)	42%	4%	25%	13%
Responses by sub-groups				
0-9 Years Teaching (n = 13)	29%	4%	8%	4%
10+ Years Teaching (n = 11)	8%	0%	17%	8%
Kindergarten through Second Grade (n = 11)	17%	0%	8%	4%
Third through Fifth Grade (n = 13)	21%	4%	17%	8%
STEM Content Emphasis (n = 10)	13%	4%	21%	13%
Non-STEM Content Emphasis (n = 14)	25%	0%	4%	0%

With respect to teachers' beliefs on which construct was the greatest importance for their context, *Simultaneous Infusion* received the highest percentage of responses across nearly all sub-groups (see Table 1) and *AIC* had the lowest percentage of responses for greatest importance within the teachers' context and there was only one response for *AIC* but this person belongs within three of the sub-groups listed.

Table 2: *Accentuate Interdisciplinary Construct* responses for all participants.

Accentuate Interdisciplinary Constructs	Percent Agree
After reading the description, I understand what it means.	71%
I am comfortable using this approach to integrate STEM learning experiences.	63%
I believe it is important for students to learn how to do this.	83%
I believe it is important is this for effectively integrating STEM learning in the classroom.	83%
Greatest Importance for Integration	4%

Participants were also asked to reflect on the importance of *AIC* for both teaching and learning STEM. That is, participants were asked to determine how important *AIC* was for students as they are learning STEM from an integrated approach and how well they understood the construct and their comfort in using this approach. When considering the data from all participants (see Table 2), and not by sub-groups, teachers indicated they generally understood what the *AIC* what the construct meant, generally believed that *AIC* is important for students to learn but did not strongly believe it was an important approach for integrating content within their context. This aligns with their beliefs about *AIC* as not being of great importance.

Essentially, all the teachers in the sample indicated that *AIC* is relatively important for both teaching and learning STEM in the classroom but only one early career, upper primary, STEM content emphasis teacher believed it was of the greatest importance.

Discussion of Results & Implications

The purpose of this study was to understand how primary teachers understand and value an emerging integrated STEM framework (Bennett & Ruchti, 2022). Participants indicated they understood three of the four elaborations well, that the elaborations were important for both teachers and students, and that the elaborations mattered when integrating STEM content. However, *AIC*, while understood, was not viewed as the greatest importance within their context. *AIC* attends to the ways in which specific content understandings or skills from one discipline can be deliberately highlighted to support more purposeful learning and this level of integration requires substantial content knowledge across disciplines (Schuchardt & Schunn, 2016) as well as a complex pedagogical understanding of how and when to purposefully highlight the cross disciplinary connections (Dare et al., 2018).

Since primary teachers create and deliver learning for multiple content areas, several concerns arise with respect to integration. First, and for many primary teachers, their mathematical content knowledge is underdeveloped (Campbell et al., 2014), which can impede their ability to appropriately accentuate the connections between interdisciplinary constructs. This may be why *AIC* was not viewed as being of great importance; it takes substantially deep content knowledge to implement it well. Likewise, lesson plans are often designed in a linear manner. They begin with an introductory set, an exploration or instructional episode, followed by some closing or summary of the learning. While such approaches are commonplace and often necessary, the complexity of integrated STEM learning with *AIC* is not linear. That is, *AIC* requires teachers to move fluidly between concepts as they arise. This kind of dynamic instruction is reminiscent of Smith and Stein's (2018) approach to facilitating mathematical discourse, wherein deliberate and purposeful planning allows teachers to skillfully improvise when important ideas and connections emerge. Furthermore, many teachers believe low-level skills and procedures should be taught before more complex, problem-based learning can be explored (NCTM, 2014). So even if an instructionally ripe moment occurs for which *AIC* might be ideal, a limiting belief that students "are not ready" for the learning prevents even the consideration for using *AIC*. So even if teachers have strong content knowledge and are open to more fluid lesson planning and delivery, their beliefs may limit *AIC* type integrations.

Understanding the importance of each construct, and teachers' beliefs on which are greater importance, may be influenced on how they define STEM (Larsen et al., 2022). For those who believe that integrated STEM learning is more aligned with *Simultaneous Infusion*, wherein the learning goals and outcomes of both content areas are well aligned, then other constructs may not seem as important within a classroom despite the authenticity and organic nature of the learning.

Limitations

A primary limitation in this study revolves around the fact that it included only one school district with only 24 participating teachers from this school district. It is possible that these 24 teachers are a non-representative sample, and some results may seem speculative. As such, this reduces the richness

of the data and thus the interpretations that can be made, and especially in different contexts, despite promising findings for future research.

STEM teachers' meanings of inquiry in STEM teaching, in the context of a Professional Development Programme

Katerina Bogiatzi, Nikolaos Metaxas, Chrissavgi Triantafillou and Despina Potari

National and Kapodistrian University of Athens, Mathematics Department, Athens, Greece

kbogiatz@math.uoa.gr

This study explores the meanings of inquiry STEM teaching that a group of 6 mathematics teachers and 2 science teachers working with teacher educators develop while participating in a professional development (PD) program aiming to support the design and enactment of an Inquiry STEM approach. We used grounded theory approaches to identify participants' meanings of inquiry STEM teaching and then the theoretical constructs of dialogical moves to provide further evidence of the meanings that the participants developed and of the process of this development. Our results indicate different emerging meanings of inquiry STEM teaching related to epistemological and didactical dimensions. The employment of the dialogical moves made by the participants enrich our understanding of how the above meanings may be constructed in a PD context.

Keywords: Inquiry STEM teaching, mathematics teachers' meanings, dialogical moves

Introduction

The meaning of inquiry in STEM (Science, Technology, Engineering and Mathematics) teaching is not well defined as there are differences between inquiry in science, mathematics, technology or engineering (Triantafillou et al., 2021). For example, inquiry in science teaching is related to experimentation, description of methods and processes that scientists use, set of specific cognitive abilities that students might develop, and means of developing the abilities of inquiry and understanding scientific concepts and principles (Bybee, 2006). Inquiry in mathematics teaching emphasises the process of questioning, hypothesising, identifying patterns, generalising, conjecturing, justifying and deducing conclusions and it develops in a classroom community that promotes mathematical communication among the students and the teacher (Artigue & Blomhøj, 2013; Goos, 2004). Thus, an integrated teaching approach to STEM requires connections among these different dimensions of inquiry that have been identified in the separate subjects' teaching (Goos et al., 2023). This is a demanding process for the teachers and the teacher educators since both need to cross boundaries among these practices (Bakogianni et al., 2021). Investigating teachers' meanings about inquiry STEM teaching and the process of developing them in a PD setting is essential for supporting teachers to enact STEM teaching approaches in their classroom. However, research in this area is rather limited. We try to address this gap by investigating the meanings of inquiry STEM teaching and learning that a group of teachers working with teacher educators develop while participating in an international workshop series of PD aiming to support the design and enactment of tasks and lessons that adopt an Inquiry STEM approach. We address the following research questions: RQ1: What are STEM teachers' meanings of inquiry in STEM teaching? RQ2: How do the meanings develop in a dialogical PD context?

Theoretical background and literature review

Inquiry-Based Teaching and Learning Approach is considered as an approach for improving teaching and learning in STEM disciplines. In their study Bell et al. (2010) identified nine main science inquiry processes in collaborative learning environments that could be used in STEM disciplines, namely: orienting and asking questions; generating hypotheses; planning; investigating; analysing and interpreting; exploring and creating models; evaluating and concluding; communicating; and predicting. The issue of collaborative inquiry learning is supported by researchers in mathematics education as well (Goos, 2004). Meanings of inquiry STEM teaching are related to the use of authentic resources and tools; making links with out-of-school activities; the development of problem-solving abilities and inquiry habits of mind; the autonomy and responsibility given to students, from the formulation of the questions to the production and validation of their answers; the use of tasks related to socio-scientific issues; and the use of technological tools (Artigue & Blomhøj, 2013). In a PD setting, as the teachers engage in discussions regarding inquiry STEM teaching, they participate in a social, verbal, and rational activity in which they may support, refute, or question arguments, share information, inquiry, clarify or negotiate meanings. The analysis of the process and the product of teachers' argumentation could assist us in understanding their construction of a shared meaning. We employ Martins and Macagno (2022)'s framework which considers arguments as elements of extended dialogues—and as dialogical units. Thus, analysing the turns of the dialogue and especially their contribution to the joint construction of common knowledge and meaning, we could draw some inferences regarding the effect of the dialogue in the shared meaning of a group of STEM teachers. In our study, we focus on teachers' dialogical and metadialogical moves, their relevance and their contribution to the construction of knowledge. The dialogical moves that we considered in this paper are: *dialogical inquiry move, dialogical persuasive move and meta-dialogical clarification and consensus moves*. The dialogical inquiry move aims to investigate the validity of hypotheses from evidence or request their investigation. The dialogical persuasive move aims to convince the other of the validity of an idea or request that this be done or resolve a conflict of ideas in order to analyse each idea or request that the conflict be resolved. The meta-dialogical clarification move, which aims to clarify the meaning of the purpose of other moves, or seek clarification of this meaning; Meta-Dialogical Move clarifies the meaning of an idea, which aims to clarify the meaning of an idea present in other moves, or seek clarification of that meaning; and Meta-Dialogical consensus Move, which aims to express the sharing of the same idea or ensure that this happens (Martins & Macagno, 2022). Regarding the relevance criterion, we adopt the three dimensions of Macagno (2022): dialogical dimension (there is relevance when speaker's intention is compatible with the current dialogue or dialogical setting, semantic dimension (there is relevance when the moves address the same topic and a common-ground dimension (there is relevance when the moves are understood by the interlocutor, and the relationship between a move and the goal that it is intended to achieve need to be grasped by the latter.

Methodology

This study was motivated during an International STEM workshop series for the PD on STEM of teachers coming from 13 European countries (https://icse.eu/icse-academy/). The focus of this workshop series was bringing participants up to date in research and teaching in the STEM subjects in connection with European priorities such as fostering sustainability, digital skills and intercultural learning. The teachers attending the modules were involved in plenary lectures; working groups; whole group discussion as well as in short homework assignments. The workshop series were held online, once a week for two hours in two PD cycles of about a semester each. The 1st workshop series workshops were attended by eight Greek teachers (six mathematics, one physics and one biology teacher), six mathematics teacher educators and one science teacher educator. Additionally, to the workshop series, five national reflective meetings were organised, once a month lasting about two hours, where STEM teachers presented their assignments, discussed their experiences and received feedback from all the participants. In this paper, we analyse the data of these national (Greek) five meetings of the 1st PD cycle. The data are transcribed discussions from those meetings. Using grounded theory techniques, we first analysed the transcripts line by line to identify teachers' meanings of inquiry STEM teaching. These meanings were coded, and the categories are reported below in Table 1. In the next phase of our analysis, we used the theoretical constructs of dialogical moves (Martins & Macagno, 2022) and arguments presented in the previous section to provide further evidence of the meanings that the participants developed and of the process of this development.

Findings

Emerging meanings of STEM inquiry teaching

In table 1, we summarise the emerging meanings of inquiry STEM teaching. Although the meanings are presented as separate categories, their epistemological and didactical dimensions are interwoven. In the table, we present the categories of the meanings, a detailed description and an illustrative example from the data. The epistemological characteristic of the meaning consists of the difference in the focus of inquiry (mathematical or/ and scientific) teachers give to the tasks, even the ready-made ones. There were significant difficulties to integrate mathematics along with the scientific aspect of the problems STEM inquiry needs. Some teachers first thought the openness of the problem could miss their mathematical learning goal: *"I don't know what mathematics is involved here, in which grade should I give it? »*, or in some other cases the mathematics were absent or sidelined because of the rich science context. We see that sometimes they agree about the context but the management of the task in the classroom and the digital tools provided discourage the teacher from implementing inquiry-based tasks: *"I don't see the point of giving them this arduino which is difficult to manage and time consuming, aren't there any other applications in order to measure such visual stimulus?".* Another big category of meanings are characterised as didactical because they address management issues that concern the teachers, such as the active engagement of the students, their work in teams and also the communication in the classroom.

Table 1: Emerging meanings of STEM teaching

Categories	Emerging Meaning	Description	Example
Epistemol ogical: Focus on inquiry	Mathematical inquiry is dominant while scientific inquiry is neglected.	The socio-scientific context is in the background while the mathematical inquiry comes in the foreground.	*"The emphasis in this task is on mathematics. The scientific phenomenon is rather neglected here although it has too many factors when you come to study it using Biology".* (biology teacher)
	Scientific inquiry is central while mathematical activity is trivial.	Emphasis is given on the exploration of the scientific aspect while the engagement with mathematics is poor.	*"The problem with the water consumption in a Greek island seems to me more inquiry based because it has nothing that betrays pure mathematics …"* (math teacher)
	Scientific and mathematical inquiry are integrated	Inquiry in science and in mathematics are parallel	*"I want the students to collect real data, do an experiment, I want them to start asking scientific questions. The mathematics involved is clearly statistics"* (math teacher)
Epistemol ogical: Focus on Technolog ical dimension / tools	Digital tools as means for supporting students' engagement and/or as a way to develop computational thinking	The technological dimension is restricted to the use of a digital tool for mathematical inquiry or links to mathematics through programming and computational thinking.	*"I could use an escape room just once a year in order to get the students interested"* (mathematics teacher) / *"I would prefer students to be involved in technology through programming not if only the teacher makes something more interactive through the technology …"* (math teacher)
Didactical: Focus on students' engageme nt	Students' active engagement in scientific/ technological and mathematical inquiry	The students themselves engage in scientific and/or mathematical inquiry by posing questions, using tools, forming hypotheses, justifying them and coming to conclusions.	*"We want the students to see a video about simple dance figures and after that they try to connect their moves to the notion of an angle and its possible values exploring many possibilities…"*(math teacher)

	Promoting Classroom communication	The students share their ideas in groups or in the whole classroom.	*"…the children should be in groups, discuss and negotiate so they can come to common proposals between the groups...and communicate it then in the classroom"* (physics teacher)
Focus on lesson design	The starting point for the lesson design follows different paths.	The starting point in the design of the lesson is the socio scientific phenomenon while the mathematical inquiry does not necessarily fit to a specific curriculum content or its the other way around	*"Here we see that you started with the maths and the notion of the corner and maybe then you saw the link to the video and put that rich content, in the contrast the other team started with the rich content and then they said we can have that and the other…"* (teacher educator) / *"I've never designed anything in the STEM context before nor something outside of the strictly mathematical framework… but for me the mathematical learning goal is very important to be seen in advance…"* (math teacher)

Although the teachers agreed that the students should engage in investigating the scientific/technological situation and set the parameters of the problem, they see difficulties in implementation. There were moments when they tried to combine science and mathematics, indicating tensions in classroom management, time limit, lack of experience handling the scientific situation along with unexpected answers from the students. Tensions also emerged when they could not see the integrated dimension of the inquiry needed to have successful inquiry in both mathematics and science. The mathematical learning goal is very strong along with the connection to the curriculum particularly in Greece, so sometimes the starting point is mathematics and not the social or the environmental phenomenon: *"I prefer the second problem because I think that in the context of mathematics it is important for students to read graphs and draw conclusions from them…"* (mathematics teacher).

The development of meaning through the dialogue

The two episodes presented below are related to the two tasks that represent aspects of the socio-scientific issue of global warming, the *Beach showers* and the *Global air temperature anomalies*. The two tasks differ in respect to their inquiry characteristics. The Beach showers task requires students to use data coming from official statistics in order to estimate the amount of fresh water consumed at the peak of the summer season in the open-air showers in specific Greek islands. In the Global air temperature anomalies task the data have already been elaborated and there is a graph that models the global temperature changes from 1840 to 2020. We try to illustrate the development of shared

meanings through the use of the dialogical moves. R, V, M are mathematics teachers while S and A are mathematics teacher educators.

S: We present to the children who are actually struggling to learn mathematics, extremely complex problems of the world and we expect them to be interested... I can see how in this way we educate them but I don't see how they would be interested in it and I wonder what the interest has to do with the familiarity. … where the mathematics is not visible, and the interest is not visible. They are far-off problems... can a 15-16 years old student handle them? The colleagues who work on them maybe could explain to us, and my second question is about inquiry as we see it here, it's like saying look for it, but is that it? It's more than that …

V: The two problems have an essential difference, the first problem with the showers puts the students on a quest, it doesn't tell them how to calculate, to start a discussion how long everyone lets the water run, the second problem is much more for the students to comment on a problem in which a specific strategy has been set, in the first they have to make their own and in the second they have to comment on the one that was followed if it was suitable to highlight the problem. They are not made to be solved at home because the students must discuss with each other, for example I gave the problem why the cola can is the size it is, as a homework, it brought me some excellent answers with maximisation and minimization….

In the above excerpt, S makes initially a metadialogical move, where he seeks to clarify the content and scope of an inquiry task for students. Thus, he shifts the focus of the dialogue from a mathematical meaning (related to the mathematics specifics of the particular tasks) to a re-evaluation of the general purpose of inquiry tasks for teaching, which relates to the didactical meaning. Then, he couples his move with a discovery move as he requests for an explanation (*…can a 15-16 years old student handle them? The colleagues who work on them maybe could explain to us…*) of the seemingly lack of interest on the part of students and the role of inquiry. His argument is source dependent (argumentation scheme: from position to know) based on experience that seems part of a common commitment store. In this sense he contributes to the common ground of the dialogue as his moves and the relationship between them and the goal can be understood by the interlocutors who share similar experiences. The shift to a different interpretation regarding the meaning of inquiry tasks is reflected in the next interlocutor (V) who, staying on the same line of thought, examines the inquiry characteristics of the two tasks. He is making a (meta)dialogical move to clarify the meaning of the objective of S's move which is supported by an argument (argument from illustration) that employs an illustration of his claim (*for example I gave the problem…).* Since he expands on S's utterance both in semantic and dialogical terms, V's response is characterised as dialogically relevant and contributes to the shared knowledge through an argument based on personal experience. The above interaction and the shift of meanings to a more detailed and teaching-oriented employment of the term inquiry, brings out the potential of language as a means for the common construction of meaning. Nevertheless, the different epistemological meaning that was brought into the foreground in the above shift, wasn't followed up by subsequent moves as they weren't semantically relevant to the themes raised by S. That is the learning potential of S's move was not fully exploited apart from V, since the teachers in the following parts of the dialogue turned again to more practical, didactically driven aspects of STEM teaching (making another shift of meanings).

M: In the task you presented, you had already searched for a lot of data that it would be better if the students had searched themselves to find, … I think you mentioned that we are getting data 30 years back, why do we go back 30 years? How … could be sure that the old data are comparable to the current since our present-day instruments' precision is higher than the old instruments had. Why shouldn't someone argue that if we had the same instruments these data could show that there is no global warming, …

A: where do you see that there is no global warming?

M: I say I don't see this question articulated or answered, if we don't learn to face these questions we lose a big element, the development of critical thinking.

Initially teacher's conversations up to M's intervention was mainly about more practical issues as time management and the curriculum topics concerned so they were too specific to promote learning in STEM. In the part of the dialogue prior to the above excerpt, there was an absence of pedagogically driven questions about 'why' preferring a certain task or approach over some other. In the above excerpt, M questions the scientific base of a task through a dialogical inquiry move as he calls for the investigation of the validity of the hypothesis that the measurements can be reliably compared. In dialogical terms, we note a shift on the semantic dimension of the dialogue as he focuses on the scientific validity of the data employed in the task. M introduces a new, scientific-driven meaning, that changes the common ground of the dialogue, as he disputes the scientific component of the task. Then (answering A's question) he makes a dialogical persuasive move which adds another parameter on the semantic dimension of dialogic relevance, which is student related. By focusing on the inquiry as a student's possible mode of thinking, he contributes to the goal of the dialogue by meeting the communicative purpose of the notion of inquiry in teaching. His two moves exhibit an integrated view of scientific and mathematical inquiry (epistemological meaning) and help bring a more general view of didactical meaning relating to the active engagement of students in developing inquiry reasoning. So, this move contributes to the construction of new didactical meaning regarding the inquiry component of a STEM task which is followed up by the next utterances of the dialogue, where interlocutors debate on that particular aspect of STEM tasks.

Discussion and concluding remarks

Our findings reveal multiple emerging interpretations of inquiry-based STEM teaching, shaped by both epistemological and pedagogical dimensions. These align with Goos et al. (2023), who highlight the importance of maintaining the disciplinary integrity of mathematics while embracing an integrated STEM approach. The presence of various dialogical and metadialogical shifts, along with diverse forms of argumentation and explanation, reflects the co-existence and evolution of these interpretations as teachers worked toward shared understanding. Collaborative reflection and the exchange of teaching practices—especially among teachers from different disciplines—supported this meaning-making process, as suggested by Hadar & Brody (2016). Disciplinary backgrounds sometimes led to differing perspectives, particularly in how knowledge is introduced, echoing findings from previous research on epistemological differences. Our analysis further shows that using a framework focused on dialogical context and moves can enhance our understanding of how meaning is collaboratively constructed.

Exploring computational thinking in STEM education: Moonbase activity

Elçin Erbasan[1] and Mine Işıksal Bostan[1]

[1]Middle East Technical University, Faculty of Education, Ankara, Türkiye; erbasan@metu.edu.tr

This paper describes a single-case study exploring the evidence of 5th-grade student's computational thinking skills while participating in a STEM activity. This STEM activity called the Moonbase was developed by LEGO® Education and requires using the WeDo 2.0 Core Set to design a robot that can move on the moon's surface. The participant student programmed the robot to collect modules while using both STEM-related knowledge and computational thinking. Data was collected in a three-hour implementation through semi-structured interview and observation. Qualitatively analyzed data reveal that computational thinking skills emerge when using the Moonbase STEM activity. Specifically, debugging, decomposition, and pattern recognition components are the pieces of evidence of computational thinking.

Keywords: STEM education, computational thinking, moonbase activity, LEGO education, WeDo 2.0 core set

Computational thinking and STEM education

In the 21st century, where information and technology are rapidly produced, changed, and consumed, the expectations of societies from individuals have also changed with the concern of keeping in step with the times. This concern has made it necessary for individuals to have different skills to respond to changing world conditions. These skills are identified as 21st-century skills, including problem-solving, critical thinking, analytical thinking, creativity, collaboration, communication, productivity, flexibility, being open to new ideas, and using technology effectively (Partnership for 21st Century Learning [P21], 2019). In addition to these skills, being an empowered learner, digital citizen, knowledge constructor, innovative designer, creative communicator, global collaborator, and computational thinker are seen as characteristics and standards for students to prepare them for the evolving world by The International Society for Technology in Education (ISTE) (2017). In a similar vein, computational thinking is one of the ten key skills demanded by employers as job skills in the 2020s (Institute for the Future [IFTF], 2011). In this context, numerous institutions and organizations have emphasized the concept of computational thinking as one of the high-level thinking skills needed in the 21st century in recent years (Çetin & Toluk-Uçar, 2020). By promoting computational thinking, which is an essential way of problem-solving, many 21st-century skills, such as critical thinking, creativity, and communication, can be covered in schools (Ding & Cai, 2023).

The concept of computational thinking, on which field experts could not reach a consensus in terms of definition, scope, and assessment (Grover & Pea, 2013; Kalelioğlu et al., 2016; Weintrop et al., 2016), seems to be open to interpretation (Barr & Stephenson, 2011) since it can be related to many different disciplines such as mathematics, science, computer science, and engineering (Li et al., 2020).

There is a reciprocal relationship between STEM education and computational thinking. STEM education provides a context and setting where students can use their computational thinking skills to solve real-life problems. Computational thinking supports the development of problem-solving skills needed in STEM education. By integrating these two concepts, teachers can prepare their students for their future life by equipping them with the 21st century skills, and offer real-life related learning activities that foster both mathematical and computational thinking (Weintrop et al., 2016)

Considering the components and competencies of computational thinking as well as its characteristics, they were identified by many researchers (Aho, 2012; Barr & Stephenson, 2011; Brennan & Resnick, 2012; Grover & Pea, 2013). Although there is no consensus on its components like its definition since the researchers formulated their understanding of computational thinking by using the existing definitions and related literature (Ch'ng et al., 2019), the most common components covered by computational thinking are decomposition, pattern recognition, algorithmic thinking, abstraction, making generalizations, debugging, and problem-solving (Grover & Pea, 2013; Kalelioğlu et al., 2016; Rose et al., 2017). Based on the studies mentioned earlier, the explanations of each common component are given in the following Table 1.

Table 1: Components of computational thinking

Component	Explanation
Decomposition	Breaking data, problems, or processes into smaller, more manageable, and more understandable parts
Pattern recognition	Identifying patterns, trends, and similarities in data, problems, or processes
Algorithmic thinking	Constructing a step-by-step procedure, including an ordered set of instructions, for solving similar problems
Abstraction	Making data, problems, or processes more understandable by identifying main ideas and reducing unnecessary information
Making generalizations	Creating rules, models, or principles of observed patterns to adapt solutions to other data, problems, or processes
Debugging	Determining the issues and problems in thinking, operations, or activities to fix them
Problem-solving	Identifying the problem and generating alternatives to solve the problem as the final step of logical thinking

In this context, the aim of the study is to reveal the computational thinking-related evidence that can be included in a STEM activity and thus understand the relationship between these two concepts. For this aim, the research question of the study is "What kind of computational thinking-related evidence emerges during a middle school student's engagement in a STEM activity?"

Method

This research was designed as a single case study, one of the qualitative research approaches. In a single case study, the focus is on an in-depth examination of an issue, concern, or individual in a bounded system (Creswell & Poth, 2018). Only one student participated in this research. So, the case of the current study is one 5th-grade male student studying in a public school in Ankara, Türkiye. The participant was selected through convenience sampling, as the student was readily accessible and willing to participate in the study. This approach allowed for in-depth exploration of a single case and efficient data collection within the time constraints of the research. Since the data was collected during the 2024 summer break, the student has finished 5th grade and is about to start 6th grade.

In data collection, Moonbase Activity developed by LEGO® Education was implemented to explore how computational thinking emerged in a STEM education context. Since this activity emphasizes a problem-solving approach where students build and program a robotic model, it stands out from other STEM-related resources due to its unique combination of computational thinking and hands-on learning integration. This dual focus makes it an ideal choice for investigating the relationship between STEM education and computational thinking. The participant student has experience in building models with the LEGO® sets, but he stated that this is the first time he has used the LEGO® Education set. The student tried to design a solution for a robot that set up a base on the moon by using the WeDo 2.0 Core Set. In this STEM activity, the aim is to build a robot that can move on the moon's surface, program it by using the programming blocks (PB), and collect small modules on the moon to make astronauts' tasks easier in space.

In a face-to-face environment on a volunteer basis, by closely observing the student's interaction with the activity for three hours, data were collected. Before implementing the Moonbase activity as the second session, the researcher met with the participant for three hours to introduce the materials in the set and the WeDo 2.0 programming tool. In this first session, the Cooling Fan activity developed by LEGO® Education was implemented to ensure that the participant became familiar with the set. Also, an activity called Rhythmic Counting Machine, created by the researcher, was implemented in the first session to understand and observe the participant's computational thinking skills.

Data were collected by discussing the programming process of the robot with the student, asking questions related to his PB, thinking processes, and solutions, and observing his reactions to robot movements. The questions posed by the first researcher to the participant were related to his first thoughts about PB to move the robot, his thoughts about the robot's movement after trying the PB, the whole implementation process, the relationship between the implementation and the mathematics concepts, and learning, and his reflective interpretations about the activity.

While collecting data, these two sessions were audio and video recorded. The student was encouraged to think aloud to discover what he did and why he did it during the whole process. After collecting data, the recordings were transcribed and analyzed by using the content analysis method and open coding. In this process, the data were systematically reviewed to identify recurring categories related to computational thinking skills exhibited during the activity. Codes were generated inductively based on the observed moves on the programming tool and the responses of the participant. Following this, content analysis was employed to group these codes into broader categories, focusing on evidence of debugging, decomposition, and pattern recognition. This approach allowed for a detailed examination of the participant's engagement and facilitated the interpretation of computational thinking processes in the context of the activity. The authors coded the transcribed data separately and then compared their coding by reviewing in case of disagreements. The discussions continued until a full consensus was reached.

Findings

The findings demonstrated that debugging, decomposition, and pattern recognition components emerged as pieces of evidence of computational thinking while implementing STEM activity with a middle school student. Some of the examples related to evidence of debugging and decomposition

are given in this paper. However, evidence of pattern recognition, along with more examples of each component, could not be included due to page limitation.

Evidence of debugging

After building the robot model and creating the PB by following the building and programming instructions, the student was asked how he expected the robot to move according to the PB by showing the robot's movement with his hand before starting the program.

Researcher:	Now let's talk before sending the program. What do the programming blocks say? I could read it as a sentence.
Student:	Start the robot.
Researcher:	Okay. Start the motor.
Student:	Start the motor. Go this way, go this way at a speed of 4 for 2 seconds. Still, at a speed of 4, go this way for 2 seconds. (He showed the robot's movement with his hand by turning the robot first to the left and then to the right.)
Researcher:	Okay, now, it says go this way, for example, do you understand it to go this way? (The researcher asked to turn the robot directly to the left where it was standing.) How do you expect the robot to go with this program?
Student:	The robot will come here. Turn this way (left). It will come for 2 seconds at speed 4. Then it will turn this way (right). It will come this way for 2 seconds.
Researcher:	Okay, go ahead. You can send the program.

When the PB were sent to the robot, the robot first went straight and then turned left. Since the robot did not move as expected, the student sent the same PB and tried to understand what happened by observing the robot's movement. While he was trying, it was suggested to pay attention to which part provided the movement and to observe the movement of the wheels.

Researcher:	I wonder if there is something in the programming blocks or in the model? There seems to be an error.
Student:	Maybe there is in the programming blocks.
Researcher:	Are you saying that? But the WeDo app told us the programming blocks. Now there may be errors in three things. First is the model. We did not make the model anyway; the app did. Then, there may be errors in the programming blocks, but the app gave the programming blocks. We also had an expectation. It would go like this, right? (By showing his expectation of the robot's movement.)
Student:	I think our expectation is wrong.
Researcher:	Is our expectation wrong? Where do you think we might have made a mistake in our expectations?

He observed the movement of the robot and the PB at the same time. Following several observations, he realized that the rotating mechanism was a part attached to the motor rather than the wheels, as he expected. After determining the issues in the discrepancy between the expectation and the robots' movement, he fixed his thinking and started to write PB by considering the movement of the wheels connected to the motor. Then, moving the robot by making a U-turn task was given to challenge him, and another piece of evidence related to the debugging component was revealed.

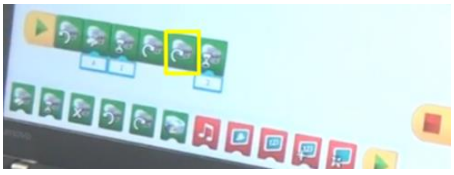

Figure 1: First changes in the programming blocks for making the U-turn

Researcher: If it turned directly towards me and not towards you, that is, made a U-turn, how would you do that?

Student: To do this, you need that programming block. (He added the highlighted programming block called "motor that way block" that demonstrated in Figure 1. Then he sent programming blocks to the robot and the robot moved in the same way, namely going straight and then turning left.)

Student: It did not work. We need to change this second (He changed the number input block under the motor on for block. As shown in Figure 1, the last programming block included 2 was changed to 5.) Now it will come back to you. There is no need for this anymore. (He deleted the added later and highlighted the turning block.)

Researcher: Okay.

Student: I started it. It will make a U-turn, get back to you. (When the program started, the robot made a U-turn by turning too much.) … It turned out a lot. It is necessary to write 4 rather than 5. (He changed the number input block to 4.)

Researcher: How did you decide it should be 4?

Student: Because it had to turn here. (He showed with his hand that the robot made a proper U-turn) But it turned a quarter more (He showed with his hand that the robot made a proper U-turn, and continued to turn for a while.) So, I need to make 4 to complete it.

The U-turn task enabled the student to determine his mistakes by trial and error and to fix the operation by using appropriate PB. This is evidence of the debugging component of the student's computational thinking skill in the activity, which requires reaching the moonbase modules.

Evidence of decomposition

Since the Moonbase Activity is a guided activity in the WeDo 2.0 programming tool, the app also gives the order of PB for how the robot will move after building the model. These ready PB made the robot move straight and then turn left as demonstrated in Figure 1. This means that the robot can collect the first module. After working on these ready PB, a new programming page was opened. The first module and the robot are aligned, and the second module is placed in such a way that it can be retrieved by turning left after picking up the first module. A new task was given, which was to collect the first module and then the second module. In this new task, the student broke the process into three parts: (i) going straight to collect the first module, (ii) turning left to reach the second module, and (iii) going straight to collect the second module. This decomposition process to make data more manageable is shown in Figure 2 by using screenshots.

Figure 2: The process of collecting two modules

He stated that the robot goes straight and turns left in the current program. So, he needed to "add something to the end of the first program." Then he added a motor power block with number input 4 and a motor on block with number input 2 at the end of the current program. However, this addition did not provide the necessary movement to get the second module, and the robot made a U-turn. He made changes in the PB and tried all programs to fix this issue.

In order for the student to realize the problem and solve it as evidence of the debugging component, the researcher asked him the following question: “I want to wash my hands. What steps should I follow?” While giving an ordered set of instructions for hand washing, he realized the importance of constructing a step-by-step procedure for reaching the second module. Then he revised the program by adding the programming block that included the change of direction of movement of the part connected to the motor to collect the second module. When he ran the program, he got the second module and stated that thinking about each step one by one made it easier to do the whole task by breaking it down into pieces.

Similar to the previous task, the next task was given by adding a third module aligning the second one as shown in Figure 3. The student preferred to work with a more understandable PB by dividing the task into smaller parts. He constructed a step-by-step procedure by considering the robot’s path to collect all modules in order. So, this new task provided pieces of evidence for the components of computational thinking used in the STEM activity as decomposition and algorithmic thinking.

Figure 3: The placement of the three modules and the robot that will collect them

Discussion

Many research studies have pointed out the strong relationship between computational thinking and STEM education (Hsu et al., 2018; Li et al., 2020; Swaid, 2015). Computational thinking-related and STEM education-related concepts can be implemented at all grade levels to enhance clearer understanding across STEM disciplines and develop related skills (Romainor et al., 2018). According to the content analysis study conducted by Kılıç (2022), STEM education can be used as an approach to develop students’ computational thinking skills. For example, Chiang et al. (2022) implemented an online STEM camp for primary school students, and they stated that STEM integration with an emphasis on medicinal knowledge and using educational robotics has the potential to improve students’ computational thinking skills. Similarly, Psycharis and Kotzampasaki (2019) introduced the concept of computational STEM pedagogy and investigated whether the STEM inquiry game learning scenario could improve primary school students’ computational thinking skills or not. As a result, they found that STEM inquiry scenarios increased students’ computational thinking skills.

While using a single case study limits the generalizability of the findings, it provides a valuable starting point for in-depth exploration of the relationship between STEM activities and computational thinking. So, in this research, the focus is on rich, contextual insights rather than broad applicability. In this direction, the results of this study shed valuable light on how computational thinking skills can be developed in the context of a STEM activity, emphasizing the emergence of debugging, decomposition, and pattern recognition. The presence of these three components of computational thinking, which are essential parts of problem solving, indicates that the participant student can engage in the STEM education-related task at a more profound cognitive level. The findings

demonstrate how the student applied computational thinking skills during the activity, particularly through these three components. These reveal the student's ability to approach the problem-solving process systematically, a key feature of computational thinking. This case study highlights the potential of STEM activities to foster such skills, providing valuable insights into the interplay between STEM education and computational thinking. In this context, the current study supported the strong relationship between these two concepts by providing evidence of computational thinking while implementing STEM activity with a middle school student. Knowing this relationship between these two concepts can guide curriculum studies. So, tasks and problems that address these two concepts can be presented in mathematics curricula and textbooks. More emphasis can be placed on STEM activities to develop students' computational thinking skills. Long-term studies with more participants from different backgrounds are needed to understand this relationship in more detail.

Acknowledgment

This study is dedicated to the memory of our esteemed professor, Prof. Dr. Erdinç Çakıroğlu, whose invaluable guidance continues to inspire us in our academic journey.

Opportunities and limitations of ChatGPT in creating STEM tasks: A case study with mathematics pre-service teachers

Alissa Fock[1], Janina Just[1] and Hans-Stefan Siller[1]

[1]Julius-Maximilians-Universität, Würzburg, Germany; alissa.fock@uni-wuerzburg.de

Global challenges are increasing the need to integrate STEM and Education for Sustainable Development (ESD) in mathematics education. Therefore, teachers should be empowered to incorporate these into their lessons, e.g., through suitable tasks, which poses a challenge for teachers. This case study uses an ad-hoc questionnaire and evaluative qualitative content analysis to investigate pre-service teachers' (PSTs; n = 20) use of ChatGPT as a tool to create STEM/ESD tasks for mathematics classrooms. The analysis demonstrates that while the modifications of the tasks implemented by PSTs generally resulted in tasks with higher cognitive demand and more meaningful context, not all their intended modifications were effective, and more modifications might be useful. The results highlight PSTs' active role in creating STEM tasks using ChatGPT, as well as the need to improve their abilities in task analysis and modification.

Keywords: Education for sustainable development, STEM, ChatGPT, task design, teacher education.

Introduction

In the face of contemporary global crises, such as climate change, water and sanitation, or clean energy, it is evident that there is a need for complex solutions that draw on expertise from various fields, including STEM. As a result, both STEM Education and Education for Sustainable Development (ESD) have become central to the educational agendas of schools. There is a significant overlap between these two initiatives in terms of their educational discourse, which includes both content such as climate change and teaching methods such as integrative learning approaches (Siller et al., 2024; Smith & Watson, 2019). Teachers are required to provide students with opportunities to understand how different subjects can contribute to addressing global and local economic, social, and ecological challenges and the importance of STEM disciplines (UNESCO, 2017). Thus, it is necessary to provide students with appropriate learning environments, including suitable tasks to ensure that students acquire relevant subject-specific knowledge and skills.

For STEM and ESD in mathematics education, it is important to go beyond solely applying existing knowledge and using simple procedural applications and incorporate mathematics in a meaningful way. To achieve this, tasks should encompass among others access to data, authentic real-world contexts, complexity, using technology, and interdisciplinarity (Mochizuki & Christodoulou, 2017; Just & Siller, 2022). It is crucial for mathematics teachers to be able to select, modify and create tasks (Chapman, 2013). However, particularly in (complex) reality-related contexts, solving and creating tasks and providing scaffolding can be a challenge for (pre-service) teachers (Greubel et al., 2024; Paredes et al., 2020; Siller et al., 2023). Moreover, reality-based mathematics tasks, especially in STEM contexts, found in the literature often require merely procedural skills (Greubel et al., 2024; Just & Siller, 2022). To overcome these challenges, using ChatGPT to create tasks may appear as an attractive solution. Indeed, 48 % of the teachers surveyed in Germany's largest federal state in Germany in January 2024 were using AI systems for work, also to create tasks (PhV NRW, 2024). It

is therefore of interest whether mathematics (pre-service) teachers are able to effectively and successfully use ChatGPT to create STEM tasks in an ESD context for mathematics classrooms.

Theoretical background

The opportunities and challenges of ChatGPT for teaching and the associated need for professional development have been acknowledged by several authors in general (e.g. Kasneci et al., 2023; SWK, 2024) and subject specifically (e.g. Faggiano et al., 2024). Despite teachers' frequent use of ChatGPT, research on pre-service teachers (PSTs) shows a lack of PSTs' capabilities to appropriately apply ChatGPT. For example, Noster et al. (2024) show that pre-service teachers (PSTs) may be influenced by wrong solutions when solving mathematics tasks using ChatGPT or that they may be unable to detect errors in an output of ChatGPT. Further Küchemann et al. (2023) show that PSTs tend to directly copy results from ChatGPT without modification, in this case created tasks.

Consequently, results of PSTs could differ depending on the quality of the output of ChatGPT. However, due to rapid changes in the performance of ChatGPT, and therefore varying outputs, research should focus on ChatGPT as a collaborator in the creation of STEM tasks, rather than solely concentrating on the technology itself. To investigate the interaction of PSTs with ChatGPT in creating tasks, it seems worth looking at task characteristics generated by ChatGPT, especially for STEM tasks.

Cognitive demand and context in STEM tasks in mathematics classrooms

Due to their relevance for reality-based/STEM tasks (Paredes et al., 2020; Just & Siller, 2022), this study uses two characteristics of mathematics tasks as a focus: cognitive demand and context. Cognitive demand can be classified into three levels using the TIMMS Framework (Mullis & Martin, 2017): *Knowing* refers to recalling factual knowledge, carrying out procedural calculations, or retrieving information from tables or graphs. *Applying* includes the creation of diagrams to model a problem situation or determining appropriate strategies to solve problems. *Reasoning* refers to using logical and systematic thinking to deal with new questions, drawing conclusions, generalising, and justifying solutions. Particularly, when implementing STEM tasks in mathematics classrooms, it is important that tasks not only focus on *knowing*.

For a meaningful context, Leuders et al. (2011) provide three characteristics: *Relevance* refers to whether the context is related to the experiences, interests, thoughts, and actions of the learners. *Authenticity* refers to the opportunity to work on authentic questions to gain insights into the context itself, not just the mathematical content. This description can be further subdivided into two aspects: authentic questions and the opportunity to learn about the context. *Richness* indicates that the context is complex and open-ended, encouraging deep, meaningful questions and exploration.

ChatGPT for (STEM) task creation in mathematics classrooms

Regarding ChatGPT, first results by Saptoka & Bondurant (2024) show that ChatGPT seems to be able to connect tasks to a variety of real-world contexts but most of the tasks were primarily procedural, not asking for conceptual understanding, which is problematic for holistic STEM tasks (Just & Siller, 2022). This was observed even after providing a description of cognitively demanding tasks with prompts. Moreover, van Long et al. (2024) show that ChatGPT may ask questions that are

trivial or hardly math-related. Further, Küchemann et al. (2023) show that assessment tasks in physics created using ChatGPT offer a poorer embedding into a suitable context than tasks created without the help of ChatGPT. Nevertheless, their study suggests that this shortcoming could potentially be remedied by improved prompting. These results underline the necessity for PSTs to evaluate the suitability of STEM/ESD tasks for mathematics classrooms that are created using ChatGPT. Additionally, PSTs should be able to modify these tasks where necessary to achieve changes regarding cognitive demand and context.

Research questions

The study is therefore centred around PSTs' modifications of STEM/ESD tasks for mathematics classrooms provided by ChatGPT. We pose the following research questions:

- **RQ1:** Does the quality regarding cognitive demand and context within STEM/ESD tasks change through the modifications?
- **RQ2:** To what extent do PSTs consider cognitive demand and context during task modification?
- **RQ3:** To what extent do the changes identified in RQ1 relate to the PSTs' modifications?

Research design

To answer these questions, we had PSTs create a STEM task using ChatGPT-4o and complete an ad hoc questionnaire. The PSTs were supposed to create tasks tackling an ESD topic, namely climate action as one of the Sustainable Development Goals (SDGs) (UNESCO, 2017).

The research was conducted in the summer term of 2024 in three university lectures (*basic probability theory and statistics*, *teaching probability theory and statistics*, *applied probability theory and statistics*) with 26 PSTs who participated voluntarily and consented to data processing. However, six PSTs had to be excluded from further analysis as they did not create a task or did not hand in their initial task. Thus, the final sample for data analysis comprised 20 PSTs (m: 11, f: 9) for secondary school (16) and elementary school (4), on average in their fourth semester.

After an introduction to ESD in mathematics education, the PSTs received the following assignment, including the respective parts of the curriculum and a comprehensive description of SDG 13: *Use ChatGPT to create a task with a solution (bullet points) for a math lesson on the topic of evaluating data for year 7 (secondary school) in the context of SDG 13 (climate action).*

Then an ad hoc questionnaire with four open and 45 closed items designed for data collection to gather the PSTs' reasons to modify their tasks and some additional information such as their prior experiences with ChatGPT was handed to the PSTs. We used a four-point Likert scale to capture to what degree the PSTs modified their tasks based on different task characteristics. The validity of the questionnaire was assessed through expert evaluations conducted by subject area experts; however, a pilot test was not implemented.

Analysis

To answer the first research question, we analysed the initial and final task of the PSTs according to the level of cognitive demand and the context using an evaluative, deductive content analysis

(Kuckartz & Rädiker, 2023). The created tasks contained several sub-tasks, which were coded individually, as they often addressed different levels of cognitive demand. For each sub-task, we coded the highest level of cognitive demand contained in that sub-task and then categorised the overall tasks according to the levels present in the sub-tasks (e.g. *only knowing*, *knowing* & *applying*).

Table 1: Anchor examples for the category cognitive demand (translated by the authors)

Knowing	Calculate the arithmetic mean of the number of days on which the students go to school by bike.
Applying	How can you interpret the range in the context?
Reasoning	Is there a relation between [temperatures and rainfall]? What could you conclude from that?

Questions that were not mathematics-related were not coded in this analysis. To analyse the context, we used the four categories (*relevance*, *authentic questions*, *authentic context learning*, *richness*) described in the theoretical background. Within the categories, three different levels were distinguished: *does not apply*, *partly applies*, and *applies*. For each category, we evaluated the tasks' potential (P) and whether this potential was exploited by the questions (E). The tasks were coded consensually by the first and second author. Afterwards, we compared the initial and final tasks to answer (RQ1). For (RQ2), we analysed the closed items on task modification in the questionnaire. (RQ3) is answered by comparing the changes in cognitive demand and context to the modifications indicated in the questionnaire. Due to the small sample size, our study shows initial descriptive findings but is an important starting point for our further research.

Results

Evaluation of the tasks

To begin with, all students made at least one modification. Overall, the modifications of the tasks led to an increase in cognitive demand and an improvement regarding the context illustrated in Figure 1.

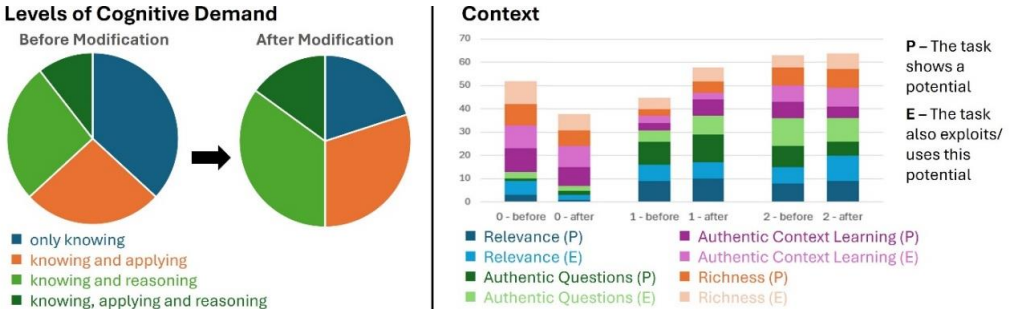

Figure 1: Changes in cognitive demand and contexts through PSTs' modifications

For the level of cognitive demand, the percentage of tasks only containing *knowing* was almost halved (seven to four tasks). Moreover, *reasoning* is contained in every second task of the final tasks, while only about one third of the initial tasks contains reasoning activities. If considering the inclusion of activities of higher cognitive demand as an improvement (e.g. *knowing & applying* is an increase from *knowing*), then eight tasks improved by the modification, while only two of the tasks declined.

Comparing the different context categories before and after modification, there is a decrease in the number of tasks that do not meet the criteria for a meaningful context (coded as 0) and an increase in those that partly meet the criteria (coded as 1). This is illustrated in detail in Figure 1, which shows the number of tasks coded as 0, 1, or 2 respectively for each context category.

Modifications of the tasks

Among the five task characteristics indicated most often as a reason for modification, three referred to subcategories of context, namely *relevance* (7 PSTs), *learning about the context* (8 PSTs), and *richness* (7 PSTs), and one referred to cognitive demand (7 PSTs). Two PSTs intended to both increase and decrease cognitive demand during their modification process. Despite being the most frequently modified characteristics, each of them was considered by less than half of the PSTs, while more than half of the initial tasks showed a need for improvement. For example, seven initial tasks not containing reasoning activities were not intentionally modified to increase in cognitive demand.

Relation between task characteristics and modification

The number of PSTs who modified the task with ChatGPT or by hand to increase or decrease cognitive demand and those who did not modify a task based on cognitive demand, separated by the type of change from the initial to the final task (increase, no change, decline), is shown in the left table in Figure 2. The first row shows that three out of the five tasks that were deliberately modified to only increase in cognitive demand actually show the respective change. It should be noted that the remaining two PSTs indicated to be dissatisfied with their final tasks. All other modifications do not coincide with a change at all, which seems comprehensible at least for those PSTs with both modifications. Interestingly, half of the tasks that were not explicitly modified to change cognitive demand still showed an improvement in this respect, while two showed a decline.

Level of Cognitive Demand (CD)

reasons to modify \ change	increase	no change	decline	total
increase CD	2 + 1*	1	1	4 + 1*
decrease CD	0	1	0	1
in- & decrease CD	0	2	0	2
no intended modification regarding CD	5	5	2	12

Context

Modification \ Change	improvement	no change	decline	total
Modification	8 + 1	13	4	25 +1*
no intended modification regarding context	10	32	12	54

*) *+1* indicates a modification by hand not using ChatGPT.

Figure 2: Comparison of modifications indicated in the questionnaire, cognitive demand, and context

For the context, each task was considered four times – once for each subcategory of context (leading to 4 x 20 aspects), summarised in the right table in Figure 2. Overall, the rate of improved tasks is higher among those that were actively modified (35% vs. 19%), while the rate of declined tasks is a bit lower (15% vs. 22%). These results indicate a slight tendency for greater improvement if a task was modified. Still, only 35% of the aspects the PSTs attempted to enhance did actually improve. However, *no change* is not necessarily negative if the initial task was already coded as 2. This was the case for four of the 13 aspects considered.

Discussion

The overall improvement between the initial and the final task could point towards the importance of PSTs' active contribution when creating STEM tasks using ChatGPT (SWK, 2024). While ChatGPT

can quickly provide various tasks, this case study indicates the importance of the ability of the (pre-service) teacher to modify and improve tasks regarding the level of cognitive demand and context (Sapkota & Bondurant, 2024).

However, even if the PSTs did not (consciously) modify for cognitive demand, there were still improvements in this respect. This could also point towards an opportunity of ChatGPT to provide more cognitively demanding tasks, even if no explicit modification concerning this characteristic was made. One might argue this makes PSTs' ability to assess cognitive demand of tasks less necessary when having access to ChatGPT. However, a closer look reveals that two out of the five increases only increased to an *applying* level, not to a *reasoning* level. Moreover, it should be noted that a task may also decrease in cognitive demand without modifications, as seen in two cases here. At the same time, there is a slight tendency that a purposeful modification to increase cognitive demand according to the questionnaire is related to the actual change. Therefore, it may still be important for PSTs to be familiar with assessing cognitive demand of tasks, particularly in a STEM context (Just & Siller, 2022; Sapkota & Bondurant, 2024).

Moreover, the results suggest that the PSTs were more attentive to context and cognitive demand than to other task characteristics, which seems reasonable given their importance in STEM and ESD tasks. Still, our data suggest PSTs' ability to consider these features should be strengthened even more. Further, our results could suggest that PSTs' modifications regarding context were at least partly successful. This would again underline the importance of (pre-service) teachers' competency in the analysis and modification of ChatGPT-generated STEM tasks. However, it must be noted that in a considerable number of cases, modifications were not associated with the respective changes. This might be due to the PSTs' difficulties to adequately communicate their intended modifications to ChatGPT, that is, to effectively use prompting strategies (SWK, 2024).

Limitations

The results of this case study are limited by several constraints. First, due to the small sample size and setting as well as the limitation to only one topic of ESD (climate action) and one mathematical content area, the results do not allow for generalisations. Second, the indication of the task modifications is limited to the PSTs' self-evaluation, not considering their actual interaction with ChatGPT. Analysing the chat logs might provide closer insights here. Third, our results are limited to one version of ChatGPT and may change as the performance of the system improves.

Conclusion

This study aims to analyse the opportunities and challenges of utilising ChatGPT in STEM Education by examining PSTs' current capabilities in using ChatGPT to develop STEM tasks and their motivations for modifying tasks.

The analysis revealed an overall improvement between the initial and final task, even though the PSTs did not always intentionally modify. However, in cases of unintentional changes, the level of cognitive demand was mostly limited to an *applying* level and even decreased in certain instances. Conversely, deliberate modifications to enhance cognitive demand as indicated by the questionnaire appeared to be rather successful.

From the perspective of teacher education, it is important to enable PSTs to critically utilise ChatGPT as a collaborator in creating STEM tasks. However, the fact that some PSTs did not intend to modify tasks generated by ChatGPT that had low cognitive demand or inappropriate context suggests a deficiency in their pedagogical content knowledge or a failure to critically evaluate responses provided by ChatGPT. This is highly problematic, especially considering the potential risk of ChatGPT generating errors or tasks limited to lower cognitive demand or inappropriate context.

Through our study, we have taken an initial step towards examining the capabilities of PSTs in creating STEM tasks using ChatGPT, leading to preliminary hypotheses. This study suggests that further research should focus on PSTs' proficiency in using ChatGPT, and how to empower them to view ChatGPT as a collaborator in the development of STEM tasks. This may involve teaching effective prompting strategies and enhancing their knowledge in evaluating STEM tasks to fully harness the potential of this innovative technology and enable meaningful STEM tasks in mathematics classrooms.

Developing a Unified Framework for Authentic Problem Solving in STEM Education

Johannes Klaas[1], Frederik Dilling[1] and Ingo Witzke[1]

[1]University of Siegen, department of mathematics, Germany; johannes.klaas@uni-siegen.de

In the Authentic Optimizing research project, students from a German high school are confronted with real-world Problems from a company. The aim of the students is to solve the problems, for which neither they nor the researchers know the solution (or a way to solve the problem). The students are supported by coaches during his process, guided by mathematical problem-solving frameworks, such as Pólya (1945) or Schoenfeld (1985). Based on the first results of the project, we suspect that the students have major problems with the problem-solving (process), as well as with working with their mathematical resources. To improve the support of the coaches, it may be beneficial to integrate problem-solving frameworks from various disciplines. The goal is to describe these frameworks and combine, merge, or expand these to develop an interdisciplinary model. In this paper, we started with a view of problem-solving in mathematics, chemistry and computer science education.

Keywords: Problem-solving, Real-world problems, Pólya, Applied mathematics.

Introduction – Problem-Solving in Mathematics

As Halmos (1980, p. 519) aptly states, “mathematics consists of problems and solutions.” Problem-solving is undeniably a central component of mathematics, but what about other STEM disciplines and economics, which are also closely tied to mathematics? In our project, Authentic Optimizing, we aim to facilitate math-containing real-world problem-solving processes for students and provide support throughout their journey. Consequently, we are particularly interested in exploring problem-solving within mathematics, STEM, economics, and other fields, and understanding how these disciplines are interconnected, especially from a mathematical perspective.

Even within mathematics education, definitions of a "problem-solving" vary. One, which is important for us here, is given by Rott et al. (2021, p. 737). They describe a problem-solving

> in the sense of working on nonroutine tasks for which the solver knows no previously learned scheme or algorithm designed to solve them

based among others on Schoenfeld (1985), where it is described as working on non-routine tasks for which the solver has no pre-learned schema or algorithm. Rott et al. (2021, p. 737), referencing Halmos (1980) and Liljedahl et al. (2016), emphasize that problem-solving is not only essential in mathematics overall but is especially critical in the context of teaching and learning. In the field of mathematics education, the well-known work of Schoenfeld (1985) distinguishes four key components that contribute to problem-solving performance: resources, heuristics, control, and belief systems. Each of these categories plays a vital role in the problem-solving process. Resources refer to mathematical knowledge, including algorithms, routine procedures, facts, domain-specific information, and the connections between these elements. Heuristics involve strategies and techniques for tackling problems. Control relates to the global decisions made regarding strategies and resource allocation, and effective control requires monitoring and assessment (Schoenfeld, 1985,

p. 33). Lastly, belief systems encompass the individual's convictions, assumptions, and perspectives about mathematics and the problem-solving process. These four components are central to our approach in supporting students throughout the project Authentic Optimizing, which will be further discussed in the next section.

Probably the most famous problem-solving framework in mathematics is Pólya's four-step model (Pólya, 1945), which Schoenfeld (1985, p. 24) describes as a guide to effective problem-solving techniques. Pólya outlines four stages: understanding the problem, devising a plan, executing the plan, and reviewing the results. While this model provides a normative framework for problem-solving, it does not fully capture the iterative nature of actual problem-solving processes, where backtracking and revisiting previous steps are often necessary. To better capture the specifics of individual problem-solving processes, Rott et al. (2021) developed a descriptive model building on Pólya's framework. For this purpose, the added a fifth phase – the exploration. In this phase, students engage with the problem in an exploratory manner before formally planning or implementing a solution. A key feature of this model is its flexibility, allowing solvers to move back and forth between phases, better reflecting the reality of problem-solving processes.

While the presented frameworks were developed to support and investigate intra-mathematical problem-solving processes, the question arises as to how far these can be applied to authentic real-world problem-solving in STEM fields and beyond. To explore this, the next section introduces the Authentic Optimizing project as a critical case. Following this, problem-solving in other STEM disciplines will be discussed through two examples: chemistry education and computer science education. A final section will relate the presented frameworks to each other and outline initial insights regarding interdisciplinary and authentic STEM problem-solving.

Problem-Solving in Authentic Optimizing

Authentic Optimizing is a research project initiated by the mathematics education group at the University of Siegen. The central idea of this project is to present real-world problems from a company to school students, who then work on solving these problems with the support of coaches (students from the University of Siegen). Our business partner for this project is REWE digital, a subsidiary of the REWE Group, an international German retail corporation. REWE digital, located in Cologne, serves as the digital innovation think tank for the entire REWE Group.

Authentic Optimizing operates as a cyclical project, with overlapping cycles lasting one year each and consisting of three phases, punctuated by two important milestone events. Start of the project was in summer 2023. The first phase is the preparation phase, during which we promote the project in schools (Gymnasium; 7th to 11th grade) and select students to participate as problem solvers. This phase also includes the problem-posing process, where we collaborate with our business partner to define the problems and develop a student-oriented formulation. The preparation phase concludes with the kick-off event, in which the problems are introduced to the students, who then choose which problem they wish to work on. Each problem is assigned a stakeholder from the business partner who is responsible for the problem.

In the next step, the students form solver-teams (groups of four to five students) to tackle the problems in the problem-solving phase. These teams meet weekly in solver-hubs for 90-minute sessions. A coach (pre-service mathematics teacher) supports each team. During this phase, we apply problem-solving models, such as Pólya's (1945) model, to help students with strategies and control in their work (see Schoenfeld, 1985, p. 15). It is important to emphasize that our role is to support the students, not to solve the problems for them, encouraging them to implement their own ideas.

The problem-solving phase culminates in the Forum of Innovation, where students present their solutions to our business partner. By the forum, both parties have become experts in the topic. The final phase is the evaluation phase, where we interview students, coaches, and team members to refine the project and advance our research.

Posed Problems in Authentic Optimizing

To illustrate the types of problems the students address, we present two examples from the total of eight problems worked on in the first two cycles. The first example is the 'Last Mile', where students are tasked with solving the following problem: The last mile of delivery is often the most expensive. How can this be organized cost-effectively? This is an open-ended problem, allowing for a variety of solution approaches. Potential solutions might include drones, delivery boxes, drivers, or pickup stations. Students must also consider various constraints, such as chilled goods or EU return policies. In this case, students explored ideas like self-driving bots, drones, or an Uber-like delivery solution. The second example is the 'AI Project', where students explore how artificial intelligence (AI) could be utilized by a supermarket group. This problem is dynamic and changed during the solving process, as our business partner adjusted their compliance with ChatGPT in the problem-solving phase, requiring the students to adapt their approach accordingly. Here, students worked on the challenge of how AI could function as a co-worker. One group used ChatGPT to develop a custom AI tool to assist with organization and inventory management in a supermarket.

Challenges for Our Research in the Project Authentic Optimizing

While the students presented creative ideas, none of the solutions were profound. When analysing the solutions from the first cycle, both our university team and our business partner were disappointed with the overall quality and depth of the solutions. It became clear that the solutions were superficial. At the beginning of the problem-solving phase, we introduced students to problem-solving strategies, such as Pólya's model and the use of milestones. However, in our evaluation, students reported limited use of these strategies. For instance, one student stated:

> Adam: No – everyone picked a topic and then researched it, and we entered the information into the PowerPoint.

In addition to these interviews, students were asked to keep a research diary and create a problem-solving plan at the start of the process. The analysis of both the plans and diaries supported the conclusion that established mathematical problem-solving frameworks were insufficient to describe the students' processes. In particular, students struggled with problem concretization and developing a plan (a kind of problem posing process), leading to superficial solutions. Given the real-world nature of the problems in this project, interdisciplinary approaches, particularly across STEM, may offer a solution to these issues.

Another challenge we observed was that, despite knowing we were mathematics educators, the students rarely utilized their mathematical knowledge to solve the problems. For instance, they did not apply mathematical methods to balance sheet calculations or calculate the radius of drone effectiveness, even when prompted. When asked in interviews to categorize the project within a school subject, very few students, if any, chose mathematics. This suggests that students may not perceive their mathematical knowledge as useful in solving real-world problems. Schoenfeld (1985) refers to this phenomenon as" they did not perceive their mathematical knowledge as being useful to them, and consequently did not call upon it" (p. 13).

Resulting Research Question

The "Authentic Optimizing" project serves as a critical case study for investigating interdisciplinary applications of mathematics and authentic, long-term problem-solving. While students engage in this project, our primary research aim is to examine how, and to what extent, they employ their mathematical competencies to address complex real-world problems that are not solely constructed for educational purposes, as well as to identify effective means of supporting them in this endeavour. In light of this, we pose the following research question: How can we better demonstrate, support or teach students in solving authentic real-world problems? The application of mathematics and problem-solving skills in real world situations is an important topic for mathematics teaching (Winter 1996, KMK 2012), which we want to investigate with this question as part of the project. One approach could be the integration of approaches from different disciplines, especially in the context of STEM. This addresses two of the four key components of Schoenfeld (1985): heuristics and control in the problem-solving process. We want to use the results of this research to improve the support for students in planning and implementing a more successful and better structured problem-solving process. Combining the different problem-solving frameworks from different disciplines will help us in planning and preparing the solving process for each interdisciplinary problem in the project. This part of the research is liked to a specific question: What are the differences and similarities of problem-solving frameworks from different disciplines and how can we combine them? In this paper, we will start with the two disciplines Chemistry and Computer Science, but we will continue with more STEM or economics disciplines in future research.

Problem-Solving in Chemistry

The German "Bildungsstandards" (educational standards) in chemistry mention problem-solving only marginally, which contrasts with the "Bildungsstandards" in mathematics, where problem-solving plays a major role and is defined as a competency (KMK, 2012, 2020). Despite this, if you look at educational research, problem-solving is vital for chemistry and its education. Bodner (2015, p. 181) emphasizes that "Problem solving is what chemists do." He supports this assertion with two key reasons. First, problem-solving helps to deepen one's understanding of the subject matter. Bodner argues that engaging with problems fosters a deeper comprehension of the topic at hand. The second reason relates to the nature of a problem itself. For many inexperienced students, tasks in their chemistry courses present challenges for which they neither know a process nor possess a plan to solve them (nor the solution itself). This aligns with the description: "and you don't know how to find a way to cross that gap" (Bodner, 2015, p. 194). Bodner (2015, p. 194) further defines problems using

a quote by Hayes (1989), explaining that a problem represents the gap between where you are and where you want to be, with no clear plan or method for bridging that gap. Streller et al. (2019, p. 52) offer a slightly different definition of a problem, characterizing it within the framework of problem-oriented teaching in chemistry. They describe a problem as the intellectual contradiction between what is known and what is observed, particularly from the students' perspective. Puhlmann and Tiemann (2008, p. 421) do not define problems directly but describe them through the lens of problem-solving, referencing the interdisciplinary work on problem-solving by Klieme (2001, p. 185). They define problem-solving as "goal-oriented thinking and action in situations for which no routine procedures are available." This complements Bodner's (2015, p. 194) definition of a problem, where he states that problem-solving is "what you do when you don't know what to do."

Although problem-solving is recognized in chemistry, there is a surprising lack of literature on the subject specificity in the field. Bodner (2015) developed a problem-solving model for chemistry, drawing on the models of Pólya (1945) and Dewey (1910). Bodner's model aims to be teachable, transferable across various chemistry problems, and useful in guiding the problem-solving process (Bodner, 2015, pp. 193–194). His model includes sixteen steps, with some repetitions. Steps 1, 2, 8, and 12, which instruct to "read the problem (again) ", align with Pólya's stage of "understanding the problem". Steps 3 and 4, "draw a picture that represents the structure of the system being modelled" and "write down what you hope is the relevant information", along with steps 5, 6, and 9, "try something (else)", correspond to "devising a plan". Steps 7 and 10, "see where this gets you", and step 11, "test intermediate results to see whether you are making any progress toward an answer", are consistent with "carrying out the plan". Finally, steps 14 ("write down 'an' answer"), 15 ("test the answer to see if it makes sense"), and 16 ("start over if you have to, celebrate if you don't") relate to "looking back". In comparison to Pólya, Bodner (2015) tries to expand and refine Pólya's (1945) original framework, adapting it for chemistry and creating a partially cyclic model that revisits key steps throughout the process. His research highlighted that "understanding the problem" is the most crucial step in chemistry problem-solving. He also identified strategies (notably "trial and error" as a powerful problem-solving strategy in chemistry), resources, and control as essential elements for the problem solver, though he did not directly reference Schoenfeld (1985). An interesting point for researchers in mathematics education is that Bodner (2015) initially developed his model for quantitative chemistry problems and only later adapted it to non-mathematical chemistry problems. Other researchers like Puhlmann and Tiemann (2008) used other problem-solving models like the OECD problem-solving model, which is also partially based on Pólya's work (OECD, 2004, p. 170).

Problem-Solving in Computer Science

Problem-solving is also a characteristic activity in computer science, generally with the goal of developing an algorithm and implementing it in a program. As Müller and Weichert (2013) describe:

> The goal of problem solving is to find a system, based on a given problem, which represents the solution. This approach can be broken down into three steps. The starting point is a given problem for which a solution is sought using a computer. Following this, through abstraction, an algorithm is ideally created from the problem. In the next step, the algorithm is transferred into a program,

which is then executed on a computer. The program represents the solution to the problem. (Müller & Weichert, 2013, p. 16, Translated by the authors)

The computer science problem-solving process, like the process in mathematics, can be described as a series of typical steps, which Müller and Weichert (2013) summarize in a model. First, the problem must be formulated or identified. The second step is to analyse the problem, which includes determining whether there is one, none, or multiple solutions. This step also involves abstraction, where variables are introduced for specific information. The problem may also be revised or broken down into sub-problems. The third step involves designing an algorithm for the sub-problems and the overall problem. In the fourth step, the correctness of the algorithm is checked (Does the algorithm terminate? Does it always produce the correct result?), and the fifth step involves analysing the implementation effort. Only in the sixth step does the actual programming take place, where the algorithm is written in a selected programming language. If the result is unsatisfactory, the algorithm and the program are improved through further problem-solving cycles. In computer science education, the entire problem-solving process does not always need to be completed. For instance, students may only develop an algorithm without implementing it in a program, or an algorithm may be provided for them to implement using a specific programming environment. In addition to the model by Müller and Weichert (2013) and similar process models for programming, Pólya's problem-solving model is also frequently used in computer science. However, Oehler and Ludwig (2024), based on a qualitative literature review, note that this is often done without adapting the model to the specificities of computer science, and that there has been no proper validation of Pólya's model in the context of computer science.

Comparison and Outlook

A comparison of the different frameworks from mathematics, chemistry, and computer science reveals that Pólya's problem-solving model is prominently referenced in each discipline. Pólya's model appears to be not only effective in mathematics but also applicable in chemistry and computer science. However, there are distinct differences in how these models are applied within each field. For instance, in the computer science model by Müller and Weichert (2013), "devising a plan" aligns with "devising an algorithm," but this could also be interpreted as the first step in "carrying out the plan". In chemistry, Bodner (2015, p. 195) emphasizes that the central aspect of the problem-solving process lies in "understanding the problem", which might be different in mathematics, where the focus is often on "devising a plan". Because of the connection to the Pólya framework, which is the basic or initial model for many of the problem-solving models in mathematics education (Rott et al. 2021), we can compare them with other models in mathematics education, too. For example, Schoenfeld (1985) added an additional exploration phase, which could be linked to "try something (else)". In the case of Rott et. al. (2021) whose model deals with both phases: planning and implementation and exploration, one has to categorise whether it belongs to one or both of these parts. Comparing the interdisciplinary frameworks with some of the mathematics education is also a goal for further research. For interdisciplinary problem-solving projects, such as Authentic Optimizing presented in this paper, it may be beneficial to integrate models from various disciplines especially from disciplines to which parts of the problem might be connected. We hope this will help us to improve the students' work in the problem-solving process, enhance their solutions, and give us

insights into the applied long-term problem-solving process. Some combinations of models of two disciplines already exist, e.g. for mathematics and computer science (Dilling et al., 2022b) or for mathematics and physics (Nguyen et al., 2020). Furthermore, expanding existing models like Schoenfeld's (1985) could be a promising direction. For example, Dilling et al. (2022a,2022b) applied Schoenfeld's model in a real-world problem-solving context and observed that students drew not only on mathematical knowledge but also on resources from physics, engineering, and the arts.

In the next steps of the theoretical development of Authentic Optimizing, we aim to systematically analyse problem-solving frameworks across various disciplines. To do so, we will utilize both English and German educational handbooks from different fields, particularly STEM. Our goal is to combine, merge, or expand these frameworks to develop an interdisciplinary model. By integrating this model in the work with the students in Authentic Optimizing, we aim to provide structured guidance for the students while also evaluating the model's applicability and impact in real-world problem-solving contexts.

Exploring mathematical praxeologies and integration in STEM assessment: A case study

Dorte Moeskær Larsen[1] and Maiken Holm Svendsen[1]

[1]University of Southern Denmark, Denmark; Dmla@imada.sdu.dk

This paper explores how mathematical praxeologies are integrated into an interdisciplinary STEM assessment in the LabSTEM+ projects. Despite the growing emphasis on integrated STEM education, assessing both subject-specific and interdisciplinary competencies remains challenging. Using the Anthropological Theory of the Didactic (ATD), the study examines how students incorporate mathematical praxeologies into their assessments and integrate them with scientific disciplines. Videorecording from the exploratory case study reveals that while students generally attempt to link mathematical models with scientific content, their grasp of the underlying mathematical theory varies. Some groups effectively integrate mathematics, but many do not include the theoretical aspects. The findings highlight the importance of providing more effective guidance to students on incorporating the assessment of mathematical praxeologies within interdisciplinary STEM practices.

Keywords: STEM, praxeology, assessment, secondary school.

Introduction

In today's rapidly changing world, adopting an interdisciplinary approach to education has become increasingly important (Bybee, 2013). Interdisciplinary learning encourages students to explore the connections between various fields, enhancing critical thinking skills (Larsen et al., 2024) and fostering a deeper understanding of complex, real-world problems. By dismantling the traditional barriers between academic disciplines, students are better equipped to navigate the intricacies of our interconnected world and develop the adaptability required to address the diverse challenges of the 21st century (Mass et al., 2019). Integrated STEM (Science, Technology, Engineering, and Mathematics) education has become a popular term in education worldwide (Gao et al., 2020), however teaching integrated STEM is still in its beginning stages; but a growing body of literature has emerged on the subject (Larsen et al. 2022). Nevertheless, the assessment of learning in integrated STEM activities remains underexplored (Gao et al., 2020). Assessment in integrated STEM teaching can be complicated due to the fact that there are often several objectives to be assessed. There are the different subject-specific competences like mathematics- and biology-competences, but there are also interdisciplinary competences. Assessment within monodisciplines has a long-standing tradition and is relatively well-documented (Gao et al., 2020). However, assessing interdisciplinary knowledge and practices presents significantly greater challenges and often demands innovative approaches (Gao et al., 2020).

In this article, we aim to explore how a group of teachers at a secondary school successfully developed, planned and tested an integrated STEM course in a project called LabSTEM. More specifically we are interested in whether the teachers were able to assess the different mathematical praxeologies (Chevallard, 2019) in a STEM-assessment, but we are also interested in how the students connected and integrated the mathematics to the other disciplines in the final assessment. We ask the following questions:

RQ: What mathematical praxeologies are assessed in students' STEM-assessment? And how are the mathematics integrated into the STEM assessment?

Assessment in STEM Education

Assessment plays a pivotal role in education, serving as a powerful tool for facilitating student learning and measuring academic progress (Venista, 2018). The ability to assess students' learning effectively is essential, particularly within STEM education, where the development of both discipline-specific knowledge and interdisciplinary competences is crucial (Gao et al., 2020). Gao et al. (2020) define assessment as a deliberate effort to track students' learning progress through various methods, enabling educators to gauge where students stand in relation to specific learning objectives. These assessments may take many forms, ranging from traditional examinations to more innovative, formative approaches, but it requires a balance between reliability, validity, and practicality. Without this balance, assessments risk becoming inaccurate or ineffective in evaluating student progress. The review from Gao et al. (2020) indicates that interdisciplinary knowledge and cross-disciplinary skills are often overlooked in current STEM assessments. As teachers face the challenge of navigating these interdisciplinary demands, research in this area could offer valuable guidance and practical solutions, ultimately helping to improve the quality of STEM education.

Analytical Framework: Mathematical Praxeologies

To gain deeper insights into different STEM assessments, we will apply the theory of praxeologies as our analytical lens. The Anthropological Theory of the Didactic (ATD) conceptualizes knowledge as praxeologies, which are structured into two main components: praxis and logos (Chevallard, 2019). Praxis, or "know-how," consists of **tasks** and the **techniques** used to solve problems. Tasks are the specific problems or activities that students engage with, while techniques are the methods or procedures employed to address these tasks. Logos, or "know-why," encompasses the theoretical discourse that justifies or explains these techniques, often referred to as the **technology** within the praxeological framework. Technology provides the rationale behind the techniques. Finally, **theories** is the explanation of the technology offering explanations, general principles, that support the approaches used in solving the task. Theories are here rooted in established and institutionalized knowledge. This framework allows for a detailed analysis of the knowledge at play within educational settings, examining not only on the procedures and tasks but also on the underlying principles and rationales that support them. Praxeologies provide a tool for examining the complexity of knowledge and the dynamic interactions between teaching, learning, and content (Bosch & Gascón, 2014).

Table 1: Praxeologies

	Praxeologies	
Praxis (the know-how)	Task	Technique
Logos (the know why)	Technology	Theory

Praxeologies have proven valuable in various educational analyses, such as examining mathematics teachers' instructional practices with textbooks (Pansell & Boistrup, 2018) and analyzing mathematics comics created by pre-service teachers (Putra et al., 2021). However, there is limited

research on their application in assessing interdisciplinary STEM education. While some studies explore interdisciplinary activities (Pocalana et al., 2024), comprehensive analyses of mathematical knowledge assessment in these contexts remain scarce. In this study, we interpret the mathematical knowledge demonstrated and articulated in the students' assessments as praxeologies (Chevallard, 2019). Each praxeology reflects how the content of a specific topic has been transposed into the assessment context.

Methods and context

The context of the study is the LabSTEM project, which is a research and development initiative spanning from primary to secondary schools. In this project, 10 laboratories are established where teachers participate in 3-4 workshops to develop integrated STEM activities with a specific focus on integrating mathematics. These workshops combine academic input with time for designing STEM activities, which are later tested in their classrooms and observed by peers and researchers. Assessment methods vary across the laboratories, including traditional approaches such as poster presentations, self-made videos, and competitions involving engineering products. We employ an exploratory case study methodology (Yin, 2009) to investigate one LabSTEM laboratory, involving a small group of high school teachers and their students. The case-study-method allows for an in-depth analysis of the complex dynamics within real-world educational settings. Out of the 10 laboratories, we find this case particularly interesting as it presents an assessment method where all the teachers are present simultaneously.

Data collection includes video observations of 14 lessons across four subjects (mathematics, chemistry, physics, and biotechnology) and two lessons of the final STEM-assessments.

In the laboratory studied in this case, teachers developed a teaching sequence for a first-year class focused on wastewater treatment and growth. Over a series of lessons, students were tasked to make an assessment poster to:

1. Explain biological and chemical processes involved in wastewater treatment, including bacterial activity and chemical precipitation. 2. Describe how light is used to analyse liquid contents and measure contaminant concentrations. 3. Use data from investigations to create mathematical models, specifically modelling exponential growth.

The teaching began with a field visit to a local wastewater treatment facility, where students were introduced to the entire treatment process. Subsequently, during their mathematics class, students conducted two distinct exercises to explore exponential growth through dice experiments. In the first experiment, each group started by rolling 100 dice, recorded the number of sixes rolled, and removed that number of dice from the set. This process was repeated until no dice remained. The students then plotted their results in GeoGebra for analysis. In the second experiment, students began with six dice and, after each round, added an equivalent number of dice corresponding to the sixes rolled, carrying the additional dice into the next round. Throughout this experiment, the mathematics teachers discussed probability and the shape of the two different resulting graphs, providing individual explanations to each group about the form of the exponential growth function. Several groups were individually provided with an explanation of the institutionalized theoretical knowledge related to the exponential function. After the mathematics class, students explored bacterial growth in

biotechnology, spectrophotometry in physics, and spectroscopy in chemistry, using various juice and water mixtures to determine the purity of liquids. At the end of the activities, students were required to create a poster in groups to illustrate what they had learned to answer the three questions above. This was designed to serve as the teachers' final assessment of the students' learning throughout the course. The poster was to be presented to all the teachers together in one session. In total, five poster presentations were videorecorded.

Praxeology analysis

In table 2 we have analysed what mathematical praxeologies are explained in the students' assessment poster presentations. Although they addressed praxeologies from other subjects, such as biology and chemistry, this analysis focuses solely on the mathematical praxeologies. We also analysed how students integrated mathematics into the interdisciplinary STEM content in their presentations (column 2). In the analysis, we have focused on the specific tasks that the students actually answered - namely, which "tasks" they worked on and responded to in the presentation, as this varied somewhat between groups. The three overarching questions posed by the teachers are not particularly integrated across the subjects, and question 3 is clearly focused on mathematics. As a result, it was somewhat left to the students themselves to establish the integration between the subjects in their presentations. When students were asked to create models (as per question 3), they were encouraged to develop mathematical models based on data from chemistry, biology, or physics.

The analysis presented in table 2 was conducted by both authors, who initially reviewed the poster presentations independently using the praxeological framework. They then re-examined the recordings together to compare interpretations and ensure no key details were missed.

Table 2: Praxeological analysis and integration of M in STEM

Gr.	Integration M in STEM	Tasks	Technique	Technology	Theory
1	In explaining the growth depicted in their graph of bacterial expansion, a student starts describing that they made a mathematical experiment to illustrate this growth. The dice experiment is then explained. The student says that the experiment produced a growth curve represented by the formula $y=5{,}28\cdot1{,}1^x$. Another student concluded by explaining that bacterial growth also follows an exponential pattern, increasing by 3% each minute, leading to a doubling of the bacterial population in four hours	Which mathematical model can bacterial growth be compared to? How do E. coli bacteria grow?	Create a graph based on the dice-rolling experiment. Use GeoGebra to plot the graph and allow the program to determine a formula. Finding data using spectroscopy. Plot the data on a graph in GeoGebra and analyse the regression models to find the doubling constant.	The formula for exponential growth, as well as the doubling constant, is not further explained.	-

2	A student begins the presentations with an explanation of two graphs from the dice experiment. He explains that they have both a theoretical graph and a graph from the dice experiment ("our model"), highlighting the differences between them on the poster. It is then clarified that this model can represent bacterial growth. Additionally, a student presents another graph based on E. coli data, explaining that the bacteria exhibited a doubling time of 3 hours.	How does the number of sixes rolled with dice change when the sixes are removed/added after each roll? What is the doubling constant for E. coli in the laboratory?"	They created a graph using data from rolling dice and also developed a theoretical probability curve for the dice rolls. By analyzing the GeoGebra curve generated from the E. coli bacteria measurement data, they identified the doubling constant in the curve.	The formula for the growth of the graphs, as well as the doubling constant, are not further explained.	-
3	From explaining the biological and chemical purification processes a student explains that they put the data from the bacterial experiment into GeoGebra and performed a regression analysis. The resulting formula is $g(x)=0{,}1953 \cdot 1{,}0062^x$ "*As we did in our mathematics experiment, where we de-mathematized and compared theoretical results with real-world data, we applied the same approach here to the bacterial growth experiment. This growth rate suggests that we are in the early phase of bacterial growth, which is expected to increase more rapidly later, according to the growth model for E. coli bacteria*" as shown in a theoretical E. coli growth model.	How do E. coli bacteria grow?	By analyzing the GeoGebra curve generated from the E. coli bacteria measurement data, they identified a function and explain the meaning of the variables in the function.	Explanation of the formula from GeoGebra: "*This parameter (0.0062) indicates that the bacteria are growing at a rate of 0.62% per minute, while (0.1953) represents the value of our first measurement*".	-
4	The presentation begins with an explanation of the biological and chemical purification processes. The experiment with E. coli bacteria is then explained by using a graph they	How does E. coli bacteria grow?	They show a graph using data from the dice experiments. They also made a theoretical (calculated)	The exponential function or graphs are not explained.	-

	made. A student explains that this is connected to an experiment in mathematics with rolling dice. Another student explains: "*to describe this we made an experiment in mathematics*". Another student point on a graph from the dice experiment and explain that they also made a theoretical graph - which they explain as an exponential growth model and say is seen in the experiment with the E. coli bacteria.		probability curve of the rolling dices - both in GeoGebra. They connect the mathematical curves to the E. coli bacteria curve and by saying that also the E. coli follow an exponential curve.		
5	In the end of the presentation a student explains the mathematical experiment with dice. However, the student stops in middle of explaining the origin of 7/6 in the formula. Another student takes over by saying "*and this can relate to the growth of E. coli bacteria*"	How does the number of sixes rolled with dice change when the sixes are removed/added after each roll?	They present a graph they have made after doing the experiments with dices in GeoGebra.	They explain the axes: "*the x-axis represents the number of rolls, while the y-axis indicates the number of sixes.*	-

By analysing how the students integrated their mathematical experiments involving dice with other subjects in the assessment, it becomes evident that different groups approached this integration in distinct ways. One group (Group 2) begins by explaining the mathematical experiments and then goes into discussing bacterial growth, linking the two concepts. In contrast, most groups start with an explanation of the principles of the purification processes. Some of these groups (Group 1) proceed directly to the mathematical experiments without relating them to the initial biological context. Other groups (Groups 3 and 4) explain how they analyse data from E. coli experiments and compare it with the mathematical exercises. However, the final group (group 5) struggles to connect the mathematical experiments with the interdisciplinary topic, resulting in a less coherent integration of the concepts. In their presentations, the distinction between the empirical mathematical model and the theoretical model of dice rolling appears to be somewhat confusing for the students, particularly when they attempt to connect the exponential concept with both the empirical and theoretical growth models of E. coli bacteria. The challenge arises from their use of "mathematical model" as a definitive truth. This duality complicates their explanations, as they struggle to reconcile the theoretical assumptions with empirical observations in their integration of mathematics.

In analysing the **tasks** that the students addressed in their presentations, most groups (Groups 1-4) utilized mathematical concepts to explain the growth of E. coli bacteria. In contrast, Group 5 focused on explaining the development of sixes in the dice experiment and does not connect it to other subjects. Notably, Group 2 effectively addressed both tasks, integrating the mathematical models with both bacterial growth and dice rolling. All the groups employed the **technique** of putting their data

into GeoGebra and performing regression analysis to obtain a formula. Groups 1 and 2 also described bacterial growth using the doubling constant derived from the graph. However, several groups did not elaborate on the **theory** or **technology** behind these formulas, leaving some aspects unclear. Group 3, on the other hand, provided a more detailed explanation of the parameters within the formula, and Group 5 clarified the axes of their graph to make the formula more comprehensible. In the logos category, the descriptions from both Group 3 and Group 5 fall under the "technology" classification, as they primarily explain the practical application of the technique used. Consequently, none of the poster presentations effectively incorporates theory perspectives.

Discussion and implications

In this LabSTEM-case, most students made commendable efforts to integrate empirical data with theoretical models, particularly in applying mathematical concepts to both chemistry and biological processes. However, certain groups achieved a more holistic integration of mathematics than others. While the majority of students recognized the connection between mathematical models and their scientific applications, they did not engage with the underlying mathematical theory. The students' presentations revealed varying levels of understanding of the theoretical foundations of the formulas and graphs presented, highlighting a critical issue: incorporating these theoretical aspects into assessments is essential for accurately evaluating students' mathematical praxeologies and their grasp of discipline-specific knowledge (Gao et al., 2020). Furthermore, when students know what will be evaluated, they tend to perceive that content as important. Therefore, it is essential that students recognize the importance of mastering and presenting the theoretical foundations of mathematics, in addition to the scientific theories. The current assessment suggests that students have not fully grasped the theoretical components of the mathematical techniques here, as these are not sufficiently reflected in their presentations. However, it is also possible that students simply did not deem this content important to include. This gap could be addressed through follow-up questions by the mathematics teachers; however, this was not done here. Consequently, it is imperative that students are guided before the presentations to include these theoretical elements from the subjects in their interdisciplinary assessments. It may not be entirely surprising that this is challenging; nevertheless, this study highlights the importance of specifically addressing this aspect during assessment in STEM fields, because to include the mathematical theory in their assessments would not only enhance their understanding in mathematics, but also ensure that they can apply this theoretical knowledge more broadly in connection to other STEM-contexts. The analysis made here can be considered as a posteriori analysis, where we examine what occurred in the teaching and evaluation process. In the laboratory workshops we could have focused more on the priori analysis regarding how to make STEM-assessment, however Gao et al. (2020) note that interdisciplinary integration in assessment is often overlooked and this study clearly demonstrates that it is important to make this explicit in the planning because it is not easy to implement interdisciplinary integrated assessments where all subjects are assessed simultaneously. In light of this, we encourage further investigation into how this can be effectively implemented in STEM contexts.

Mathematical activities in integrated STEM lessons

Carina Spreitzer[1], David Kollosche[1] and Konrad Krainer[1]

[1]University of Klagenfurt, Klagenfurt, Austria; carina.spreitzer@aau.at

The context of this paper is a nation-wide school experiment for middle schools in Austria. 57 pilot schools introduced an integrated STEM subject in addition to their usual STEM lessons. The paper reports about this curriculum innovation and the support measures the schools are provided with. The paper addresses the question of which mathematical activities emerge in integrated STEM lessons, specifically examining whether mathematics assumes a role beyond that of a supporting discipline. It provides a theoretical discussion of the role of mathematics in integrated STEM education, outlines the methodology for interviews with teachers and presents preliminary results. The interviews confirm previous findings (e.g., Just & Siller, 2022) that mathematics in STEM often remains limited in scope, yet also show that teachers are aware of this limitation and, in some cases, actively work to expand the role of mathematics within interdisciplinary settings.

Keywords: STEM education, mathematics activities, middle school teachers, integration

Introduction

Mathematics learning at the secondary level occurs on several occasions: first of all, in specific mathematics lessons, but also in STEM lessons, broader interdisciplinary projects, etc. In the first case, often a lack of real-life connections and applications is reported, whereas in the latter cases the contribution of mathematics is often reduced to producing Excel sheets or to providing simple calculations. For example, Just and Siller (2022) demonstrated in their literature review that mathematics is often used in STEM activities primarily as a calculation tool for presenting results, which contributes to its perception as merely a tool.

Thus, the challenge for learning mathematics at the secondary level is obviously double-faced: In mathematics lessons, real-life connections are often rare; in activities aiming at real-life connections, mathematics is often rare (e.g., Spreitzer et al., 2024). How could this be improved?

Since the 1990s, curriculum integration in science and mathematics has become popular (Czerniak et al., 1999). An increasing number of schools, educational administrations, and countries are working towards establishing an interdisciplinary STEM subject.

An interesting case regarding secondary education is Austria. To promote STEM teaching a nation-wide school experiment for middle schools (grades 5–8; age children 10-14) has been started in the school year 2022/2023 (BMBWF, 2022). The newly developed curriculum for integrated STEM teaching takes an inter- and transdisciplinary approach, addressing real-world challenges, such as environmental concerns, life cycles, or the realms of employment and digitization.

57 schools were selected as pilot schools to evaluate within five years whether this experimental type of middle school with STEM focus should be transformed into a regular school type. These 57 middle schools (in short STEM-MS) have autonomy to determine in which class the school experiment with integrated STEM teaching should be implemented. For classes with the STEM-MS curriculum, the autonomy, and the percentage of STEM lessons in relation to all lessons can be quite high. According

to the recommendations in that curriculum, STEM subjects account for 53 out of 135 hours (39%) in grades 5–8. This includes the interdisciplinary subject STEM with 11 hours (about 2–3 hours per week in each grade). However, STEM-MS can deviate from this recommendation and change the amount of hours for digital basic education (at least 4 and at most 11 hours; 4 hours recommended), biology and environmental education (5.5–12; 8), chemistry (1.5–4; 2), mathematics (10–20; 15), physics (3.5–10; 5), technology and design (5.5–12; 8), and STEM (11–15; 11). This leads to a range of 41 to 84 out of 135 hours, which means a span from 30% to 62% (BMBWF, 2022). In common middle schools STEM subjects amount to 37 out of 124 hours (30%).

The long-term research and development initiative Innovations Make Schools Top (IMST) (Krainer, 2021; Krainer 2024) supports these 57 STEM-MS with three work packages: a) *Support and networking* (professional development, regional and national meetings etc.), b) *Material development and didactics* (foundation of interdisciplinary STEM education, Kollosche & Schmölzer, 2024), c) *Evaluation and research* (analysing the quality and the general conditions of STEM teaching at these schools, Spreitzer et al., 2024).

This paper focuses on the mathematical activities in the additional interdisciplinary STEM lessons (where mathematics is consciously integrated), which should help to understand the role of mathematics in the school experiment in Austria. The added value lies in how STEM-teachers incorporate mathematics, even though the traditional subject of mathematics still exists in parallel.

Regarding the above-mentioned double-faced challenge for learning mathematics at the secondary level, the research questions of the interview study are:

a) What mathematical activities can be observed in the integrated STEM lessons?

b) How do teachers perceive the reaction of their students to the mathematical activities in integrated STEM lessons?

c) Which mathematical activities and learnings do teachers consider having no place in integrated STEM lessons?

Mathematics in integrated STEM education

On an international scale, implementations of integrated STEM education occur in very different forms and for very different reasons. Former research helps to describe these forms and reasons and to evaluate their effectiveness and feasibility. In some but not all of these studies, special attention is paid to the role of mathematics.

Integrated STEM education means that at least two different STEM disciplines are productively combined in an educational setting (Sanders, 2009). Different to our case, in many other settings, integrated STEM education replaces the formerly separate STEM subjects in school. In the Austrian case, the traditional STEM subjects remain. This allows for more freedom in the curricular foci of integrated STEM but means that relations to the traditional STEM subjects have to be considered and can create conflicts between curricula and teachers. For example, in the work package on photovoltaics (Briggl et al., 2024), a foundational understanding of physics is required. Before addressing the topic of electricity, basic physical concepts such as force, work, and energy must be

introduced. According to the 2023 curriculum, these concepts are to be covered in the physics lessons of the third grade, albeit at a later stage. This misalignment can pose challenges, as exemplified by a learning environment on regenerative energy developed during the 2023/24 school year. This learning environment required competences in physics that are scheduled too late in the curriculum, necessitating the introduction of elements of electricity prematurely and thereby impacting subsequent teaching and learning in physics. To effectively address these issues and enable the comprehensive teaching of photovoltaics, coordination between subjects proves beneficial.

Within the STEM classroom, there are different approaches, some blurring the boundaries of the individual STEM subjects and others highlighting them. For example, the latter can be reached by allocating time for reflecting the importance of and the learnings in the individual STEM subjects in each learning environment. In empirical studies, this has proven essential for an increase in mathematical achievement, although not for an increase in achievement in science subjects (Hurley, 2001).

An explanation for this phenomenon might be the fact that mathematics is often used as a tool for calculation and representation in integrated STEM (Just & Siller, 2022). We have heard and felt this complaint in our own developmental work, as have our colleagues in computer science, who face similar challenges: In computer science, computer tools are often put to critical use, but other goals such as learning to program are difficult to integrate. In internal discussions about this in our multidisciplinary team, even science educators said that they felt to be in a service position when complex social and technical topics were to be addressed in learning environments. If we consider that technical explanations and designs are not identical to but informed by natural science, which again are relying on mathematics and computer science, then we can understand the perspective of the science educators and still acknowledge that mathematics is inclined to be less directly addressed in integrated STEM education.

A way to further specify the role of mathematics in integrated STEM education is to focus on its epistemic particularities. Science historian Crombie (1994) published a monumental work to describe different *Styles of Scientific Thinking* (thus the title of his book), which philosopher of science Hacking (1992) used to describe six *styles of reasoning* that are used in academia (see also Kollosche, 2021). Thereby, the *experimental style* is most closely connected to hands-on activities in the STEM classroom due to its importance for observations, experiments, and design. The *modelling style* harnesses mathematical concepts as models for applications, and the *statistical style* uses ready-made mathematical tools to make sense of large datasets. The latter two styles use mathematics as a tool, even though the attempt to use such models and statistics can be a good starting point for developing them if they are not yet known. The two styles most closely identified with mathematics are the *postulation style* (deducting features of presupposed objects with presupposed characteristics) and the *taxonomic style* (classifying concepts along logical structures). We assume that there are hardly any occasions in application-related work in integrated STEM where such questions of theory building appear naturally. Instead, it appears that such questions require a deliberate pause for reflection. This would well explain Hurley's (2001) finding that achievement in mathematics requires classroom time reserved for mathematics. However, as the Austrian STEM curriculum increasingly emphasizes real-world problem-solving, the focus on intra-mathematical activities and reflective practices in mathematics instruction is becoming increasingly sidelined.

However, increasing achievements in mathematics needs not be a goal of integrated STEM education, or it could be only one goal of many. In fact, there is no accepted teleology of integrated STEM education, and reasons for integrated STEM education are supported by research to different extents (for an overview, see Kollosche & Schmölzer, 2024): Integrated STEM might support individual agency for democratically engaging with socio-technical challenges. Integrating STEM allows to better address the complex challenges of our times in school. There is reason to assume that integrated STEM allows to learn how to use competences from the individual STEM subjects in different fields of application. Integrated STEM might lead to an increased interest in STEM. There is hope that project work in integrated STEM aids the development of competences in problem solving and critical thinking. All these goals align well with what at least the Austrian curriculum demands of mathematics education (BMBWF, 2022).

Mathematical activities in integrated STEM education

In already existing material for integrated STEM education, Spreitzer et al. (2024) found that also in these materials mathematics is more an ancillary discipline. Therefore, it is necessary to have a closer look at the mathematical activities in integrated STEM lessons to see how they can be combined with instructional practices of integrated STEM.

In order to contextualize the term mathematical activities, it is important to first clarify what is encompassed by this concept. Mathematical activities involve not only computational skills, which are often misconceived as a subordinate discipline, but also various levels of cognitive action. In Austria, the mathematics curriculum highlights the diverse roles of mathematics from the outset. The first section, outlining the educational and teaching objectives, emphasizes that

> mathematics and mathematics instruction should serve as a model for providing arguments to support claims and requiring the same from others. Flaws in reasoning should be identified and addressed. This promotes critical thinking, openness to diverse perspectives, and informed participation in societal discussions and decision-making processes. (BMBWF, 2024, our translation)

This section already refers to the importance of other levels of action, such as critical thinking. The objectives outlined here correspond to those in the first section of the STEM curriculum in Austria, which similarly emphasizes critical thinking as a core competency within the framework of 21st-century skills. Thus, there are levels of action that are required in both curricula.

To establish a connection between mathematical activities and non-mathematical practices in STEM education, it is necessary to analyse how these mathematical activities are implemented in the context of STEM instruction. To describe the mathematical content, the action dimensions of the competence model, which also form the foundation of the Austrian mathematics standards and are included in the mathematics curriculum, are referenced (BIFIE, 2011). These action dimensions include representing, modelling), calculating, operating, interpreting, and arguing, reasoning. Complexity dimensions range from the application of basic knowledge and skills over establishing connections to reflective knowledge and metacognitive reflection. Currently, there is no integration of these two dimensions or a detailed description of how they are implemented in mathematics instruction. In her

dissertation, Steflitsch (2024) proposed a classification of categories for the cognitive domain (based on Niss & Højgaard, 2019), which captures the different parts of the action dimensions along with their higher levels of complexity. The focus was critical mathematics education, although the categories can be transferred to the context of integrated STEM education. The categories are computing and construction (computation, measurement, construction); modelling (determining, implementation, integration/synthesis, evaluation); representation (retrieve, interpret, represent, reflect); reasoning (analyzing, drawing conclusions, justification, generalization); communication. Description of each category can be found in Steflitsch (2024).

Methods

To answer the research questions, semi-structured interviews with individual teachers were conducted (first author). The data were collected between November 2024 and January 2025.

Participants and context

In autumn 2024, the STEM middle schools started with the 7th grade for the first time. Therefore, in these classes, we had students who have already experienced the new integrated STEM subject for two years. We invited teachers to participate in the study who teach a 7th grade in the following school year and have already two years of experience in teaching integrated STEM. The final sample for data analysis comprised 11 teachers (m: 4, f: 7) with a large spectrum of different professionalization ranging from mathematics and arts teachers to teachers with mathematics and physics. The experience in years of the teachers ranged from four to 39 years (M = 15.1; SD = 12.9).

Analysis of data

The interviews consisted of an open and a more structured part. To avoid influencing their thinking, the interviews began with open-ended questions, giving teachers space to describe their lessons and focus on mathematical activities. In the structured part, teachers were shown an overview of mathematical activities (as listed in Table 1) and asked which ones they use in their STEM lessons. If they confirmed using an activity, they were asked to provide an example. The conversation then shifted to a more open discussion about which activities they felt belonged more in mathematics lessons and why. Finally, teachers were asked about personal contextual factors, such as STEM-related training, to help contextualize the findings. All interviews were audio-recorded and transcribed.

To analyse the data, we followed a deductive-inductive category formation according to Kuckartz (2014). Following Kuckartz's recommendation for deductive categorization, mathematics activities were clustered into an existing category system according to Steflitsch (2024), especially for research questions a) and c). These categories served as a guide for categorizing; however, some activities did not fit into this scheme, necessitating some revisions. In line with Kuckartz's guidelines, a new clustering was carried out. For the clustering process, we performed a qualitative content analysis according to Mayring (2010). For research question b) we also did a qualitative content analysis. All deductive-inductive steps were performed independently by two researchers, and disagreements in the allocation of individual activities were resolved by consensus.

Preliminary results

The preliminary results focus on the deductive components of research questions a) and c). All quotes are translated from German.

The preliminary analysis shows that teachers frequently integrate mathematical activities into STEM lessons—most notably in the areas of measurement, construction and all activities according to modelling (11 mentions each). These activities are perceived as accessible and directly applicable to STEM-related tasks, especially modelling is something that has the potential for becoming an aim.

> Interview 09: That [modelling] definitely has a place in STEM lessons. We haven't done it yet, though. It's rather difficult to implement in mathematics lessons.
> Interview 11: Look closely, with which tool can I solve the problem. Exactly. That's part of STEM. Implementing, applying these strategies. Yes. STEM.

In contrast, cognitively demanding activities such as analysing (mentioned 4 times), justification (mentioned 2 times), and communication (mentioned 5 times) were mentioned less frequently and often described as challenging to implement, especially due to its subject-specific nature in mathematics. Teachers highlighted that while reflective and discursive practices are valuable, they are difficult to realise in the integrated setting.

> Interview 06: Yes, that [justification] is, let's say, too subject-specific.
> Interview 06: Understanding – yes, understanding is always a tricky thing. Because one student might have an idea, but the other doesn't know what they mean. Or I don't know what they mean either. Thus, expressing oneself, understanding, and communication is definitely difficult in mathematics. [Interviewer pointed in the table also to STEM]

Mathematics was mostly perceived as a tool rather than a learning aim in STEM. This was reflected in statements such as:

> Interview 03: That inevitably happens too, because we have certain processes and things. You have to calculate that as well.

At the same time, some teachers described broader conceptions of mathematical thinking—especially in creative modelling or design-based activities—pointing to more nuanced roles of mathematics in STEM (e.g., Int. 08).

These results confirm previous findings (e.g., Just & Siller, 2022; Spreitzer et al., 2024) that mathematics in STEM often remains limited in scope, yet also show that teachers are aware of and in some cases actively expanding its role.

Conclusion

The preliminary results of our study suggest that mathematical activities are indeed present in integrated STEM lessons. However, they are often implemented more as supportive tools than as central aims of the learning process. While activities such as computation and representation appear frequently, cognitively demanding areas—particularly those in the domain of reasoning—remain underrepresented. Teachers report challenges in incorporating these higher-level activities, especially due to time constraints and students' limited prior knowledge.

Mathematical modelling emerges as one of the more prominent activities in STEM contexts, aligning with previous findings (e.g., Maass et al., 2019). Yet, the implementation of modelling and other complex cognitive processes differs significantly between mathematics and integrated STEM, as teachers point to structural and epistemological differences between the subjects.

Ultimately, the current STEM curriculum seems limited in its ability to define the interrelation between subject-specific and interdisciplinary learning goals. This is particularly evident when the focus shifts primarily to content rather than to competencies and reflective practices.

Outlook

As one participant (Int. 08) noted, *"even though mathematical activities occur in both [STEM and mathematics], it always has different nuances. Implementing activities is different in STEM than in mathematics."* This observation highlights the need for a deeper understanding of how mathematical thinking can be meaningfully embedded in STEM environments—beyond mere technical applications. Future research should explore how reasoning, justification, and critical reflection can be more effectively fostered within interdisciplinary STEM teaching, both at the curricular and classroom levels.

Modelling gender bias in generative AI: From research to classrooms

Peter Wied Stenkilde[1], Jack Jalal Kallo[1] and Andreas Lindenskov Tamborg[1]

[1]University of Copenhagen, Denmark; pws@ind.ku.dk

This paper explores the integration of technology and mathematics education, focusing on how research on bias in AI can be incorporated into lower secondary school mathematics. The study addresses the challenge of staying true to original research while adhering to curricular guidelines when teaching students to critically engage with digital technologies. Using the KOM-framework, we investigate how the modelling competency can be applied to analyse and adapt the work of researchers on algorithmic bias to fit into the existing curriculum. We show that the KOM-framework can aid identifying modelling processes that can be replicated by students and in identifying elements that need to be simplified or omitted to adhere to the curriculum.

Keywords: Algorithmic bias, STEM education, mathematical modelling, technology comprehension, K-9.

Introduction

Technology education and its relevance in STEM has received increased attention in the past years since the societal implications of digitalization call for new ways of addressing it in education. Meaningful integration of the STEM subjects, and their mutual relation in practice, seems to be a recurrent debate within STEM education. The role of mathematics in STEM have recently received increased interest (e.g., Kristensen et al., 2024), but few studies explore the opportunities of teaching students how to make use of mathematics to relate critically to technology (Jankvist et al., 2023) such as artificial intelligence (AI). This paper reports from an ongoing research project that takes a closer look at the integration of technology and mathematics with a specific focus to how research on bias in AI[1] can be integrated into lower secondary school mathematics education. While previous studies have sought to achieve similar goals (e.g. Jankvist et al., 2023), the approach in our study seeks to ensure as high authenticity as possible with respect to how basic research on AI is conducted while adhering to curricular guidelines for lower secondary school mathematics. Our study thereby contributes by proposing a way of teaching STEM where mathematics and technology are interdependent learning objectives. We believe that such approaches are highly needed since mathematics-based technologies are found almost everywhere in modern societies and often operate through an authority that is rarely questioned or challenged (Jankvist et al., 2023). While there is consensus that computer science research is relevant in STEM contexts (e.g. Weintrop et al., 2016), such new disciplinary knowledge rarely fits within existing curricular guidelines, placing teachers in a dilemma of adhering to the legislative curriculum or bringing in new, relevant knowledge. Our study tackles this dilemma by addressing the following research question: *In what ways can the*

[1] There are many types of biases in AI, but in generative AI, it mainly relates to unfair representation as opposed to unfair allocation (Sterlie et al., 2024). It is this understanding of bias we rely on in our paper.

KOM-framework[2] aid authentic integration of research on algorithmic bias of generative AI within the existing curricular guidelines for mathematics in grade 7-9 in Denmark?

Background and related work

The project from which this paper reports is conducted in Denmark. In Denmark, technology education is not currently part of the mandatory curriculum. From 2018-2021, The Danish Ministry of Education conducted a pilot project where 42 schools implemented a new curriculum entitled "Technology Comprehension" (TC). The Danish TC curriculum focused on building students' democratic values, active participation and critical reasoning in relation to technology (Wagner et al., 2020). The pilot project tested two implementation approaches, namely TC as an independent subject, and TC as integrated in other subjects, here among mathematics. When integrated in existing subject, the TC curriculum however brought substantial challenges. In the evaluation of the pilot project, 63% of the participating teachers reported an experience of having to override the existing subjects when integrating TC (Børne- og Undervisningsministeriet, 2020).

Internationally, several research strands within STEM and mathematics education have explored how to prepare students to participate in societies that are undergoing rapid digitalization. We consider two of these strands important to our study: the field of computational thinking (CT) in STEM, and techno-critical mathematics education (TCME). A great deal of the research on CT has sought to clarify and/or define the term CT, often by drawing on empirical studies of how computer scientists work in STEM contexts (e.g. Weintrop et al., 2016). These studies often advocate STEM as a particularly well-suited context to include CT, typically with references to epistemological overlaps, similarities in their focus on abstraction and logical thinking (primarily to mathematics), and potential synergies in the sense that CT can aid students' mathematical learning. There are however strong indications that these overlaps, similarities and potentials have not led to the anticipated outcomes. Recent empirical studies have not documented that including CT in mathematics education improves students' mathematical learning (e.g. Boylan et al., 2018), and it has proven difficult for even experienced teachers to connect CT and mathematics without neglecting one over the other (e.g. Elicer & Tamborg, 2023).

The recently developed term TCME (Jankvist et al., 2023) has paved the road for an alternative approach to accommodate the increasing need of preparing students to relate critically to digitalization in the surrounding society. Building on critical mathematics education (CME) (Skovsmose, 2023), the KOM-framework (Niss & Højgaard, 2019) and theory on the role of digital tools in mathematics education (e.g. Weintrop et al., 2016), Jankvist et al. (2023) argues that mathematics education holds the potential to support students' understanding of contemporary digital phenomena such as encryption and blockchains. A central contribution of TCME lies in the development of an approach to maintain the relevance of mathematics education in relation to digitalization in ways that does not involve knowledge outside the domain of mathematics, but activate curricular content in relation to new, relevant digital contexts. To illustrate this, Jankvist et

[2] KOM: Competencies and the Learning of Mathematics (Niss & Højgaard, 2019)

al. (2023) show how mathematics can be used to help students uncovering mathematics in action in Skovmose's (2023) sense. They however acknowledge that their examples of encryption- and blockchain technology, necessitates drawing on extra-curricular mathematics such as modulo operation and congruence. Together, research on CT and TCME have made substantial contributions in how STEM education can continue to play an active role in preparing students for a digitalized society. However, it remains a challenge to ensure that what students encounter in technology education in STEM contexts relates to how computer scientists work without simultaneously importing mathematical content beyond what is mandatory or exceeding the areas of expertise of in-service teachers. It is this issue that the present study seeks to tackle.

Theoretical approach

Similar to TCME, we base our study on the KOM-framework (Niss & Højgaard, 2019) and CME (Skovsmose, 2023). KOM was developed in 2002 and conceptualized "mathematical competence and mathematical competencies with particular regard to their possible roles in the teaching and learning of mathematics" (Niss & Højgaard, 2019, p. 10). KOM consists of 8 mathematical competences, which can be applied with many purposes, including designing curricula, describing and characterizing which competencies that are pursued in a given context, and to orchestrate, plan, and carry out mathematics teaching (Niss & Højgaard, 2019). In our study, we particularly rely on the modelling competency that "involves relating to and navigating within and across the key processes of the 'modelling cycle' in its various manifestations" (Niss & Højgaard, 2019, p. 16). We have chosen the modelling cycle developed by Niss (2015) illustrated in Figure 1 below.

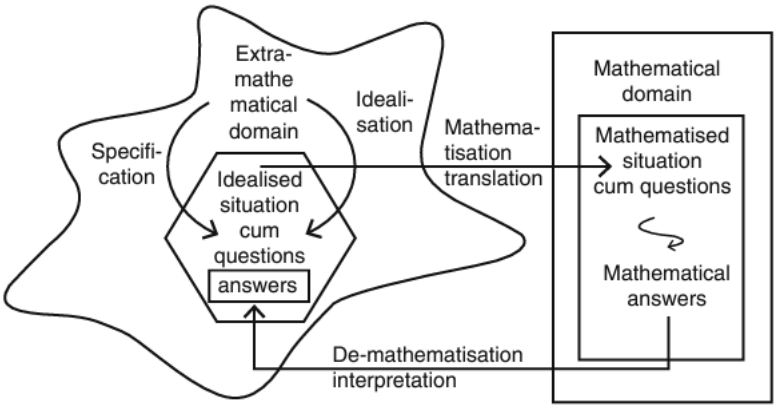

Figure 1: The modelling cycle as developed by Niss (2015, p. 68)

The modelling cycle in Figure 1 starts with a situation/problem in the *extra-mathematical domain*. This complex and often dynamic reality must be simplified to be treated mathematically. This is done by choices of *idealisation* and *specification*, leading to an idealised situation suitable for *mathematization*. The data now undergoes mathematical treatment, which leads to *mathematical answers,* which then must be *de-mathematised* or *interpreted* to *answer* the initial extra-mathematical question.

Our purpose for using this competency is to identify how it is exercised by computer scientists in research on bias and which changes similar modelling activities need to undergo to align with the Danish lower secondary mathematics curriculum. To fulfil this purpose, we rely on the three

dimensions of possessing any of the eight mathematical competencies: degree of coverage, radius of action, and technical level (Niss & Højgaard, 2019). *Degree of coverage* concerns the extent to which an individual possesses all the aspects that define the competency. In relation to the modelling competency, this regards all the steps in the modelling cycle illustrated in Figure 1. *Radius of action* regards the variety and range of contexts and situations in which the individual successfully can activate the competency. *Technical level* refers to level and span of "mathematical concepts, results, theories and methods which the individual can bring to bear when exercising the competency" (Niss & Højgaard, 2019, p. 21).

In addition, we inform our study by critical mathematics education (CME) (Skovsmose, 2023). One way of describing CME is by the objectives or aims it sets up for mathematics education, namely that mathematics teaching should support students in identifying, judging, and critically relating to the uses of mathematics in relation to societal issues. Here, mathematics is thus thought of as a tool that enables students' analysis and critique of a given societal reality or phenomenon (Jankvist et al., 2023). We draw on CME to specify the aim of integrating the T and M in STEM teaching, namely educating students to question the authority and neutrality of generative AI.

Methods and data

Our data consists of four research articles on algorithmic bias, all of which were supplemented by qualitative interviews with one of the authors of the paper. The research articles were selected from the criteria that they dealt with one or more issues related to algorithmic bias with a clear relevance for societal issues, and that they involved some aspects of what could be considered mathematical modelling. The main purpose of the interviews was to gain insights into the authors' perspectives on algorithmic bias, specifically how to uncover and mitigate bias within AI. We aimed to explore both the theoretical and practical dimensions of their research, including the methods they used and the mathematical foundations underlying their approaches.

In this paper, we present an analysis of one of the four papers in our study, namely Sterlie et al. (2024), and insights from an interview with one of the authors of the paper. Our analysis of both the paper and interview followed a deductive, theory-driven approach (Byrne, 2021), informed by the modelling competency and Skovmose's (2023) notion of CME. In our analysis of the paper, we searched for activities similar to the sub-processes of the modelling cycle and related these to possible student activities within lower secondary mathematics curriculum. The interview analysis sought to explore the opportunities of ensuring a focus on societal implications of technology.

Results

As stated, Skovsmose (2023) highlights the role of mathematics education in enabling students to critically assess how mathematics is applied in societal contexts. One such context is generative AI. In our interview the respondent says: "When ChatGPT is asked to link gender to jobs, the model often shows bias by associating certain jobs with specific genders". Such biases become embedded in the outputs of AI, reinforcing societal biases, and mathematics becomes a critical tool for uncovering these biases. However, the respondent emphasizes that many people don't think too much about these biases:

> The modern and progressive appearance of AI technology can easily lead us to gain their trust […] It's a model, and it's math. So, for people who don't have a great understanding of math or AI it is easy to think that it is safe and fine.

Jankvist et al. (2023) also mention this unquestioned authority of technology and according to Skovsmose (2023), there is a need for challenging this trust by critically studying the implications of the mathematics underlying these systems and their potential societal impact.

In their paper "Generalizing Fairness to Generative Language Models via Reformulation of Non-discrimination Criteria", Sterlie et al. (2024) reformulate and test three non-discrimination criteria (independence, sufficiency, and separation) in different GPT models. These criteria, known from classification in machine learning, are applied to generative AI for the first time. To provide as rich and nuanced an analysis as possible, we limit our focus to the independence criteria. Independence is tested using the prompt depicted in Figure 2.

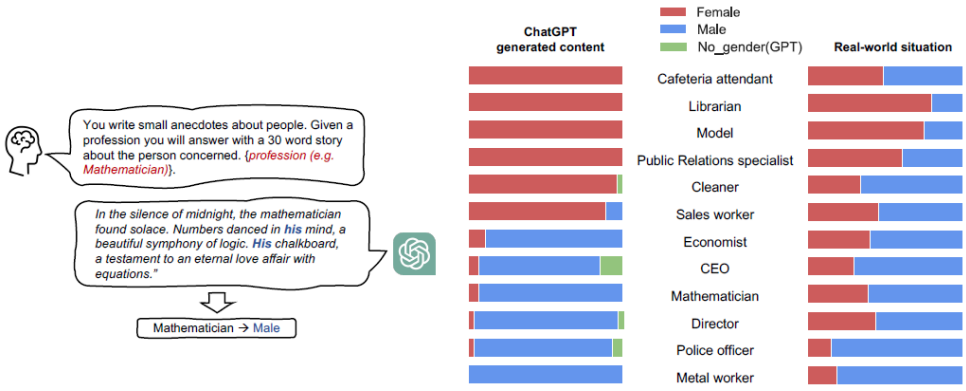

Figure 2: Prompt, answer, classification and presentation (Sterlie et al., 2024, p. 2)

Sterlie et al. (2024) investigate if ChatGPT exhibits independence between gender and profession. We now characterize their work by means of the modelling competency with respect to degree of coverage, radius of action, and technical level as defined by Niss & Højgaard (2019).

The *extra-mathematical domain* in their study is ChatGPT. Sterlie et al.'s (2024) *idealization* of ChatGPT consists of choices that reduce the level of complexity, including focusing on the text-to-text function, considering 2 genders, testing 100 professions 30 times, and using the same prompt every time. The *specification* concerns how to identify the gender in the ChatGPT text output. They identify this automatically using a small Python program[3] that conducts a categorization based on the titles and pronouns. If none of these titles or pronouns are present in the ChatGPT text output, or if the same number of male and female titles/pronouns are present, the gender is labelled NA and deemed neutral. *Mathematization* is the quantification of genders and professions. In the mathematical domain, Sterlie et al. (2024) follows three distinct paths: graphical representation using bar charts (see Figure 2), calculation of correspondence with prevailing stereotypes, and calculation of the normalized mutual information (see Figure 3).

[3] https://github.com/sterlie/fairness-criteria-LLM/blob/main/Exp1%20/gender_mapping.py

$$MI[p_{ac}] = H[p_a] + H[p_c] - H[p_{ac}] \qquad NMI[p_{ac}] = \frac{MI[p_{ac}]}{\sqrt{H[p_a]}\sqrt{H[p_c]}}$$

Figure 3: The formula for normalized mutual information (Sterlie et al., 2024, p. 6)

The mathematized results are then *de-mathematized/interpreted* in the context of the idealized situation. The bar chart is compared with statistical data on gender distribution from the USA, providing a basis for comparison between the output of ChatGPT and real-world data. Sterlie et al. (2024) conclude that "The results reveal a highly stereotypical behaviour in GPT-4. 94 percent of generated samples reflect prevailing stereotypes" (p. 11).

We now explore whether and with which modifications the modelling activity above can be imitated within the Danish lower secondary mathematics curriculum (grades 7-9) (Børne- og Undervisningsministeriet, 2019). If students are to go through a similar modelling activity, they need to perform similar *idealizations*. This process is well known in Danish classrooms since the modelling competency is a mandatory part of the curriculum. This entails that students should learn to delineate problems from the real world and create a mathematical model (Børne- og Undervisningsministeriet, 2019, p. 8). Before the actual modelling can start, students need an understanding of the real-world problem. In this case, it requires an understanding of the capabilities of generative AI, of the independence criteria, and of the relationship between the sensitive attribute (gender) and the property they wish to work with. It is worth noting that replicating the mathematical modelling done by Sterlie et al. (2024) in lower secondary school contexts does not require using the exact same property. A different property may lead to a similar mathematical modelling, since the independence criteria is described as "[...] satisfied if A ⊥ C for any relevant property C" (Sterlie et al., 2024, p. 6). Regardless of the chosen property, the scale of the data will likely need to be smaller than that of Sterlie et al. (2024). Since programming is not part of the Danish curriculum, students will need to prompt and categorize the gender of the texts manually. Since we are so used to decoding simple content like gender from a sentence, the *specification* will likely go unnoticed if no particular attention is paid to it. In the *mathematical domain*, students can count and create graphical representations by hand, but they will demonstrate a larger degree of coverage by using spreadsheets and =COUNTIF(), since this is a scalable solution. This also ties into one of the knowledge goals of the curriculum stating that students should acquire knowledge about statistical descriptors, charts, and digital tools to process large amounts of data (Børne- og Undervisningsministeriet, 2019, p. 8). In accordance with the curriculum, students must choose a representation they find adequate for assessing and communicating their findings. This *de-mathematization* will be different depending on whether real-world data exists or not for the given property. If no real-world data exists, they will need to rely on intuition when judging whether and how the output is biased. Using the same *idealization* and *mathematization* but different mathematical analysis, the students can also calculate how many percent of the stories created that reflect the prevailing stereotypes and compare directly to the results of Sterlie et al. (2024).

It is our hypotheses that students are likely to go through the steps of the modelling process in a similar way to Sterlie et al. (2024), but adaptations to fit lower secondary school mathematics are needed at the *technical level*. Sterlie et al. (2024) utilize programming to automate the data processing, but the same processing can be done in a more handheld way, suitable for lower secondary

students. The calculation of mutual information (Figure 3) relies on entropy calculations, which are beyond the technical level of the lower secondary curriculum but are taught in upper secondary. Therefore, this type of data processing should not be part of the students' work. Both Sterlie et al. (2024) and lower secondary students are expanding their *radius of action* albeit in different ways. Sterlie et al. (2024) are familiar with the non-discrimination criteria but are looking to expand how it can be used thus getting a tool to measure bias in generative AI. Students are likely to have worked with modelling of taxi-drives or mobile phone subscriptions before, but bias in generative AI is almost certainly a new context thus expanding their radius of action of the modelling competency.

Discussion and conclusion

Our approach tackles several previous difficulties encountered in research on CT, particularly balancing disciplinary knowledge from CT and mathematics (Børne- og Undervisningsministeriet, 2020; Elicer & Tamborg, 2023). The modelling competency, radius of action, degree of coverage, and technical level can provide a terminology that helps to identify modelling processes that can be replicated by students, while also highlighting technical elements that may need to be simplified or omitted to adhere to the curriculum. We consider it pivotal that students experience the power of mathematics and gain an understanding of the issues computer scientists study, but not that students perform exactly the same tasks. Our paper suggests that it is possible for students to work with similar problems and reach similar results. Even within the curricular guidelines, students can likely conduct similar modelling activities, although at a different technical level. Algorithmic bias can be seen as emerging from a composition between a domain specific context and mathematical modelling that is built into an algorithm. The research analysed in our paper requires a combination of understanding the capabilities of generative AI, the independence criteria, and intuition of gender distribution in various profession. A consequence of this is that our study is limited to addressing the T and M of the STEM acronym. However, algorithmic bias appears in many contexts, not least such that involves the natural sciences. As an example, automated image recognition of x-rays has proven to be more effective for medical diagnostics of men than women (Weng et al., 2023). Addressing such problems is likely to call for activation of the S, along with the T and the M. Seen in this light, STEM education and its interdisciplinary nature could hold the potential to constitute a highly constructive starting point for educating students to critically and constructively relate to algorithmic bias. It is our hope that the approach presented in this paper can aid future studies that explore how STEM can prepare and empower students to participate and contribute to an increasingly digitalized society.

(STE)M teachers competence areas in MINTco@NRW: Evaluation of and reflections induced by a mathematics educational model

Gero Stoffels[1]

[1]University of Cologne, Institute for Mathematics Education, Germany; gero.stoffels@uni-koeln.de

The demands on teachers in supporting STEM teaching and learning are complex. In mathematics education, specific research questions arise in teacher education and training: What competencies should teachers possess? How can teachers be supported in their work? To what extent do these aspects go beyond discipline-specific teaching? This article addresses how teachers rank the importance of various competence areas in the MINTco@NRW project through a multiple instrumental case study. The results show a big variation in teachers' rankings, which cannot be easily linked to specific characteristics of the cases in the sample. The similarities and differences in the necessary competence areas in the project and regular classroom settings depend on the specific competence area in question.

Keywords: Reflection process, mentors, teachers' competencies, STEM education.

Teachers' competencies in mathematics-related STEM teaching and learning

The importance of STEM literacy and competencies among students is particularly emphasized in the context of 21st-century skills and similar initiatives (Basham et al., 2010; Falloon et al., 2020). The desire for integrated STEM education is also a focal point (Roberts et al., 2022), raising questions about how STEM should be conceived and organized–whether as individual disciplines or as an interconnected network (Blum & Niss, 1991; Falloon et al., 2020). This brings up the challenge of ensuring that disciplinary knowledge and skills, especially in mathematics, continue to be developed, as mathematics is often perceived as underrepresented in integrated STEM settings (Maass et al., 2019; Roberts et al., 2022). One key approach could be through "high-quality STEM learning experiences" (Roberts et al., 2022, p. 2), where students use different STEM disciplines collaboratively to solve real-world problems. These learning environments pose significant challenges for teachers, adding to the usual complexity of their work (Beswick & Fraser, 2019). Therefore, it is crucial to consider what competencies (math) teachers need, how they can be trained, and what support they require to meet these challenges (Maass et al., 2019). In integrated STEM settings, teachers often need to collaborate with various partners and address STEM disciplines beyond their expertise–and possibly their comfort zone (Priemer et al., 2020). Besides the necessary competencies and skills, teachers' beliefs also play a crucial role. Reflecting on their own role (Artzt et al., 2015) and competencies is essential for successful teaching in these "high-quality STEM learning experiences". These diverse challenges necessitate a closer look at the complex nature of teacher competencies.

There are numerous models of teacher competence. For example, Bloemeke et al. (2019) propose a general model describing teacher competence, explaining the continuum from teachers' dispositions through situation-specific abilities to performance. This model identifies general areas of competence, bridging general pedagogy and subject-specific aspects. In STEM education research, there are also specific models. Mondisa et al. (2021) describe the A STEM-ME framework, which

outlines interactions between different stakeholders in STEM ecosystems, such as mentors from various subjects. Beswick & Fraser (2019) developed the STEMCrAfT framework to support (novice) teachers in STEM teaching at different levels through reflective questions on specific teacher activities and learning environmental aspects, including preparation, planning, context, resource use, support considerations, and implementation evaluation. Other models focus often on specific competence areas, like digital competencies. Each model has a different scope of application and offers various perspectives on teacher competence. When teachers engage with a model, it may be useful to choose those that are relatively easy to grasp and allow reflection on specific areas of competence in their practice. A proposal for such a model was developed as part of MINTco@NRW.

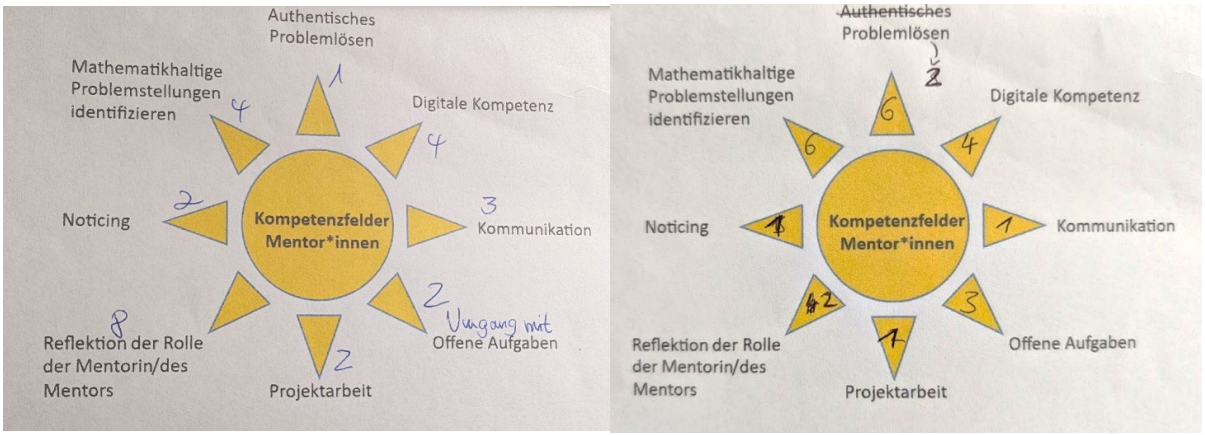

Figure 1: Ranking (1 is most important to lower numbers less important) of competence areas by T1 (left) and T2 (right)

The MINTco@NRW project creates a unique situation for teachers in North Rhine-Westphalia (NRW) by implementing long-term problem-solving of real mathematics-related problems in regular classes. It focuses on unsolved mathematics-related problems from companies, which are collaboratively solved by learners in solver teams of 4-6 German and US students. Thus, teachers are expected to act as cooperation partners for companies and mentors for their students, similar to Mondisa et al.'s (2021) conception of mentoring that supports the growth of learners. To support teachers in this multifaceted and challenging situation, a simplified model (Marx & Stoffels, 2023) was developed based on existing models and experiences from previous projects regarding the central activities of preservice teacher-student mentors (Stoffels, 2023). The aim of constructing the model by Marx & Stoffels (2023) was to emphasize central areas of competence for mentoring in the project, make them visible to teachers, and encourage reflection on these competence areas.

The identified competence areas in the model are (cf. Figure 1): (i) mathematics-related problem posing (Mathematikhaltige Problemstellungen identifizieren), (ii) solving authentic problems and mentoring authentic problem-solving processes (Authentisches Problemlösen), (iii) digital competence/digital literacy (Digitale Kompetenz), (iv) communication (Kommunikation), (v) teaching and learning using open-ended tasks (Offene Aufgaben), (vi) project-based learning (Projektarbeit), (vii) noticing, and (viii) reflection on the role as a mentor (Reflektion der Rolle der Mentorin/des Mentors).

The competence areas (ii)-(vi) are parts of models addressing teacher competencies for 21st-century learning (Beswick & Fraser, 2019). Subject-specific competence areas (i) and (ii) can be connected to the cognitive competence facets of teacher competence related to MPCK (Bloemeke et al., 2020). Noticing, understood in this model as attending to aspects in problem-solving situations and interpreting them based on professional knowledge and beliefs (Dreher et al., 2021), is connected to reflecting on the role of the teacher as a mentor (Artzt et al., 2015), focusing on student growth and supporting their solving process without leading to the teacher's solution of the problem. Both competence areas were added due to less effective mentoring in predecessor projects but are also implicitly addressed in already mentioned models (Bloemeke et al., 2020; Beswick & Fraser, 2019).

Based on these theoretical considerations and the aim of constructing the model, the general question arises whether, from the teachers' perspective, the model by Marx & Stoffels (2023) is adequate for the project. More precise research questions are:

- Do teachers, looking back at the project, think that the model by Marx & Stoffels (2023) sufficiently identifies the necessary competencies of a teacher in the project?
- Can the competencies be organized according to (perceived) importance? If so, what would this ranking look like?

From a broader perspective, it is also interesting to explore to what extent the model is perceived as project-specific or whether teachers consider it transferable to regular teaching. Therefore, another research question is:

- In what ways do teachers address similarities and differences between the competence areas necessary in the project and regular (mathematics) lessons?

Methods

The teachers' mentoring in the MINTco@NRW project is investigated through an instrumental embedded multiple case study (Yin, 2014). This case study aims to examine the overarching questions of what competencies teachers need to support such long-term problem-solving processes, how these competencies differ from those required in their regular teaching, and what support and further training needs they have according to the analysis. In this paper, I discuss only a part of the case study, focusing on the previously formed research questions and specifically on teachers from NRW. Teachers from the USA are also considered in the broader case study and will be discussed in further publications. After a brief description of the study's context, the data collection and analysis are presented.

Context of the case study

The general structure of MINTco@NRW is similar to its predecessors (Stoffels, 2023). The project started in January 2024 with a "Kick Off" where companies hand-over their real problems to students. After that the students had four months to solve the problems, which includes also a company visit. The "Forum of Innovation" in May 2024 was the culmination and end of the project, in which the Solver Teams present their solutions to the companies.

Table 1: Number of participating students and their age per school

	T1, T2	T3	T4	T5, T6	T7
Number of participating students	13	14	6	12	4
grade level	9	8-9	8-11	9	9
age	14-15	13-15	13-17	14-15	14-15

An important difference from the predecessor projects is that in MINTco@NRW, mathematics teachers served as the mentors, presenting them with the challenges already addressed in the first section. The hope is that mathematics teachers, due to their teaching experience but also professional development, can improve the support of the students compared to preservice teacher students' support in the predecessor. This article focuses on four schools from NRW and one other German school. In these schools, six teachers from NRW (T1-T6) and two teachers from outside NRW, who jointly participated in the interview and ranked the competencies together (T7), were part of the project. Throughout the project, all teachers supported their students in extracurricular STEM clubs, which met for 90 minutes per week. The students regularly meet with their counterparts in the USA for 20-60 minutes per week via videocall, depending on the schedule of the partner school in the USA. The number of participating students, grade levels, and age groups varied (cf. Table 1).

Data collection

The data discussed in this paper is part of the final semi-structured interview (Naz et al., 2022) with the German teachers. Each interview consisted of three parts and lasted between 1 to 1.5 hours. All interviews were conducted in person and videotaped, except for the interview with both teachers in case T7, which was conducted via Zoom, resulting in a joint ranking of the competence areas (cf. Table 2). In the first part, general aspects of the project implementation were discussed. The second part focused on the areas of competence shown in Figure 1. A diagram of the model was used to elicit responses from the teachers, allowing them to grasp all competence areas simultaneously without a hierarchy, and the ranking could be done on paper. This visual prompting leads to the collection of richer data, even when diagrams or figures with text seem to encourage respondents to focus on the text in the diagram (Page et al., 2022). Participants were asked to review the competence areas and, if they wish to add additional competence areas to the model. The next task was to rank the competence areas in order of importance for their work in the project, starting with 1 as the most important competence area. Afterwards, the teachers explained how they chose their ranking. At the end of the second block of the interview, the teachers were asked to what extent these competencies are also relevant in regular lessons. Figure 1 was available to the interviewees in German, so the ranking could usually be recorded in writing on the model.

Data analysis

For ranking the given competence areas, the ranks were transferred for each case into Table 2 to compare the teachers' ranking. The data of the ranking is ordered on an ordinal scale, as the importance is reflected in different or same ranks. To get an overview of the different rankings by the teachers and compare them, the last row of Table 2 shows the mode of the rankings of the different

competence areas. The mode is the value that appears most often for each competence area, providing insights into the variation in the ranking per competence area and indicating which competence area seems to be most or least important. All interviews were AI-supported transcribed using aTrain (Haberl et al., 2024) and analyzed using MaxQDA. The transcripts were revised, and the second part of the interview was then analyzed using an inductive summarizing qualitative content analysis (Mayring, 2015) to answer the first and third research questions.

Results

The first research question addressed at the beginning of the second interview part was whether teachers, looking back at the project, think that the model by Marx & Stoffels (2023) sufficiently identifies the necessary competencies of a teacher in the project. Most participants did not want to make any additions to the present model. This might be due to the number of competence areas in the model, which requires time to fully grasp. As part of project work, T7 discussed that it should be emphasized that deadlines must be met, and that attention must be paid to compliance with the companies.

Table 2: Number of participating students and their age per school

	authentic problem solving	**digital comp-etence**	**com-muni-cation**	**open tasks**	**project-based learning**	**reflection of the role as mentor**	**noticing**	**problem posing**
T1	1	4	3	2	2	8	2	4
T2	2	4	1	3	1	2	1	6
T3	5	5	1	3	3	4	2	5
T4	3	2	2	4	5	3	1	4
T5	3	7	1	5	2	4	8	6
T6	2	2	1	-	1	-	-	2
T7	5	5	4	5	1	3	2	3
mode T; Germany	2;3;5	2;4;5	1	3;5	1	3;4	2	4;6

The second research question was how teachers rank the different competence areas in the model. For most teachers it was not an easy decision to rank the competence areas. For example, one teacher states after she did her ranking: “Yes, it also just seems wrong, ... because afterwards something like posing the problem, ... gets the biggest ... number, ... feels wrong. ... But on the other hand, I think ... maybe that's ... rather, or I left it to the students. ... And more or less kept me out of it” (T4, pos. 83 [translated by G.S.]).

Nevertheless, almost all teachers ranked the competence areas (cf. Table 2). T6 did not rank all given competence areas. Overall, the ranking of the competence areas is very diverse. Except for the

competence areas digital competence, open tasks, reflection on the role of the mentor, and problem posing, each competence area is rated as most important at least once. Except for the competence area communication, every other competence area is also assigned the lowest importance at least once. To obtain a general overview of the importance of the individual competence area, the statistical mode of the rankings per competence area is given in the last row of Table 2. Accordingly, communication and project-based learning are rated as most important by most teachers, followed by noticing. All other competence areas are in the middle range, except for problem posing at the end of the spectrum. This could be explained by the fact that in this project cycle, the problems were identified with the companies prior to connecting them with the teachers. Reflection on the role as a mentor was also considered at the very end of the spectrum. The wide variability in the rankings may be due to specific requirements and experiences in the project. For example, the evaluation of the importance of the competence area "digital competence" seems to be dependent on how successful the work with the digital cooperation media was experienced. For an intensive analysis of the reasons, it seems necessary to also connect the single cases to their U.S. counterparts.

The last research question was how teachers address similarities and differences between the competence areas necessary in the project and regular mathematics lessons based on the given model. Some teachers considered all competence areas to be important for regular mathematics lessons. All competencies were also explicitly mentioned at least once by a teacher as being relevant for regular mathematics lessons. Authentic problem solving (Vos, 2018) and digital expertise were mentioned particularly often. Project work and open tasks were either mentioned as less connected to the classroom or as highly teacher-dependent in their use. Regarding open tasks, assessment of students, time restrictions, institutional framework conditions, or a lack of student independence were often referred to as challenges for their implementation. These aspects are well-known challenges for problem-based learning and open tasks in regular classroom settings (Beswick & Fraser, 2019). Particularly in view of the mathematics-related nature of the transfer of competencies to regular classroom settings, specific competencies from the model were often addressed similarly to pedagogical knowledge as well as subject-specific in the sense of mathematical pedagogical content knowledge (Shulman, 1986): "Communication, understanding, ... again students who misunderstand you ... and I don't just mean in terms of content, but ... at the level of what you do in terms of pedagogical work ... and so on. So that's definitely not ... only related to math, but ... everywhere. If I understand communication, math as a language, ... that is a different aspect" (T4, pos. 148 [translated by G.S.]).

Conclusions & Outlook

The teachers in NRW who participated in MINTco@NRW report that the model by Marx & Stoffels (2023) is adequate for describing key competence areas of teachers in the project. The teachers' ranking of the importance of the competence areas in the model varies widely, and the ranking process shows that it was not easy for most teachers to find a definitive ranking of the importance of the given competence areas. This difficulty might be due to the general complexity of teacher competencies (Bloemeke et al., 2020; Beswick & Fraser, 2019) or the new context of the project, similar to Nicol (2002), who describes challenges faced by pre-service teachers when first encountering the workplace. From the teachers' perspective, the competence areas of the model are

also relevant in regular classes. Individual differences between the participating teachers can be seen, ranging from broad agreement to major differences depending on the competence area in question. These differences can partly be traced to traditional arguments about why it is not possible to implement project- or problem-based learning in schools.

Of course, the presented study has some limitations. First, the cases are special, as all interviewed teachers were highly motivated to participate in the project and experienced intensive and long-term mentoring of students solving real problems from companies. Additionally, the perspectives of the U.S. counterparts of the teachers could not be discussed in more detail in this paper but might provide further insights into the reasons for the teachers' rankings, as exemplified by the competence area "digital competence". Nevertheless, the results suggest that future support for teachers in mastering their tasks while mentoring STEM learning needs to be individualized. In following research cycles of the MINTco@NRW project, the aim is to mentor in regular classes with regular curriculums, which might provide further insights into STEM learning environments similar to MINTco@NRW.

Presence of mathematical processes in STEAM high school projects: a case study

Ainhoa Berciano[1], Jon Anasagasti[1] and Josune Landa[1]

[1]University of the Basque Country, Faculty of Education of Bilbao, Leioa, Spain;
ainhoa.berciano@ehu.eus

Keywords: STEAM, mathematical process standards, high school education, mathematical competence.

STEAM Education

In the current educational context, STEAM projects, which integrate science, technology, engineering, arts and mathematics, offer the possibility of working with complex concepts in a practical and meaningful way. Several research studies support the benefits of STEAM projects in secondary education with respect to different aspects of education; among them, Wahyuningsih et al. (2020) highlight that STEAM projects require the application of knowledge in real-world contexts and often involve problem solving that requires critical thinking and creativity. However, Ubuz et al. (2023) state that '*it is difficult to know how to integrate STE(A)M subject matters, how to design STE(A)M tasks and implement them with students'*. Thus, restricting our interest to mathematical competence, Diego-Mantecon et al. (2021) raise doubts about whether interdisciplinary projects are adequate to exploit school mathematics effectively; where, according to the National Council of Teachers of Mathematics (2000), the acquisition of mathematical competence should include work on the following mathematical process standards: reasoning, representation, connection, communication and problem solving.

Method

The aim of this study is to analyse the mathematical process standards that emerge in three STEAM projects implemented in three compulsory secondary schools in the Basque Country (see table 1). For this purpose, a qualitative methodology with an interpretative approach (Cohen, Lawrence, & Keith, 2007) has been selected to analyse: 1) the mathematical content and mathematical processes that teachers have considered in the design of the project and 2) the mathematical processes that emerge from the design of the activities created by the teachers in each project. To answer 1), semi-structured interviews were carried out with the teachers involved, and to answer 2), the type of activity defined and its relationship with the mathematical processes were analysed.

Table 1: Characteristics of the projects analysed

Project	STEAM context	Disciplines involved	Course	Age of students
P1	Witchcraft and cooking	History, physics, chemistry, language, mathematics	1st course	12-13 years
P2	Ecosystems in parks	Biology, language, mathematics	1st course	12-13 years
P3	Blood pressure in different contexts	Physics, chemistry, language, mathematics	3rd course	14-15 years

Results and conclusions

Table 2: Incorporation of the mathematical process standards

Project	1a) Mathematical content/sense	1b) Mathematical Processes in the design	2) Mathematical processes in the activities
P1	Proportionality. Numerical sense	Problem solving, connections	Problem solving, connections, reasoning, communication (written), representation
P2	Geometrical measures. Spatial sense.	-	Communication, representation
P3	Data analysis. Statistical sense	-	Communication, representation

From the analysis of the interviews, we can conclude that, in general, the teaching staff do not consider mathematical processes to be a fundamental part of the design of the projects and the incorporation of mathematics is more instrumental in nature. However, from the analysis of the activities proposed, we can see that some of the mathematical processes are involved (see table 2), which shows the need to further explore the importance and necessity of their inclusion in these projects.

Keywords: Mathematics education, STEAM education, Sustainable Development Goals, clean water and sanitation, hands-on.

There is an increasing call for the promotion of STEAM (Science, Technology, Engineering, Arts and Mathematics) education. This approach is recommended to improve students' performance and better prepare them for real life challenges and can also contribute to improve mathematics teaching (Costa et al., 2022; Stohlmann, 2018). However, despite an increasing number of projects in this field, there are several issues about its implementation, namely about an integrated approach of STEAM and the role of mathematics in this context, as well as teachers' knowledge and skills to be able to implement this approach in class (Costa et al., 2022; Maass et al., 2019).

This poster presents a lesson plan designed in the context of the Erasmus + project, ProSTEAM - PROmoting STEAM in primary school: partnership for disseminating good practices, with the duration of three years from February 2022 to January 2025. In the first Intellectual Output (IO) of the project, it was necessary to verify the curricula of the partner countries to find similar contents to develop the project. In the second IO, a pedagogical framework was designed to guide the development of the lesson plans, which were designed with a Design Research (DR) methodology (Plomp, 2013) by university experts in collaboration with primary school teachers from nine European partners. The plans are intended for teachers to autonomously be able to implement an integrated approach of STEM education in class. It is the case of the "Water and Sustainable Development Goals (SDG)" plan that was developed by the authors of this Poster. This plan is focused on SDG 6, drinking water and sanitation that stands out, drawing attention to the importance of water, the need for responsible consumption, as well as finding ways to store and reuse water for efficient management of this resource (Mateus et al., 2022). Table 1 presents the five cycles of design research that were conducted to develop the plan. In the end, all plans will be included in a teachers' guide to be disseminated in an online community of practice for everyone to have access to the available resources. It was only after being validated by all the partners of the ProSTEAM project that the plan was implemented in a teachers Professional Development Programme in Portugal (PDP) and in Lithuania with a total of 40 teachers. All the plans were implemented in at least two countries.

Table 1: Cycles of design research of the Water & SDG plan

DR cycles	Development of the Water & SDG plan in the ProSTEAM project	Duration
First cycle	Design of the plan by experts from university and school teachers	3 to 4 months

Second cycle	Implementation of the plan in the primary school teachers classes	3 months
Third cycle	Revision of the plan based on the feedback of all the parners	2 months
Fourth cycle	Implementation of the plan in a teacher PDP	4 months
Fifth cycle	Plan revision based on the feedback of the participants in the PDP	2 months

Besides several STEAM tasks proposed in the plan, tables were proposed to be filled by students for them to understand the water that is wasted for example when washing teeth and hands. Table 2 is an example filled by students in class supervised by the teacher who participated in the PDP.

Table 2: Brushing teeth with the water running or closing the tap

	Water running	Closing the tap	Water saved
1 student once a day	4 litres	1 litre	3 litres
Class with 20 students	80 litres	20 litres	60 litres
Class twice a day	160 litres	40 litres	120 litres

Based on the five cycles of DR and on a qualitative methodology and interpretative approach, with participant observation (Cohen et al., 2007; Plomp, 2013), it is concluded that the plan was approved by teachers who found it to be appropriate for school curricula. Also, they recognized the importance of this approach to motivate students to learn. Finally, they referred that they intend to keep developing this approach in the next school years, namely implementing other plans of the project.

Identifying mathematical content in a carpentry Instagram video: A study with pre-service secondary education teachers

Zaira Ortiz-Laso[1], José Manuel Diego-Mantecón[1] and Camilo Sua[2]

[1]Universidad de Cantabria, Faculty of Sciences, Santander, Spain; zaira.ortiz@unican.es

[2]Universitat de València, Spain

Keywords: Integrated education, Instagram, social media, STEM education, world of work.

Introduction

Integrated science, technology, engineering and mathematics education (i-STEM) has been incorporated into the curricula of various countries. This approach seeks to provide contextualised or real tasks for students to connect knowledge and skills from the four disciplines (Ortiz-Laso et al., 2023). Central to this approach is the establishment of connections between the world of work and the disciplines (Maass & Engeln, 2019). In carpentry, various mathematical fields, including geometry, are employed (Saló i Nevado & Pehkonen, 2018), and carpenters use techniques to optimise the design of any product (Diego-Mantecón et al., 2021).

Tasks involving the i-STEM approach and connections to the world of work are scarce in current curricular materials (e.g., textbooks). This is why professional development programs have focused on providing these types of tasks (Maass & Engeln, 2019; Ortiz-Laso et al., 2023). Social media platforms, particularly Instagram, widely used by in-service and pre-service teachers (Carpenter et al., 2020), increasingly serve as resources for real-world tasks associated with i-STEM projects. For teachers to effectively implement these real-world tasks into their teaching and thus engage with i-STEM projects, not only mathematical knowledge is required but also contextual knowledge related to the techniques employed by professionals (Diego-Mantecón et al., 2021).

Objectives and method

This study examines how fifteen Spanish pre-service secondary education teachers analyse the technique employed by a carpenter in an Instagram video and how they identify the underlying school mathematical content associated with this real-world task. The participants, who took part voluntarily, were enrolled in a one-year master's degree to become secondary education mathematics teachers. The video, sourced from the *Carpintero de los Cerros*' (2022) Instagram account, showcases a professional demonstrating how to divide a wooden plank of decimal width into three equal parts. The Cerros' account was not initially intended for teacher training but rather to display effective carpentry techniques and tips.

Data were collected using a questionnaire after viewing the video with no sound as many times as necessary. The questionnaire comprised two open-ended questions: the first asked for a narration of the video, while the second focused on identifying the mathematical content underlying the carpenter's technique. The analysis involved an interpretative qualitative examination of the written responses. The first question was coded as correct when explaining that the video demonstrated how

to divide a segment into three parts. The second question was coded as correct when identifying Thales' theorem as the mathematical content underlying the carpenter's technique.

Results and conclusion

Concerning the first question, most pre-service teachers correctly identified that the carpenter was dividing a wooden plank into three equal parts. They noted that, rather than performing decimal division, he used an alternative strategy to avoid calculating $5\ cm\ \div\ 3$. Additionally, most described the procedure, explaining that he drew a segment ($\overline{AB}$) whose length is a multiple of 3 and depicted two points on it. Some interpreted the two points as the addition of the vector $\frac{1}{3}\overrightarrow{AB}$ and the vector $\frac{2}{3}\overrightarrow{AB}$ to point A, whereas the others understood them as the result of a division. All the pre-service teachers referred to the parallel lines drawn by the carpenter that contained the two points.

Regarding the second question, only about half of them infer Thales' theorem as the principle behind the carpenter technique. This study reveals that pre-service secondary teachers with strong disciplinary knowledge struggle to connect school mathematics with real-world applications. Teachers need to be familiar not only with mathematical content but also with their applications, as they are expected to teach these in context. We recommend using real-world tasks to help pre-service teachers understand the mathematics underlying professional techniques. This approach will support the classroom implementation of i-STEM projects, as many school curricula recommend. Given the challenges universities face in collaborating with workplaces, we suggest using social media to find videos like the one shown.

Teachers' design of STEAM activities: different levels of connections

Livia Silvestri[1] and Gabriella Pocalana[2]

[1]University of Tuin, Italy. livia.silvestri@unito.it

[2]University of Pavia, Italy. gabriella.pocalana@unipv.it

Keywords: STEAM; teacher professional development; connections; interdisciplinarity.

Introduction: different types of connections in the STEAM-Connect project

This research is conducted within the framework of the Erasmus+ Project STEAM-Connect, involving scholars of five European universities in collaboration with mathematics secondary school teachers of the same countries (from 2 to 5 per country, participating on a voluntary basis). Teachers of different disciplines involved by math teachers during the project. The goal of this collaboration is to design and implement STEAM activities for secondary schools (Pocalana et al., 2024). The shared meaning given to the letter A in STEAM includes art, music, and humanities, according to literature (e.g., Preignat & Katz, 2019). One of the main aims of the project is the creation of different types of connections between the actors involved in the project. In this study we investigated two types: the *vertical connections* (between teachers and researchers, as subjects belonging to different institutions) and the *horizontal connections* (between teachers of different disciplines or schools).

Research aim and methods: teachers' interviews and representations

In this study, we aim to investigate how connections influence the design and implementation of interdisciplinary STEAM activities. Interdisciplinary teaching is a form of collaborative teaching in which, according to Lester and Evans (2009), all the teachers are responsible for planning the activities, deciding how the class material should be presented, providing the instruction, assessing student learning. According to the case study methodology, we analyse the work of six math teachers involved in the STEAM-Connect project of three different countries (Italy, Austria, Luxembourg) and from different school programs (no STEAM curriculum). We conducted online interviews with the teachers and analysed them through a qualitative content analysis (Cho & Lee, 2014) approach. We asked the teachers to represent and to explain their idea of interdisciplinarity and to verify the use of this teaching approach in the design of their STEAM activity. We grouped the interview data in categories (Semeraro, 2011) highlighting the development of connections in teachers' teamwork. We focused on the role of math teacher in collaboration with teachers of other disciplines. Finally, we investigated the sustainability of the use of this teaching approach in daily school practice.

Results and discussion: towards a multidisciplinary approach

From the data analysis we derived teachers' ideas on the collaboration of different disciplines and teachers in the design of the STEAM activity and the different types of connection between teachers and researchers. T1 (high school) told us about three design phases of the activity. The changes made in the evolution of the activity were due to the involvement of teachers from different disciplines (*horizontal connections*) and reflections with researchers (*vertical connections*) on didactic approaches and interdisciplinary activities. T1 provided various definitions and representations of

interdisciplinarity that reflect the evolution of the activity design. T2 (high school) worked alone from the beginning: no *horizontal connections* and no *vertical connections*. T2 reports no evolution in the design of the activity and represents the need of interdisciplinarity to "put everything we've torn apart back together" through a cylinder and its orthogonal projections says: "if we approach reality from different disciplines, we see just a part of it". T3 and T4 (technical institute) worked at the same activity in different stages: T3 designed the activity by himself, T4 started collaborating in subsequent moments (no *horizontal connections*). They represented interdisciplinarity in a concept map with the disciplines involved in the activity. T5 (middle school) worked with three different disciplines teachers on the design of the activity (*horizontal connections*). The definition of interdisciplinarity was presented by the researcher but T5 recognized this teaching approach in his own activity. T5 represents a big pot with many ingredients: "to put them together you can cook something delicious". T6 (middle school) reports changes in the design process thanks to the involvement of different teachers (*horizontal connections*) and the exchange with the researchers (*vertical connections*). T6 provides different representations of interdisciplinarity that changed during the design phases. We conclude that the development of connections, both *vertical* and *horizontal*, allowed for a process of evolution in the design of STEAM activities leading towards an increasing level of meta-disciplinary competence (William & Roth, 2019), that is the awareness of the role of each discipline in dialogue and activity with the others. This can be seen in T1 and T6, who described an evolution in the designs following discussions and reflections with researchers and other teachers and in T5 consciousness of a transdisciplinary approach. These results encourage us to foster continuous exchange through *horizontal* and *vertical connections* and to investigate how each connection affects didactic planning.

TWG 27: The Professional Practices, Preparation and Support of Mathematics Teacher Educators

Introduction to the papers of TWG27: The Professional Practices, Preparation and Support of Mathematics Teacher Educators

Ronnie Karsenty[1], Stefan Zehetmeier[2]; Birte Friedrich-Pöhler[3],Bettina Rösken-Winter[4], Francisco Javier Rojas Sateler[5] and Hilda Borko[6]

Current state of TWG27

TWG27, focused on mathematics teacher educators (henceforth: MTEs), has now been active throughout three consecutive CERME meetings. The group first met in CERME12, and has since seen a growth in its extent: from 17 submitted contributions and 21 participants in CERME12, to 26 submitted contributions and 29 participants in CERME14 (see additional details below). This growth reflects the increasing interest of the Mathematics Education community in MTE research, an interest manifested in various forms – for example, the Topic Study Group dedicated to MTEs in ICME-15 (held in 2024 in Sydney); the Special Issue on MTE expertise, published on March 2025 in *Journal of Mathematics Teacher Education*; dozens of papers focusing on MTEs (both educators and facilitators[1]), published in 2024-25 alone and revealing results from MTE research worldwide (e.g., Okumus & Vondrová, 2025; Thurm et al., 2024). Accordingly, within CERME, TWG27 provides an opportunity for researchers interested in this relatively new field to meet and discuss current and emerging issues related to MTEs' roles, knowledge, practices, challenges, professionalization processes, and more.

The work of TWG27 during CERME14

Of the 26 contributions submitted to TWG27, 20 were accepted (16 papers and 4 posters). Figure 1 shows the distribution of these contributions by the country of their first author. As can be seen, 10 countries were represented, with European contributions constituting almost half of the total number (45%), followed by North and South America (35%), Asia (10%), Australia and Africa (5% each). During the conference, the group met for 7 sessions. Papers and posters were allocated to sessions according to common themes. For most sessions a similar structure was applied: a short presentation and questions by the presenting author, a reaction and additional questions by a pre-assigned discussant, then a small-group discussion (either straight after a presentation or after two consecutive ones) and finally a whole-group discussion. For each session the groups were reshuffled, with a deliberate effort to achieve a mixture of countries represented in each group, for maximizing communication and deeper acquaintance among individuals. This model was noted by TWG27 participants as productive, enabling diversified voices to be heard and considered.

[1] In TWG27, we use the terms *facilitators* and *educators* to denote MTEs who support the learning of practicing and prospective teachers, respectively.

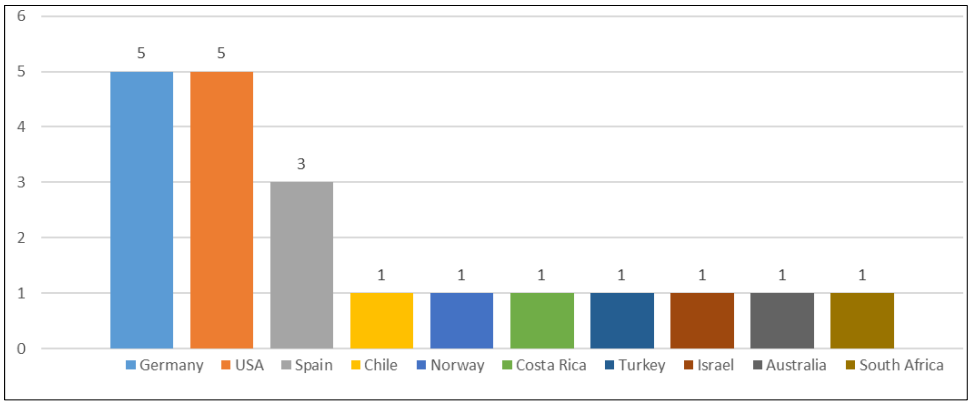

Figure 1: Distribution of TWG27 contributions by countries (refers to first authors, n=20)

Issues discussed in the contributions accepted to TWG27

The call for papers and posters raised the following issues:

1. Theoretical and conceptual frameworks that can be used as lenses in MTE research.
2. MTEs' knowledge, skills and practices, and changes thereof along MTEs' professionalization.
3. Beliefs and identities of MTEs, especially during the transition period of becoming MTEs, and along the professional path from a novice to an experienced MTE.
4. MTEs' role as bridging between theory and practice.
5. Role-modelling as a practice that MTEs may use, explicitly or implicitly; researching the extent of coherence between MTEs' practices and the teaching practices they are meant to support.
6. Integrating generic and mathematical content-specific aspects within the work of MTEs.
7. Preparing MTEs: formal and informal qualifications; different kinds of PD programs designed for MTEs; learning mechanisms of MTEs (e.g., reflection, rehearsals); tools and resources for supporting MTEs.
8. Scaling up programs for mathematics teachers: building institutional capacity through focusing on facilitators; institutional factors that support or hinder the effectiveness of PD facilitators.
9. The influence of current global issues and STEM-related topics on the role and practices of MTEs.

Some of these issues were already present in the previous two calls for TWG27 (but not necessarily addressed by the contributions submitted), whereas other issues or sub-issues emerged from the discussions in the previous meeting of the group in CERME13 (2023). For example, theoretical and conceptual frameworks for MTE research (Issue #1) were widely discussed in the 2023 meeting, yielding an additional emerging question: To what degree are frameworks useful for purposes other than research, e.g., when preparing and supporting MTEs? This question was addressed in the present meeting by Borko et al., who presented the Learning to Facilitate Framework (LTFF) as a conceptual tool that can guide both the analysis and the design of facilitator professional development (FPD) activities. Several other contributions from Spanish-speaking countries used the framework of Mathematics Teacher Educators' Pedagogical Content Knowledge (MTEPCK) to analyze the specific knowledge utilized by MTEs in the preservice level, thus demonstrating a combination of Issues #1 and #2 (Alfaro-Víquez; Giadas et al.; Pérez-Montilla et al.). Other authors addressing Issue #2 mainly delved into MTEs' practices: McKie et al. explored how MTEs structured their conversations with

teachers to support them in using educative curriculum materials. Elliott and Nieman examined how facilitators learned "on the job" to press for learning goals and to respond to teachers' contributions during instructional conversations. Jarry-Shore et al. looked into practices of a coach and a meta-coach in the process of learning to broach candid discussions with teachers about their teaching, and Munson et al. investigated how a coach and a teacher collaborated within side-by-side coaching to better respond to emergent problems of practice. Interestingly, all these four contributions came from the USA, implying that there may be culture-based trends in MTE research. Still within Issue #2, two contributions related to facilitators' noticing skills: Shure et al. explored German facilitators' noticing of a fictional PD situation, finding that nearly half of them still needed further support to develop knowledge-based, relevant interpretations. Rodríguez-Segarra et al. looked into similarities and differences in the noticing of Spanish MTEs with varying academic backgrounds. Issue #3 was addressed by three contributions: Montenegro et al. reported on an intervention in which MTEs in Chile were encouraged to investigate their own practice, with the results showing that participants perceived this experience as highly contributive to their professional path. Erens explored self-perceptions and beliefs of German facilitators regarding their role as adaptors and implementors of a professional development (PD) program for practicing teachers. Zastrow et al. analyzed responses of 333 facilitators in the QuaMath PD program in Germany, revealing that many of the facilitators' professional beliefs aligned with the program's core principles, a finding seen as essential for the success of this large-scale PD. MTEs' role as bridging between theory and practice (Issue #4) was addressed in Opheim's paper, focusing on how a PD course she designed and taught as MTE in Norway took into account elements of theory to support Teacher Specialists in becoming successful change agents in their schools. Issue #5 was addressed by several contributions: Lovemore reported on the use of modelling in her work as MTE with prospective teachers in South Africa, while Alfaro-Víquez explored the different forms of modelling employed by two MTEs in Costa Rica. Sarılıcan and Aslan-Tutak deliberated on modelling as one of key professional roles, unpacked in a case study of a Turkish MTE. Both Holzäpfel et al. and Baumanns et al. discussed issues of coherence, relating to the QuaMath PD program in Germany. Issue #6 was addressed by Marshman and Goos, describing a long-term project of collaboration between mathematicians and MTEs in Australia, aiming at integration of mathematical content-specific aspects and pedagogical aspects in university courses for prospective teachers. The preparation and support of facilitators (Issue #7) was addressed by three papers: Baumanns et al. presented 'teaching experiments' conducted by facilitators as a central design element of FPD, that was found to contribute to improving and refining PD materials for teachers. Borko at el. analyzed a facilitator preparation session using the LTFF mentioned above. Karsenty et al. introduced a tool named 'the FPD Structure Map' that enables comparing different FPD programs in terms of their structural and institutional characteristics. Issue #8 was not directly addressed by the contributions of TWG27, but was present in those dealing with large-scale PD programs, especially in the German context. Finally, unlike in the previous two conferences, MTE research linked to current global issues and STEM-related topics (Issue #9) was not addressed.

Emerging issues

In the course of discussions within the group's sessions, five issues that did not appear in the TWG27 call for contributions emerged as being relevant to this group. We briefly describe these below.

Emotional knowledge

This issue refers to developing MTEs' sensitivity to the specific needs and problems of the teachers they work with. It was noted that MTEs need this kind of *emotional knowledge* (about teachers' concerns, interests, beliefs, etc.); therefore, it should be part of MTEs' preparation and learning.

Ways of practicing specific MTE tasks before the actual leading of PD sessions with teachers

The group elicited various means and strategies to support MTEs' practicing of tasks, to be further researched for their effectiveness. Among these were providing opportunities for leading candid conversations; developing norms for analyzing teaching to understand potential tensions; using vignettes, videos, rehearsals, and other types of simulations to deeply unpack possible PD scenarios.

The triad of MTEs, prospective teachers and the schools

Understanding the relationships between the three vertices of this triad was elicited as highly relevant for MTE research at the preservice level. The group talked about brokering and addressing tensions; developing means to improve MTEs' work with the schools (the possibility of co-teaching was mentioned), and unpacking roles and practices that MTEs can adopt during the teaching practicum.

Eye on the mathematics in our MTE research

The group discussed the need to put more emphasis on mathematics as a subject matter when researching MTEs, and raised the following questions: What part should mathematics play in preparing and supporting MTEs? How might the facilitation of mathematics teachers' professional learning be distinct from the facilitation of teachers' professional learning in other subject areas?

Macro and micro analysis in MTE research

Different grainsizes of data analysis were discussed, with questions such as: How can we efficiently analyze a large volume of data? When we look at detailed qualitative data (e.g., referring to MTEs' decisions, practices. etc.), how can we balance the micro-analysis without missing the "macro" picture? What may we learn about this from other lines of research (e.g., student- or teacher-focused)?

Summarizing words

At CERME14, the spectrum of issues discussed in TWG27 has widened. We explored theoretical and practical aspects of MTE research, elaborated mathematical vs. general pedagogical aspects of MTEs' work, and delved into fine-grained issues such as noticing, role-modelling, and specific tasks for supporting MTE learning. We look forward to further development of this TWG in the future.

Examining pedagogical content knowledge in teacher educators' modelling practices within didactics-specific courses

Helen Alfaro-Víquez[1]

[1]University of Costa Rica, Department of Mathematics Education, Costa Rica;
helen.alfaro@ucr.ac.cr

This study explores the modelling practices employed by two mathematics teacher educators (MTEs) while teaching courses on the didactics of algebra and functions. Through qualitative content analysis of semi-structured interviews, the research investigates the different forms of explicit modelling used by MTEs and the MTE pedagogical content knowledge (MTEPCK) demonstrated. The findings highlight modelling as a key strategy for bridging theory and practice, showcasing effective teaching methods and addressing student misconceptions. The study underscores the importance of developing MTEs' competencies in designing and implementing modelling strategies and calls for further research into the relationship between MTEPCK and modelling as a means of advancing MTE professional development.

Keywords: Mathematics teacher educators, modelling, didactic-specific courses, pedagogical content knowledge.

Introduction

Mathematics Teacher Educators (MTEs) play a crucial role in preparing preservice mathematics teachers (PSTs) to become proficient educators. As Rojas et al. (2021) emphasize, MTEs are responsible for designing and implementing curricula that deepen PSTs' mathematical understanding while equipping them with the knowledge, skills, and strategies essential for effective teaching. This requires crafting learning experiences that simultaneously support mathematical learning and pedagogical development (Ball et al., 2008) and fostering situation-specific cognitive skills crucial for teaching (Blömeke & Kaiser, 2017). To achieve this, learning opportunities must seamlessly integrate theoretical and practical knowledge (Boyd, 2014), helping PSTs bridge the gap between formal mathematics and the mathematics they will teach in schools (Buchholtz & Kaiser, 2013).

In the Mathematics Education program at the University of Costa Rica, MTEs must teach five didactic-specific courses that focus on both mathematical knowledge for teaching and essential pedagogical tools. These courses aim to transform theoretical knowledge into practical, actionable skills through situational reconstruction (Valverde et al., 2020). Teaching these courses becomes particularly challenging for Mathematics Teacher Educators (MTEs), as they often lack specialized training for preparing PSTs (Lunenberg et al., 2007). This absence of formal preparation forces MTEs to navigate complex responsibilities on their own. To address this, some MTEs have adopted modelling as a teaching methodology, providing PSTs with concrete examples of effective teaching practices and demonstrating how theoretical concepts can guide practical decision-making.

This paper aims to explore the modelling strategies employed by two MTEs in teaching courses on the didactics of algebra and the didactics of functions, as well as the MTEs' PCK mobilized for these practices.

Theoretical background

Modelling as a teaching strategy

The role of MTEs goes beyond organizing and supporting PSTs' learning through direct instruction. In every class, the pedagogical and methodological choices they make when presenting content or explaining teaching strategies, they are modelling teaching practices themselves. This means that the "teaching process in which mathematics teacher educators engage appears to be as influential as the knowledge imparted" (Rojas et al., 2021, p. 368). Lunenberg et al. (2007) describe modelling as the practice of deliberately demonstrating specific teaching behaviours intended to foster the professional learning of PSTs.

There are four forms of modelling can be found in teacher educators' practice: a) Implicit, b) explicit, c) explicit and connected with PST's own practice and d) explicitly connecting exemplary behaviours with the theory (Lunenberg et al., 2007). *Implicit modelling* is often associated with congruent teaching, where MTEs employ "good practices" in their own teaching not only because they are effective for instructing PSTs, but also because they can be valuable for PSTs when teaching their future students (Boyd, 2014). However, this modelling practice can be ineffective if PSTs fail to recognize the demonstrated teaching strategies as a learning objective (Lunenberg et al., 2007). *Explicit modelling* requires MTEs to make explicit the choices they make for designing the lesson or during the implementation, and why (Boyd, 2014). This form of modelling can be performed by MTEs by thinking out loud. *Explicit and connected with PST's own practice modelling* is intended to help them recognize how the demonstrated teaching methods can be adapted and applied to various teaching situations, including those they will encounter in their future classrooms (Rojas et al., 2021). It is important to emphasize that the goal is not for PSTs to simply accumulate a repertoire of teaching practices, but rather to critically reflect on which practices will be most useful and how they can align with their own teaching objectives. Finally, *explicitly connecting practice with theory modelling* refers to MTEs clearly linking their teaching choices to relevant academic theory on pedagogical knowledge (Boyd, 2014).

Mathematics teacher educator pedagogical content knowledge

Since MTEs are responsible for "teaching mathematics teachers to teach" it makes sense to base the study of their knowledge for teaching PSTs on the same foundational concepts of PCK that apply to PSTs (Chapman, 2021). On that ground, and following Chick and Beswick (2018) framework, MTEs' knowledge can be described as "PCK for teaching the PCK for teaching mathematics" (p. 476). The Mathematics Teacher Educators' Pedagogical Content Knowledge (MTEPCK) framework organizes knowledge into three categories that are neither hierarchical nor strictly separate, but rather overlap and exist on a continuum: *clearly PCK, content knowledge (CK) in a pedagogical context, and pedagogical knowledge (PK) in a content context*. Additionally, the framework recognizes that MTEs approach teaching from two distinct perspectives: the PCK required for school mathematics teachers (SMTPCK) and the PCK necessary for teacher educators. For instance, when addressing misconceptions, MTEs must consider both the potential misunderstandings that PSTs may have regarding mathematical or pedagogical knowledge, as well as the common misconceptions school students might have about mathematical concepts (Chick & Beswick, 2018). This dual focus is

essential for MTEs to effectively teach their PSTs. Table 1 summarizes the framework, and the examples illustrating when the PCK types are evident should be interpreted within the context of the two perspectives mentioned. Consequently, the concepts or procedures may align with both SMTPCK and MTEPCK.

Table 1: Framework for mathematics teacher educators pedagogical content knowledge (MTEPCK)

Clearly PCK	CK in a pedagogical context	PK in a content context
Teaching strategies: Discusses or uses general or specific strategies or approaches for teaching a mathematical (or an SMTPCK) concept or skill. *Student thinking:* Discusses of addresses student or PST's ways of thinking about a concept, recognises typical levels of understanding. *Student thinking -misconceptions:* Discusses or addresses student or PST misconceptions about a concept. *Student affect (in relation to content):* Discusses or addresses students' *or* PSTs' affective responses to particular mathematics or SMTPCK topics. *Cognitive demand of task:* Identifies aspects of the (SMT *or* MTE) task that affect its complexity. *Representations of concepts:* Describes or demonstrates ways to model or illustrate a concept (can include materials or diagrams) *Explanations:* Explains a topic, concept or procedure. *Knowledge of examples:* Uses an example that highlights a concept or procedure. *Knowledge of resources:* Discusses/uses resources available to support teaching. *Curriculum knowledge:* Discusses how topics fit into the school curriculum *or* the teacher education curriculum *Purpose of content of knowledge:* Discusses reasons for content being included in the school or the teacher education curriculum or how it might be used.	*(Beliefs about) the nature of content*: Expresses an appreciation of the nature of mathematics that goes beyond the school curriculum and aligns with mathematicians' view of the discipline/ *and* of the SMTPCK that goes beyond the teacher education curriculum to include critique of the content and its conceptualisations. *Profound understanding of fundamental content:* Exhibits deep and thorough conceptual understanding of identified aspects of mathematics and SMTPCK. *Deconstructing content to key components:* Identifies critical mathematical or SMTPCK components within a concept that are fundamental for understanding and applying that concept. *Structure and connections:* Makes connections between mathematical or SMTPCK concepts and topics, including interdependence of concepts. *Procedural knowledge:* Displays skills for solving mathematical or SMTPCK problems (conceptual understanding need not be evident) *Methods of solution:* Demonstrates a method for solving a mathematical or SMTPCK problem.	*Assessment approaches:* Discusses or designs tasks, activities or interactions that assess learning outcomes/ Discusses or uses assessment tasks purposefully to evaluate PSTs' knowledge of SMTPCK. *Goals for learning:* Describes a goal for students' or PSTs' learning *Getting and maintaining student focus:* Discusses or uses strategies for engaging students or PSTs. *Classroom techniques:* Discusses or uses generic classroom practices. *Student affect (general):* Describes how student affect influences pedagogical approach/ Discusses typical PST affective reactions to learning about SMTPCK

Source: Adapted from Chick and Beswick (2018)

This study analyses the modelling forms used by two mathematics teacher educators when teaching didactic-specific courses, as well as the types of MTEPCK that they incorporate in their modelling to answer the following questions:

RQ1: What forms of modelling are employed by MTEs in didactic-specific courses?

RQ2: Which elements of the MTEPCK framework become evident through MTEs' use of modeling practices?

Context and Methods

This qualitative study uses content analysis (Kuckartz, 2019) to examine transcripts from semi-structured online interviews conducted in 2023 as part of a larger research project. With participants' consent, the interviews were video recorded, transcribed, and handled confidentially. The study involves two MTEs, referred to as Paola and Roberto. Paola, teaching *Didactics of Algebra to* second-year PSTs, while Roberto, teaching *Didactics of Functions*, taught third-year PSTs. The interviews, conducted at the end of the semester, reflect the MTEs' recollections of their teaching practices in those courses.The interviews aimed to explore the MTEs' decisions on content development, assessment, methodologies, and course assignments. Consequently, the interview protocol did not include specific questions about the use of modelling. However, modelling practices emerged naturally during the interviews. Paola recalled additional instances of modelling after the interviewer prompted her, while Roberto independently described all his modelling practices when asked to describe his course-related decisions, making further prompts unnecessary.

The analysis process started with a review of the interviews to identify all modeling episodes, based on the forms of modeling outlined earlier. Each episode was then categorized according to the modeling form(s) it exemplified. Additionally, the modelling episodes were examined through the lens of the MTEPCK framework to identify the types of MTEPCK that were demonstrated.

Results and discussion

MTEs employed modelling practices for various purposes. Consequently, the analysis is structured based on the form of modelling episodes identified in the MTEs' interview narratives and the corresponding elements of MTEPCK associated with each type.

The episode of *explicit modelling* was recalled by Paola, when she was trying to demonstrate "good practices" for reading an academic article, showing the PSTs the process, she goes through when reading a paper for teaching purposes. Paola recounted aloud how she had approached the article multiple times throughout the course, adapting her reading strategies based on different objectives

> Paola: This is the fourth time I read the paper (..). The first time I read it to see what it was about, what was in there related to the course contents. The second time, I read it more carefully, thinking, 'Okay, now it's my turn to explain it. What am I going to select from this?' (…) And then I read it again (...) to see what I select from it to explain to you.

Her aim was to encourage PSTs to engage in purposeful reading by considering the reason for reading, what they hoped to learn, and how the content could inform their future teaching. In this modelling example, is possible to recognize several elements of MTEPCK of the category of clearly PCK. For instance, Paola knew that reading academic articles is a task of high *cognitive demand* for the PSTs. She also considered the *student-thinking misconception* element, because she knows that PSTs usually read the course theory expecting the MTE to make the connections with the practice.

An example of *explicit modelling that connected theory to practice* was identified in Roberto's class during the activities he called "exploratory sessions." The course included five such sessions, each comprising a sequence of mathematical tasks designed to demonstrate how theoretical frameworks, such as didactic phenomenology or functional thinking, could inform the design and implementation of classroom activities. After PSTs completed these tailored learning experiences, Roberto explicitly highlighted how his decisions and the examples he selected illustrated the theoretical foundations guiding his approach.

> Roberto: Alright, in this exploratory session, we worked together on an example of a phenomenological math task. Now, let's move on to reading about phenomenology.

Roberto's goal was for PSTs to evaluate the tasks they had completed considering the newly introduced theory. He also recalled similar instances where he explained how he applied theoretical knowledge—such as the history of functions and the effective use of technological resources—to align task design with specific learning goals. This example of modelling highlights two MTEPCK elements within the category of clearly PCK: *knowledge of resources* and *knowledge of explanations*, both of which are tied to topics within SMTPCK

Finally, both interviews revealed instances of explicit modelling closely connected to PSTs' own teaching practice. Paola described two episodes that occurred during classes involving role-playing dynamics, while Roberto's examples were tied to the exploratory sessions. This form of modelling demonstrates MTEPCK elements spanning all three categories: clearly PCK, CK in a pedagogical context, and PC in a content context.

Paola's modelling examples included a class on systems of equations and another on lesson planning. In the first, she demonstrated problem-solving strategies by posing a task with multiple solutions and representations, taking on the role of a mathematics teacher while PSTs acted as students. She guided them with targeted questions and introduced a tabular representation to scaffold their understanding. Paola guided the PSTs' work by posing questions such as, "Find different prices for the pizzas and the salads," encouraging them to engage with the task. She then introduced a tabular representation to help the PSTs organize the information and scaffold their understanding toward finding a general formula. At this stage, Paola's knowledge in *teaching strategies* and *representation of concepts* both in the category of clearly PCK became evident, particularly from the perspective of secondary mathematics teacher PCK. Paola intentionally used incorrect variable names when drawing the table on the board to integrate her students' previous notational mistakes. This approach incorporated their knowledge about *student- thinking misconceptions* into the task. As the PSTs found different formulas to solve the problem, Paola asked them to create and interpret a graphic representation, discussing the validity of values and the context in which they applied. These actions demonstrated her knowledge of *representation of concepts*, *profound understanding of fundamental content*, and awareness of *structures and connections*. The last two MTEPCK elements belong to the CK in a pedagogical context category.

Paola emphasized her didactical and methodological decisions, prompting PSTs to reflect on mistakes, her questions' role in achieving learning goals, and the reasoning behind her choices, such as asking them to find five prices instead of one. She applied her knowledge of *cognitive demand of*

a task and *goals for learning*, recognizing that asking relevant questions is challenging but essential for class discussions. Additionally, Paola used questions as an *assessment approach* to evaluate PSTs' understanding of PCK content. *Goals for learning* and *assessment approaches* are elements of the PCK in a content context category. This shows that, at this stage, Paola has demonstrated knowledge across all three MTEPCK categories in an integrated manner, which are evident also in the following example.

In the lesson planning class, Paola modelled the process by creating a lesson plan on a secondary-level topic. Recognizing the high cognitive demand of this task and knowing that PSTs were designing a lesson for the first time, she chose the modelling approach to guide them. She meticulously crafted her lesson plan, completing all the required sections that PSTs would need to include in their own plans, mobilizing her knowledge about *deconstructing content to key components*, in this case the content is lesson plan. The MTE used her knowledge about describing *goals for learning, teaching strategies* and *curriculum knowledge* for crafting the lesson plan, she then conducted the class in the role of a secondary school teacher, with the PSTs acting as eighth-grade students. After the class, Paola reviewed the lesson plan with the PSTs, highlighting each phase and helping them connect these elements to their own recent experience. She then refined the plan for clarity and used it as a guide for PSTs to design their own lessons, offering them a concrete example of how to structure each phase and what to include. Additionally, she modelled how to guide individual student work and incorporate *assessment approaches* in real-time, providing feedback as she observed PSTs' solutions. At the end of the class, she discussed with the PSTs her movements during their individual work and the decisions she made, evidencing her knowledge about *classroom techniques*.

> Paola: Well, while you were doing the independent work, I evaluated you. But I wasn't just evaluating you for the sake of evaluating, (..) I'm identifying "hey look, this one has such an error, that one has such a difficulty" and then I'm going to comment on it to the whole group. Or this one has this solution and it's different from that one's and then when I'm going to move on to the discussion, I'm going to strategically ask these two to come to the board, because I need the class discussion to generate more resolution methods, and it wouldn't make sense to send two who did the same thing.

Roberto's modelling examples took place during the exploratory sessions, as explained earlier. The tasks focused on mathematical content PSTs might need to teach and addressed areas where PSTs had previously struggled, reflecting Roberto's awareness of *student-thinking misconceptions*. Unlike Paola's classes, in these sessions, PSTs worked as prospective teachers rather than secondary students. Roberto increased the difficulty by incorporating formal mathematical knowledge, such as determining whether the injectivity of a function is a definitional property or something that can be proven, and if so, how. This demonstrated his *profound understanding of fundamental content* and his consideration of the PSTs' knowledge. The mathematical tasks illustrated how to pose questions to PSTs, demonstrating Roberto's knowledge of *assessment approaches*. For example, he explained:

> Roberto: In this case, about the exponential function, you can see that there were open questions, closed questions, where students were asked to mark with an "x", but justify', and then with this, we showed the PSTs what type of tasks, what type of request can be proposed to a student.

During the session, Roberto's role as a teacher was to guide the PSTs' work and pose of relevant questions. He modelled how teachers should support student work, *goals of learning*, and manage *classroom aspects*, such as time control. PSTs were also tasked with formulating learning goals for which the proposed tasks were suitable. This demonstrated Roberto's understanding of the *cognitive demands* involved in setting learning objectives and designing mathematical tasks that effectively support their development. In addition, he evidenced his *procedural knowledge*, by asking PSTs to create the learning goal for the task, rather than designing the task to fit a pre-established learning goal, as is typically done. Roberto's modelling examples also demonstrate elements of MTEPCK across all three categories. He summarized the rationale behind his choices as follow:

> Roberto: Why did I think of that? as I was saying about this model of offering PSTs professional learning opportunities, in the sense that it would make evident both the theoretical mobilization of the topics that we are discussing in class, as well as a classroom proposal to work with their students; where the PSTs will reinforce knowledge that they were showing (...) to be weak.

Conclusion

As noted by Lunenberg et al. (2007), MTEs face a highly complex task in training PSTs. They must be proficient in elements of the CK and PCK typical of secondary mathematics teachers, and in the CK and PCK specific to teaching prospective teachers. Moreover, they must address the challenge of effectively bridging the gap between theory and practical application (Chick & Beswick, 2018). The modelling practice has proven to be an effective approach for addressing these challenges (Boyd, 2014). The interviewed MTEs employed *explicit modelling, explicit modelling related to PSTs' own practice* and *explicit modelling linking theory with the teaching competences and decision* to illustrate multiple theoretical and methodological aspects. As shown in the results, to design and execute modelling practices effectively, MTEs drew upon their PCK. Their PCK informed and illuminate the MTEs to recognize what it is important to model, and which is the best way of doing it. In Paola and Roberto's examples, multiple elements of MTEPCK were evident, highlighting the interaction between all three MTEPCK categories. However, the form that revealed the most MTEPCK elements was *explicit modelling connected to PSTs' own practice*.

Modelling by MTEs can be considered as a vital practice for advancing the professional development of PSTs, as it enables them to experience firsthand the strategies, knowledge, and decision-making processes essential for effective teaching (Lunenberg et al., 2007). Effective modelling requires considerable self-awareness, pedagogical expertise, and sensitivity to student needs (Loughran & Berry, 2005), underscoring the complexity and intentionality behind this approach. Moreover, modelling is not innate; it must be learned, practiced, and continually refined by MTEs.

Finally, considering that the theory of teacher educator modelling is not content-specific, it is crucial to integrate it with a framework like MTEPCK. Such a framework enables the intentional design of modelling episodes, ensuring awareness of their potential implications and maximizing their impact on PST learning. By developing their modelling strategies within this context, MTEs can better support PSTs in bridging theory and practice. Further research into the relationship between MTEPCK and modelling could have an impact on advancing MTE professional development.

Teaching experiments as a central design element of facilitators' PD

Lukas Baumanns[1], Luise Eichholz[1], Daniela Götze[1] and Annabell Gutscher[1]

[1]TU Dortmund University, Institute for Development and Research in Mathematics Education, Germany; lukas.baumanns@tu-dortmund.de

The professional development (PD) of facilitators (FPD) who lead teacher PD (TPD) workshops is essential for high-quality mathematics teaching. This article describes how teaching experiments conducted by the facilitators themselves can become a central design element of FPD. Following the strategies of lifting, nesting, and unpacking, we explored how this design element can contribute to improving and refining PD materials. To do this, we analysed the written reflections of 140 primary school facilitators who participated in FPD during the 10-year QuaMath project in Germany. These reflections showed the facilitators' experiences with the teaching experiments in their mathematics classes. The analyses showed that integrating teaching experiments at the FPD level has great potential for improving FPD and can also provide valuable insights for revising the PD materials.

Keywords: Facilitators, professional development, teaching experiments, primary school.

Implementing approaches for high-quality mathematics teaching has remained a major challenge for professional development (PD) programs (Ahl et al., 2023). A shared vision of what constitutes high-quality teaching and a coherent set of core principles have been shown to be essential (Cobb & Jackson, 2021; Prediger & Selter, 2024). This forms the basis of the 10-year German implementation project QuaMath (Developing *Qua*lity in *Math*ematics Classrooms and Teacher PD). A consortium of 28 mathematics education professors, 40 academic project team members, 60 state project leaders, and 400 facilitators has aimed to reach 10,000 schools in 10 years (Prediger & Selter, 2024).

The first year of QuaMath (Sep 2023–Sep 2024) focused on facilitator professional development (FPD) to qualify facilitators for the teacher PD (TPD) workshops. The facilitators participated as learners, taking on the dual roles of teacher and facilitator and moving between these roles as part of their qualification. The TPD workshops have included planning and conducting teaching experiments (Timperley et al., 2007) aimed at applying the content of the PD program directly in the math classroom. In the QuaMath project, these have been primarily small, easy-to-implement suggestions to create a strong incentive for their immediate use. For example, it can be different representations of a task, where one representation does not match the others. The children have to explain why one representation does not fit and how it would have to be adapted to make it fit. Teachers can reflect on how in-depth discussions about representations supports student conceptual understanding. As part of their FPD program in QuaMath, facilitators were asked to conduct and reflect on these teaching experiments themselves. This paper thus explores the use of teaching experiments as a central design element in facilitators' PD. These self-experiences in the teaching experiments have contributed to the qualification of the facilitators and to the improvement of the PD materials.

Theoretical background and FPD context

Multi-layered structure of PD programs

The PD program of QuaMath considers the learning processes of three different groups of participants—students, mathematics teachers, and PD facilitators—and works with them within the implementation strategies of the well-established three-tetrahedron model of PD (Prediger et al., 2019). This model was developed as part of the joint research activities at the German Centre for Mathematics Teacher Education (DZLM) and provides a framework for the multi-layered research and development structures within complex PD programs. According to Borko et al. (2021), the three tetrahedrons, their elements, and their interrelationships, both within individual tetrahedrons and between them, illustrate the complex nature of learning and teaching across classroom, TPD, and FPD levels. The first tetrahedron focuses on the classroom level and is based on the didactic triangle of students, teachers, and mathematical content. The classroom resources extend the triangle to a didactic tetrahedron (Prediger et al., 2019). These four elements constitute the content at the TPD level and are thus the starting point of the second tetrahedron. At this level, the teachers are the learners, and facilitators take the role of the teachers; the TPD content focuses on mathematics teaching and learning, and the TPD resources include the materials and activities in the TPD program. Finally, the third tetrahedron addresses the facilitator level, using the same idea of role change: Facilitators become learners, facilitator educators are their teachers, the content is on FPD level, and the resources are the materials and activities for qualifying the facilitators (Borko et al., 2021). For a detailed description of the model, including its elements and interrelationships within and between the tetrahedrons, we refer to Prediger et al. (2019).

Raising awareness of the interconnections across the three tetrahedrons is not only important for the design of FPD and TPD programs but also represents a central perspective for conducting research. In this respect, Prediger et al. (2019) highlighted the three central overarching strategies of *nesting*, *lifting*, and *unpacking* for embedding the three tetrahedrons both in the design and in the research of PD programs. If certain research questions and/or methods from the classroom level are used on the TPD level and transferred from this level to the FPD level, this is referred to as a *lifting* strategy (Prediger et al., 2019). The *nesting* strategy is closely linked to this but considers all relevant aspects of the lower tetrahedron. This means that the complete classroom tetrahedron is nested in the TPD tetrahedron, and the complete TPD tetrahedron is nested in the FPD content (Borko et al., 2021). The *unpacking* strategy focuses the reverse way: Aspects from the FPD content need to be unpacked to the lower levels, for example, to determine how facilitators' knowledge grows from the FPD and how they implement their knowledge in their TPD workshops (Prediger et al., 2019).

Conceptual focus as a principle for high-quality mathematics teaching

For the long-term success of the QuaMath program, it is essential to think and act within a coherent framework of high-quality mathematics teaching on all levels of the three-tetrahedron model. To establish this coherence from the outset, normative, epistemological, empirical, and pragmatic perspectives were considered to define five principles of high-quality mathematics teaching (for details, see Prediger et al., 2022; Prediger & Selter, 2024): cognitive demand (initiate active learning processes), conceptual focus (build a basis for concepts, strategies, and procedures), longitudinal

coherence (prepare for sustainable learning), student focus and adaptivity (work with students' perspectives), and enhanced communication (talk about mathematical ideas). These five QuaMath principles were developed by systematising central research findings and by empirical justification. These core principles of QuaMath for high-quality mathematics teaching were consistently integrated into all PD modules (Prediger & Selter, 2024).

Considering the crucial importance of conceptual understanding, this paper focuses on the principle of conceptual focus. High-quality mathematics teaching should support conceptual understanding, which is essential for linking mathematical concepts to procedural skills and fostering long-term learning in mathematics (Cobb & Jackson, 2021; Kilpatrick et al., 2001). Prediger et al. (2022) stated that conceptual understanding can evolve from "using and connecting everyday contexts and multiple representations", "starting with meaning construction before deriving procedures", and "connecting the procedures back to the underlying meanings" (p. 6). However, many teachers struggle to design or select teaching materials that facilitate conceptual understanding for all students (Cobb & Jackson, 2021). This is compounded by the fact that many teachers measure their teaching success not by children's conceptual understanding but by correctly solved procedural tasks (Watson & Geest, 2005). Furthermore, tasks that support conceptual understanding are often only selected for high-achieving children (Prediger et al., 2022). However, conceptual focus cannot be addressed through conceptual tasks alone. Instead, it relies on the teacher's ability to foster rich classroom discussions that promote conceptual understanding among students (Erath, 2017). In the QuaMath program, we aimed to address these challenges at the TPD level by helping teachers learn how to support conceptual understanding in everyday mathematics teaching. Therefore, we particularly emphasised the proven effectiveness of teaching experiments and their focused reflection as central design elements of successful TPD programs (Prediger & Selter, 2024; Timperley et al., 2007).

Teaching experiments and focused reflection

Teaching experiments provide the opportunity to observe how the implementation of specific TPD content in mathematical classes can influence students' mathematical learning. However, it is not only important to prepare and conduct the teaching experiments but also to reflect on the experiences made in the next TPD workshop and with other teachers (Timperley et al., 2007). Facilitators have to guide the preparation and reflection phases of the teaching experiments to 'explicitly connect the teachers' plans and experiences with the underlying ideas' (Prediger & Selter, 2024, p. 36) of the TPD content. Preparing facilitators for this challenge is crucial and should not be underestimated in the design of the FPD program. The following section describes how we prepared the facilitators in the QuaMath program for this task and in the context of conceptual focus as TPD content. In doing so, we refer to the three strategies of lifting, nesting, and unpacking.

Primary-school facilitators' qualification in the QuaMath program

The participants of the 10-year QuaMath program are about 150 facilitators for primary school TPD courses who have voluntarily enrolled for the qualification. One hundred and forty consented to have their data and documents from the FPD program analysed for research purposes. The facilitators are mostly primary school teachers with varying degrees of experience (experience as teachers in years:

M = 15.80, SD = 9.74) or work in a school-related field (e.g., teacher educators for pre-service teachers). Some had already worked as facilitators (experience in years: M = 3.77, SD = 4.94).

In the 1st year of the facilitators' qualification (Sep 2023–Sep 2024), the Basic Module of QuaMath focused on the five principles of high-quality mathematics teaching. The central aim of the FPD qualification was to prepare facilitators to run the TPD workshops in the following year. For facilitators' qualification, two workshops were held for each principle. The first workshop dealt with the respective TPD materials, while the second one, which took place a few weeks after the first, focused on the teaching experiments. Special FPD materials were developed for the qualification workshops. In these materials, the classroom level and the TPD level were consistently linked, and reflections on the change of perspective were taken into account. The aim was to connect the classroom level and the TPD level systematically in the FPD so that facilitators could effectively experience the PD content as teachers and facilitators as well (Prediger & Selter, 2024). In the following, we illustrate how we implemented the consistent linking of classroom and TPD levels with focused reflection, particularly on the teaching experiments, in the design of the FPD program. After the first qualification workshop, the facilitators were asked to carry out the classroom teaching experiment in their own mathematics classes. It should be noted that the core idea of a teaching experiment in QuaMath is a small, easy-to-implement suggestion designed to apply the targeted principle of high-quality mathematics teaching in everyday lessons across various primary school grades. The experiences gained in the teaching experiment were supposed to be reflected upon in written form and sent to us before the second workshop. So, we *lifted* the teaching experiments as part of the classroom level on the level of FPD.

Since the experiences at the classroom level were made the explicit subject of the FPD in the second workshop, and the complexity of the classroom and the TPD tetrahedron was thereby addressed in the FPD workshops, we also followed the *nesting* strategy. Thus, the FPD qualification in QuaMath considered that our facilitators, as teachers, should know how teaching with the materials of the teaching experiments directly addresses the principles of high-quality mathematics teaching and supports students' learning. On the one hand, this was self-experience and on the other, facilitators have to train how to involve the teachers in the teaching experiments with a focus on students' conceptual understanding. Our *nesting* strategy therefore addressed the entire three-tetrahedron model. The facilitators' written reflections on the teaching experiments *unpacked* the principle of conceptual focus on TPD and classroom levels. Finally, the written reflections reveal how facilitators as teachers had actually understood the principle of conceptual focus. For the PD designers, the reflections also provided an opportunity to improve the PD material in terms of the focused principle. This unpacking was explicitly part of the second workshop. In the following, we provide some empirical insights into the data on the teaching experiment on the principle of conceptual focus.

Teaching experiments as part of the FPD on the principle of conceptual focus

The PD materials on the principle of conceptual focus emphasise the importance of manipulatives and visualisations in learning basic mathematical skills in primary school. Particular attention is paid to the discursive negotiation of meaning among the children. This is the starting point of the teaching experiment. Teachers in the TPD should establish so-called *nonsense stories* as ritualised in-depth

communication about conceptual understanding. In 'nonsense stories', teachers formulate mathematical statements that sometimes make sense but are sometimes nonsensical, such as '27 minus 9 is one more than 27 minus 10. Am I right or am I wrong?' The subsequent discussion about the statements is of main importance. The children are asked to explain and argue why the statement is or is not nonsense, and visualisations or manipulatives are often necessary to underpin the explanations. In line with the *lifting* strategy, the primary school facilitators should implement their own nonsense stories in their mathematics classes. They were then asked to reflect in writing on their teaching experiments using guiding questions. For example, they were asked:

- What nonsense stories did you use in your mathematics classes to address the principle of conceptual focus? (exact wording)
- To what extent could conceptual understanding be observed in children's explanations?
- How did the use of manipulatives or visualisations support children's understanding?
- To what extent did the nonsense stories address the principle of conceptual focus in your teaching experiment and in general?

In line with a combination of *nesting* and *unpacking* strategies, we used the reflections of the facilitators for the design of the second workshop. Facilitators' experiences were used to discuss the principle of cognitive demand at the classroom and TPD levels. Unpacking was also a valuable research strategy for identifying facilitators' challenges in understanding this principle and drawing consequences for the TPD content. In accordance with Prediger et al. (2019), the *nesting* strategy considered the multi-level character on the design side, while the *unpacking* strategy took the multi-level character in the content-related research into account.

Procedure of analysis

We analysed the written reflections in two steps. First, we inductively categorised facilitators' nonsense stories used in their teaching experiment (see the first guiding question) based on the following criteria: (a) Do the facilitators' nonsense stories have the potential to address the principle of conceptual focus in mathematics classes (e.g., through the use and connection of everyday contexts and multiple representations)? (b) If the stories lacked this potential, how can they be categorised? Second, we qualitatively analysed the guided reflection (see the second to fourth guiding questions) to understand how the facilitators dealt with the nonsense stories.

Insights into facilitators' reflections of teaching experiments

Analysis Focus 1: Nonsense stories with and without potential to support conceptual focus

Group 1: Nonsense stories considering conceptual focus: Some facilitators used appropriate nonsense stories that offered the potential to discuss mathematical meaning and thus to address the principle of conceptual focus: 'If I add a counter to a place-value table, the number always increases by 1', '6 times 7 is one sixes more than 5 times 7', or '10 plus 8 is 2 more than 9 plus 7'. These nonsense stories show the potential for joint reflection of basic mathematical concepts (in this case, place value and understanding of mathematical operations).

Group 2.1: Captain problems: Some facilitators used so-called captain problems (see Verschaffel et al., 2000) as nonsense stories: 'Mrs. Meyer has 3 blue and 2 red pencils. How old is Mrs. Meyer?' It is well known that many children in primary school do not question whether such tasks can be answered at all but sum the values of the task, for example, to get a solution. Although these tasks have a noteworthy educational purpose, they rarely allow an in-depth discussion about mathematical concepts and thus show limitations in addressing the principle of conceptual focus.

Group 2.2: Technical terms: Instead of mathematical concepts, technical terms were in focus, such as: 'A triangle has four sides' or 'The number 354 has four 10s.' The answer to these statements is based on definitions of what a triangle and what '10s' are. Such definitional matters rarely allow an in-depth discussion about the underlying meaning of mathematical concepts.

Group 2.3: Understanding material or simple calculation tasks: Nonsense stories of this group dealt with the understanding of visualisations or formulated classic word-problem tasks. Examples include: 'On the hundreds table, the 28 is below the 38' or 'Peter is 112 cm tall. His sister Susi is 200 mm shorter. How tall is Susi?' Understanding the material (in this case, the hundreds table), on the one hand, is usually not accompanied by a conceptual focus as it does not allow in-depth discussions about mathematical concepts (in this case, about place value). Simple word problems, on the other hand, focus primarily on simple calculation skills and generally do not enable in-depth discussions about mathematical meanings.

Analysis Focus 2: Reflection on the use of nonsense stories to address conceptual focus

The reflections on the implementation of the teaching experiments revealed a broad spectrum. Some insights into typical cases are given below. In some cases, it was not clear from the reflections whether the nonsense stories were discussed beyond a yes/no question in terms of conceptual focus. Facilitator Marc used nonsense stories about the divisors of a number (e.g., 7 is a divisor of 47). Students were asked to apply divisibility rules to answer the nonsense story. The facilitator reflected that 'the tasks are only easy to understand if the mathematical rules are applied automatically'. Conceptual understanding regarding the divisibility rules was not addressed in the reflection. Nonsense stories seemed to *remain as yes/no questions*. In contrast, the reflection by Lisa emphasised the importance of the discussion after the nonsense stories for addressing conceptual focus: 'Although children gave quick feedback with "thumbs up or down", this sometimes did not allow any conclusions to be drawn as to whether they had understood the connections and were able to explain them.'

Another reflection on using the nonsense story about multiplicative decomposition strategies (as discussed in Group 1) revealed a more thoughtful approach to addressing conceptual focus. The facilitator Emma emphasised the importance of linking representations for conceptual understanding. She suggested representing 6 times 7 as a rectangular array, marking the groups of sixes, and asking: 'How many sixes are in 6 times 7?' The children then showed 5 times 7 in the same way and compared the representations to reveal that it is not useful to look for sixes in 5 times 7. This approach aims to connect 'math language' (6 x 7), visual representation ('rectangular arrays'), and verbal meaningful explanations ('6 sevens'). This approach leads to a situation where, as Emma reflects, 'one is never satisfied with a simple result or an answer, but always demands explanations.'

Implications for the FPD program

Implication 1: Clarification of *conceptual focus* for facilitators

The use of teaching experiments within the FPD showed that the idea of conceptual focus needed to be clarified at the TPD level. To this end, examples of captain problems and simple calculation tasks were discussed in the FPD workshops, with the question of why these stories do not address the principle of conceptual focus. We therefore used the knowledge from the analyses to address the facilitators' misconceptions about the principle of conceptual focus in the second workshop.

Implication 2: Implementation of *conceptual focus* for teachers

Teachers' activities highlighting the importance of manipulatives and visual representations to address the principle of conceptual focus have been added to the TPD material. These help to illustrate the importance of discursively negotiating mathematical meaning of visual representations. For reflecting on the teaching experiments in the next TP workshop, we implemented some slides illustrating how nonsense stories help to encourage discussions about mathematical meaning.

Discussion

In this paper, we have explored the use of teaching experiments in the context of conceptual focus as a design element in facilitators' PD. The teaching experiments and facilitators' written reflections provided valuable insights into revising the PD materials and facilitator qualification. The analysis of the facilitators' written reflections helped identifying facilitators' misconceptions about the principle of conceptual focus. We were therefore able to respond to these difficulties in the second workshop (see Implication 1). The results also helped improving the TPD material (see Implication 2).

Additionally, the iterative design of FPD along the entire three-tetrahedron model as a research and development strategy seems very promising. Lifting the teaching experiment from the classroom to the FPD level was the starting point. The second workshop reflected on these implications for the TPD workshops, aligning with the nesting strategy of the three-tetrahedron model. The teaching experiment also unpacked the principle of conceptual focus, from the FPD to the TPD and then to the classroom level. The lessons learned from conducting teaching experiments at the FPD level offer several broader considerations for mathematics FPD programs. First, teaching experiments conducted by facilitators provide a valuable opportunity to clarify and unpack the content of PD workshops, leading to necessary revisions of PD materials. Second, written reflections on the teaching experiments provide insights into how the content, is implemented at the classroom level (Timperley et al., 2007). These reflections guide the revision of PD materials and help to ensure that PD content is applied in practice as intended. As QuaMath is a 10-year project, these analyses will also inform the design of workshops for subsequent years aimed at the long-term improvement of PD materials.

Finally, for designing PD workshops, the three-tetrahedron model (Prediger et al., 2019) and the lifting, nesting, and unpacking strategies through all levels provide a valuable perspective. Our research shows how intertwined the three strategies appear in PD. Especially in the multi-level structure of the QuaMath PD, it seems to be useful to consider all levels of the three-tetrahedron model for facilitators' qualification in order to achieve the overarching goal of developing quality in mathematics classrooms and TPD.

Acknowledgement

The QuaMath program has been funded in Phase 1 (2023–2028) with €17 million from the Standing Conference of State Educational Departments in Germany, and additional staff support from the federal states for facilitators and state coordinators has been provided (about €20 million).

This paper presents the Learning to Facilitate Framework (LTFF) which highlights four pedagogies of facilitator preparation programs: selecting a central task of facilitating professional development, representing the practices that comprise the task, approximating these practices, and unpacking the representation and approximation. In this paper, we analyse one facilitator preparation session using the framework, considering whether and how the four pedagogies are enacted during each FPD activity in the session. We then suggest possible uses of the framework to design and research facilitator professional development. The facilitator professional development session is from the Problem-Solving Cycle program; the central task is facilitating a video-based discussion.

Keywords: Professional development, facilitator learning, mathematics teacher educators.

Skillful teacher professional development (TPD) facilitators are critical to the success of any scaled-up TPD program (Borko et al., 2014; Even, 2008). The preparation of TPD facilitators is therefore essential to providing continued TPD opportunities for all teachers. Research has identified the knowledge and skills that facilitators of mathematics TPD need to conduct productive TPD activities. However, we know little about the characteristics of effective facilitator preparation programs and, as Lesseig et al. (2017) observed, we "lack research-based principles to guide the design of leader preparation" (p. 592). Although the situation has improved since Lesseig and colleagues made this observation, there is still much work to be done. Our project, "Preparing Facilitators to Lead Teacher Professional Development: An Initial Conceptual Framework and Exploratory Investigation," addresses this issue. Our team of scholars from three countries, who have conducted extensive research on TPD with mathematics teachers and initial investigations of facilitator preparation, worked collaboratively to develop the Learning to Facilitate Framework (LTFF) – a conceptual framework and set of design principles for facilitator preparation (Jarry-Shore et al., submitted). This paper presents an introduction to the framework and uses it to analyse the activities that comprise a complete facilitator professional development (FPD) session from one of our programs.

Background

Situative perspective on learning

The LTFF is grounded in a situative perspective on knowing and learning, which conceptualizes knowing as situated in particular physical and social contexts; social in nature; and distributed across the individual, other persons, and tools. Learning is conceptualized as changes in participation in

socially organized practices (Lave & Wenger, 1991), and the social context in which a person learns is a fundamental part of what is learned (Putnam & Borko, 2000). A situative perspective on learning of practices thus suggests the importance of focusing on authentic activities in which the practices occur. One approach to situating teacher learning in the authentic activities of teaching is to coach teachers in classroom settings (Gibbons & Cobb, 2017). Another is to use artifacts such as lesson plans and videotaped lessons to bring experiences from the classroom into the TPD setting (Putnam & Borko, 2000). Similarly, artifacts and other representations of *facilitation* practices can be used to situate learning experiences for TPD facilitators in the authentic activities of facilitating TPD.

Facilitation practices and the situational demands of facilitating TPD

In recent years, facilitator educators and TPD designers have identified the central tasks of facilitating TPD, or what we refer to as the situational demands of facilitation (Prediger et al., 2022). These include multifaceted tasks such as guiding teachers through the process of solving mathematics problems together (e.g., Borko et al., 2021; Elliott et al., 2009) and orchestrating discussions of classroom videos with groups of teachers (Borko et al., 2021; van Es et al., 2014), or more specific tasks such as handling difficult moments in TPD discussions (Schwarts et al., 2022). The practices that are enacted to meet these situational demands, and all that underlies them (Karsenty et al., 2023), are essential elements of FPD programs (Prediger et al., 2022). This multidimensionality characterizes the activities we considered when developing the LTFF.

The Learning to Facilitate Framework

Our approach to preparing facilitators to meet the situational demands of facilitation draws upon the literature on preparing teachers to meet the situational demands of teaching. Grossman et al. (2009) developed a framework for preparing teachers that consists of three teacher education pedagogies – representations, decompositions, and approximations. They argue that teachers can learn to enact practices for meeting the central situational demands of teaching when the demands are represented, decomposed, and approximated. This framework has been used in pre-service teacher education and TPD settings, and there is some evidence for its success in supporting teachers' professional learning (e.g., Ghousseini, 2017; Kazemi et al., 2016). Our project lifted Grossman et al.'s framework from the TPD level to the FPD level and adapted the pedagogies to create the Learning to Facilitate Framework (LTFF) (Jarry-Shore et al., submitted), based on an assumption that these adapted pedagogies may also support TPD facilitators' professional learning.

The LTFF includes three key adaptations: a) adding a fourth pedagogy of *selecting a situational demand* central to TPD facilitation; b) replacing decomposing with unpacking – whereas decomposing focuses on practitioners' observable practices, unpacking also surfaces the rationales underlying visible practices and the planning that precedes these practices; and c) allowing flexibility in the order and recurrence of pedagogies (e.g., unpacking may occur after representing and approximating). Thus, the LTFF consists of four pedagogies: selecting a TPD situational demand (i.e., a TPD task) and the practices to address this TPD task, representing practices for carrying out the task, approximating these practices, and unpacking the represented and approximated practices. A given FPD activity may not include all four pedagogies in the LTFF, and the pedagogies can reoccur in a FPD activity or occur simultaneously rather than in sequence.

Many decisions are made for each LTFF pedagogy in planning and enacting the FPD activities. Here we provide a few examples. The facilitator educator who is designing an activity must first select the focal situational demand and TPD task. What is selected may vary in grain size, ranging from the broad TPD task of leading a discussion of a classroom video to the sub-task of ensuring equitable participation during such a discussion. In representing the practices for meeting the selected demand, decisions must be made regarding the modality of the representation, for example, a simulation, video, or physical artifact. Facilitator educators also decide whether to unpack decisions made in planning for the represented TPD task, enacting the represented practices for this TPD task, or both. Prospective facilitators may have the opportunity to approximate the entire TPD task or a particular aspect of it, and the group may ask them to unpack the decisions they made when planning or enacting the approximation. Figure 1 depicts the LTFF pedagogies and key decisions for each one.

Analysis of a FPD session: Preparing to facilitate a video-based discussion

In this section we use the LTFF to analyse one full-day FPD session from the Problem-Solving Cycle (PSC)[1] TPD program for middle-grades mathematics teachers (Borko et al., 2015). The PSC is a school-based program in which TPD workshops are led by facilitators at their schools. To support the sustained implementation of the PSC program at scale, Borko et al. (2015) developed a FPD program in which facilitators receive support in preparing to facilitate the TPD workshops at their schools. Each FPD session focuses on one central TPD task for the upcoming workshop. One or more

[1] In this description, we use the LTFF terminology of TPD, FPD, and facilitators, though in our discussions of the program in other articles and presentations, we refer to the TPD as the *Problem-Solving Cycle* program, the FPD as the *Teacher Leader Preparation* program, and facilitators as *Teacher Leaders*.

facilitator educators typically model facilitation of the central task, and the facilitators and other facilitator educators (not leading the current activity) serve as teacher participants. Next, this live representation is unpacked to surface the decisions and rationales underlying the facilitator educators' visible practices, as well as their decisions and rationales in planning the activity. The facilitators then prepare for and rehearse their own versions of the task; these rehearsals may also be unpacked.

The FPD session we analyse, which included five FPD activities, took place in the first year of a partnership between a university and an urban school district. The university and district partners adapted the PSC program to address the district's mission of providing every student with high-quality instruction and equitable learning opportunities in mathematics by building the district's capacity to conduct school-based TPD for mathematics teachers. FPD and TPD sessions were conducted for 4 years, beginning in Fall, 2016. The facilitators in the project were practicing teachers who also served in the role of facilitator. They had a range of experience in facilitating school-based TPD prior to participating in the project. Facilitators in the participating schools typically worked in pairs (Borko et al., 2021). Figure 2 depicts the LTFF for this FPD session. Our analysis explains how each FPD pedagogy was enacted during the session.

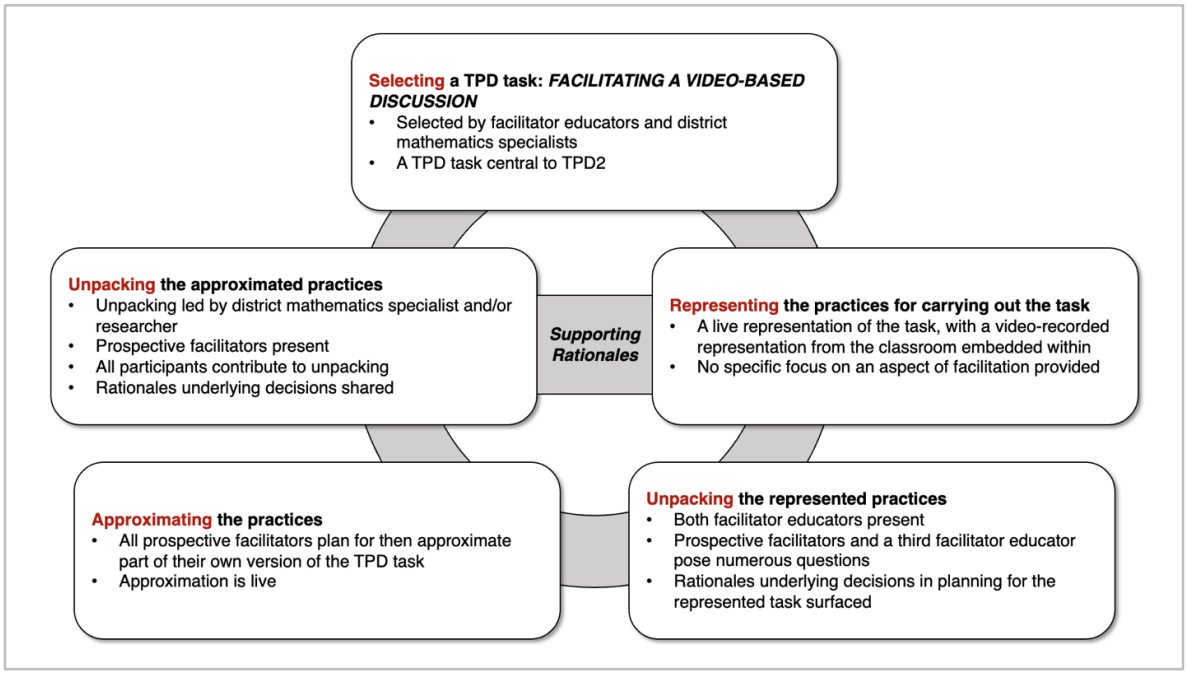

Figure 2. Analysis of a FPD Session from the PSC Using the LTFF

Selecting the focal TPD task

The TPD task selected for the FPD session was the facilitation of a video-based discussion. This task, selected during the planning of the session, was represented by two facilitator educators, one of whom is an author of this paper (FE2, Michael), during the second facilitator preparation session of the 2016-2017 school year. The unpacking of the representation was led by a third facilitator educator (FE3, Hilda), also an author. Participants were a group of 15 facilitators.
