Paint Task 1: Teacher D drew a rectangle for 1 m^2 and had divided it into 4 parts and shaded 3 parts (see Figure 6a). She then said this was not right and she decided to have two figures separately (see Figure 6b): 1 m^2 an unpartitioned wall and 4-part rectangle where 3 parts were shaded for the paint and its unit was dL. At that point she made a direct proportion relationship to help her think about the pictures (see Figure 6c) and the interviewer asked her to show the situation with pictures (instead of continuing with "direct proportion"). She then focused on her picture and she made another set of drawing underneath to show the relationship (see Figure 6d): for extra 1/4 dL she needed second m^2 and interestingly she divided each of the two 1 m^2 board into three. She justified that "if each part of the 3-part (paint, which she explicitly said, "one fourth of paint") makes one of the 3 parts of the wall (1 m^2) then for the extra fourth of the paint we need one (third) of the wall so 1/3 m^2 then it would be four over three m^2" and wrote 4/3 m^2 (see Figure 6d). She said she could not write an equation.

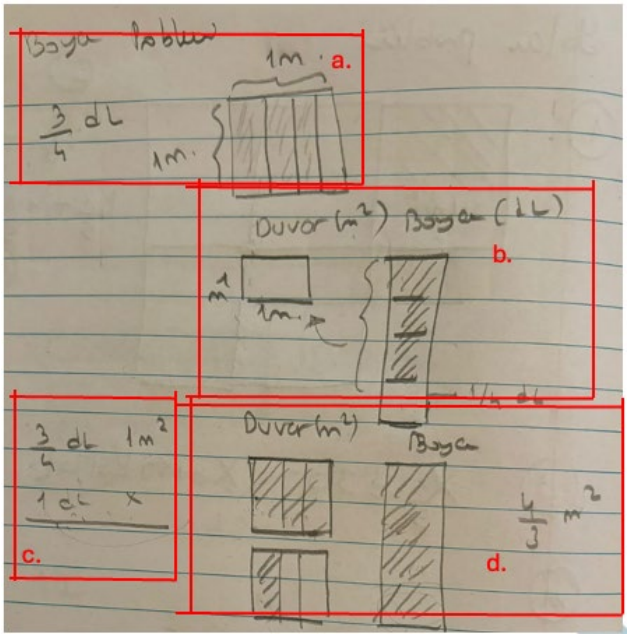

Figure 6: Teacher D's solution to Paint Task 1

Discussion and future research

In this study, we aimed to explore teachers' representations in equation formulation with fractions and the role of their multiplicative concepts. We investigated teachers' understanding of multiplicative relationships between two varying quantities, which have not been reported before to our knowledge. Compared to the other two types of tasks (Seat Tasks and Plant Tasks), the Paint Tasks were found to be the most difficult for all participants. Difficulties were observed in understanding the structure of the problem, and the presence of two quantities in a proportional relationship. This fact seems to indicate that there is a difference in the knowledge required by the teachers between comparing two quantities of one type (only length (plant) or only a discrete quantity (seat)) with a varying relationship and two quantities of two types with a varying relationship.

In the Paint Task, the drawings for presenting volume and area as rectangles, and then dividing them to represent fractions were observed by teachers from both countries. On the other hand, there were some differences between these two groups, one of which was the use of the double number line observed in Teacher B's actions. Although familiar to both Japanese pre-service teachers, the use of double number line was only seen in one of the two participants. The second was the expression of "direct proportion" observed in Teacher D's activities. This is also a familiar expression taught in middle schools in Türkiye, but again, it was recognized by only one teacher. Teachers B and D, who

were able to use other expressions as well as rectangle and square diagrams, were at the MC3 level for Bar Problems when we analyzed their activities using Norton et al.'s (2015) Rubric for Units Coordination Structures. Interestingly, for Paint Task 1, both teachers were able to recall alternative figures or expressions and use them as cues for their thinking when faced with difficulties. However, Teacher B did not develop the equality of the area quantity that corresponds to 1/4dL paint. It was only Teacher D who had two rectangles to represent dL and m^2, and successfully made the varying relationships of the quantities. Making the equivalency relationship of 1/4dL and 1/3 m^2 was a key step in Paint Task 1, and this was very difficult even for MC3 level teachers. It is also noteworthy that neither Teacher B nor Teacher D could write an algebraic equation for Paint Task 1. Writing an algebraic equation that includes two varying quantities, such as paint and board, proved to be a difficult matter regardless of previous teaching experience or educational background. Since only Paint Task 1 was analyzed in this paper, it is necessary to examine each teacher's thought processes for the remaining two Paint Tasks. An interest is on whether the teachers exibit or make progress on units coordination or equation writing at some points because they seem to move between categories on different tasks or different representations. As for the future, we will also explore how teachers with different multiplicative concepts might anticipate potential difficulties their students may encounter when solving a similar set of problems. Lastly, we also hypothesize that if teachers' approaches are symbolic and procedural in writing equations for representing these problem situations or they have different MC levels, their expectations of middle schoolers' mistakes and their responses to them will also be symbolic and procedural.

Proportional reasoning unleashed: How gifted minds tackle diverse proportional reasoning tasks

Zeynep Tuncer[1], Berna İnci[1] and Mine Işıksal Bostan[1]

[1]Middle East Technical University, Faculty of Education, Ankara, Türkiye; zeynept@metu.edu.tr

The present study aims to investigate 7th-grade gifted students' performance in alternative types of linear and nonlinear proportional reasoning tasks, namely, missing value, numerical comparison, and qualitative problems. The participants of the present study were three 7th-grade gifted students who attended the Science and Art Center in İstanbul, Türkiye. The findings elucidated that gifted students' performance differed in alternative types of proportional reasoning problems. Specifically, their performance was the highest in missing value problems, while they showed the poorest performance in qualitative problems. In terms of linear and nonlinear problem types, gifted students were more successful at nonlinear problems compared to linear ones.

Keywords: Gifted students, proportional reasoning, problem-solving, illusion of linearity.

Introduction

Proportional reasoning was defined as "detecting, expressing, analyzing, explaining, and providing evidence in support of assertions about proportional relationship" (Lamon, 2020, p. 4). It is a vital concept because it is regarded as the basis of the arithmetic, number, and measurement concepts (Lesh et al., 1988). Furthermore, as proportional reasoning involves expressing the relationships between quantities and covariation, it is closely tied to algebraic thinking (Lesh et al., 1988). Due to being a pivotal concept, a variety of studies were conducted to explore middle school students' proportional reasoning. However, research specifically focusing on the proportional reasoning of special students, such as gifted students, is lacking. Considering that gifted students have above-grade-level ability (Renzulli & Reis, 2021), their proportional reasoning might differ from their peers. Hence, in the present study, we aimed to focus on the proportional reasoning of gifted students.

Theoretical Background

Despite its relevance with diverse topics in mathematics and with other disciplines and its widely accepted importance (Lamon, 2020; Özgün-Koca & Kayhan-Altay, 2009), numerous studies revealed that middle school students have difficulty in developing proportional reasoning (Ayan-Civak et al., 2024). The most frequently cited difficulty in the literature was students' inability to discern the multiplicative and additive situations and select the appropriate strategies for different situations (Ayan-Civak et al., 2024; Tourniaire & Pulos, 1985). Besides, the other difficulty of students was noted as the illusion of linearity (linearity trap), which means students' inability to distinguish proportional and nonproportional situations and overuse of linearity in nonproportional situations (De Bock et al., 2007). A review of the literature indicated that a profound comprehension of (non)-proportionality was not attained by many students (De Bock et al., 2007). The commonality of these difficulties is that both stem from students' inability to recognize and express the relationship between quantities, which is foundational to functional thinking, a crucial aspect of algebraic thinking (Blanton & Kaput, 2011).

Several studies (e.g., Tourniaire & Pulos, 1985) have examined the potential reasons influencing students' difficulty in proportional reasoning. Those reasons can be summarized as problem type,

context, and numerical features (Tourniaire & Pulos, 1985). Moreover, an overemphasis on proportionality and overuse of missing value problems, students' insufficient knowledge of geometry, teachers' inability to connect geometry and proportional reasoning, and the intuitive and straightforward nature of the linear relationship also affect students' performance and illusion of linearity (De Bock et al., 2007). In conclusion, a literature review indicated that problem type stands out as a common reason affecting students' performance and difficulties. For that reason, many studies (e.g., Ayan-Civak et al., 2024; Özgün-Koca & Kayhan-Altay, 2009) were conducted to elucidate students' performances in alternative types of proportional reasoning problems, such as missing value, numerical comparison, qualitative, linear, and nonlinear problems. Nevertheless, there is still room for research on the proportional reasoning performances of special students, such as gifted students.

National Association for Gifted Students (NAGC) defined gifted students as "Students with gifts and talents perform—or have the capability to perform—at higher levels compared to others of the same age, experience, and environment in one or more domain" (NAGC, 2019, p.1). As the definition implies, those students have unique characteristics distinguishing them from their same-age peers. More specifically, those students learn faster (Cross & Coleman, 2014), demonstrate above grade level ability (Renzulli & Reis, 2021), and possess a wide range of knowledge of strategies and adaptability in their use compared to their nongifted peers (Jaušovec,1991). Because of these characteristics that distinguish gifted students from their nongifted peers, gifted students' performances in alternative types of proportional reasoning problems and the possible reasons that affect their performances might show variation. Furthermore, investigating these students' proportional reasoning in alternative problem types holds paramount importance in gaining insight into gifted students' proportional reasoning performance, identifying their difficulties and the underlying reasons behind their performance, and determining the differentiation these students need in proportional reasoning. Hence, the present study aims to investigate the performance and possible reasons for incorrect responses of 7th-grade gifted students in six alternative types of problems: missing value linear problem, missing value nonlinear problem, numerical comparison linear problem, numerical comparison nonlinear problem, qualitative linear problem, and qualitative nonlinear problem. In line with these aims, the research questions that guided the present study were as follows: To what extent are gifted students successful in solving alternative types of proportional reasoning problems? What are the possible reasons behind those students' incorrect responses?

Methods

This case study authorized deeper investigations of a few individuals on the specific topic (Creswell, 2012). In this case study, the participants were three 7th-grade gifted students whose area of giftedness is general mental ability. The participants were selected conveniently and assigned pseudonyms Zenia, Edward, and Andrew. While Zenia attends the Science and Art Center (SAC) for three years, Edward and Andrew attend SAC for five years. SACs are special education institutions for gifted students regulated by the Ministry of National Education. In SACs, gifted students do activities rather than being taught a topic outside school hours. Although the participants in this study learned about ratio and proportion in their schools, they did not receive any instruction about proportional reasoning in SACs. According to the Turkish mathematics curriculum (Ministry of National Education [MoNE], 2018), a 7th-grade student who has learned the subject of ratio and proportion is expected to have skills such as deciding whether two quantities are directly or inversely proportional by examining

real-life situations, expressing the relationship between two quantities, and solving problems related to ratio and proportion.

The researchers of this study generated the data collection instrument. The instrument covers six proportional reasoning problems, namely, missing value (linear and nonlinear), numerical comparison (linear and nonlinear), and qualitative problem (linear and nonlinear). Due to page limitations, one example each for linear and nonlinear problems is given below to shed light on linear and nonlinear problems. The nonlinear numerical comparison problem that was used in this study is presented below:

Simay wants to enlarge two different photos of her with her mother for Mother's Day. The original sizes of the first rectangular photograph are 4 cm and 8 cm. The area of the enlarged version of this photo is 128 square centimeters. The original sizes of the other rectangular photograph that Simay will enlarge are 12 cm and 24 cm. The area of the enlarged version of the second photo is 576 square centimeters.

Which photo is enlarged more?

Following the nonlinear problem example, the problem below represents one of the linear problems, i.e., the linear numerical comparison problem, used in this study.

The true distance between Ankara and Bursa is approximately 388 km, and the distance measured on the map is 2 centimeters. While the true distance between Aksaray and Adıyaman is approximately 582 km, the distance measured on another map is 5 centimeters.

Which map is smaller in scale? (Paper sizes are assumed to be the same.)

The nonlinear and linear problems presented above are both numerical comparison problems in which students were expected to compare two ratios. However, since there is a nonlinear relationship between the side lengths and the area of the rectangle, the first problem was called a nonlinear numerical comparison problem. On the other hand, since there is a linear relationship between the lengths (the true and map distance), the second problem is a linear numerical comparison problem.

While designing the data collection instrument, the researchers pay attention to including problems in real-life contexts and several solution approaches. Once the researchers finalized designing the data collection instrument, they took the opinion of an expert who has previously worked with gifted students, conducted studies on proportional reasoning, and is familiar with the literature on proportional reasoning problem types. The mathematics education expert confirmed the categorization of the problems and the mathematical and pedagogical appropriateness of the problems. Once this process was completed, the researchers began collecting data. Semi-structured task-based interviews were utilized to collect the data. Early in the interview, instead of informing the students that they would be posed with proportional reasoning tasks, it was stated that they were expected to solve real-life problems. Content analysis was employed while analyzing the data, and inductive coding was used to code the data. The researchers individually identified students' correct and incorrect responses and possible reasons for students' incorrect responses. Afterward, they discussed their identifications until they achieved a 100 % agreement. Based on the analysis, the findings will be presented under two main headings: the performance of gifted students, which

included their correct and incorrect responses, and possible reasons for their incorrect responses, which were contextual and conceptual reasons.

Findings

The Performance of Gifted Students in Alternative Proportional Reasoning Tasks

Table 1 presents the correct and incorrect responses of each student to the six alternative types of proportional reasoning tasks.

Table 1: Performances in alternative types of proportional reasoning tasks

Problem Types / Students	Missing Value		Numerical Comparison		Qualitative	
	Linear	Nonlinear	Linear	Nonlinear	Linear	Nonlinear
Zenia	Correct	Correct	Correct	Correct	Correct	Incorrect
Edward	Correct	Correct	Correct	Correct	Incorrect	Correct
Andrew	Correct	Correct	Incorrect	Correct	Incorrect	Correct

As can be seen from Table 1, students provided correct responses to most of the problems. All students answered all missing value problems correctly, regardless of whether they were linear or nonlinear. Moreover, an investigation of students' performances in numerical comparison problems indicated that only one student answered the linear numerical comparison problem incorrectly. On the other hand, when the questions to which students provided incorrect responses were examined, it was evident that they gave incorrect responses most to qualitative problems. Specifically, each student responded incorrectly to one of the two qualitative problems. To be more precise, two students answered the linear qualitative problem incorrectly, and the other answered the nonlinear qualitative problem incorrectly. Due to the page limitation, a few examples of students' correct and incorrect responses will be shared. First, some examples of students' correct responses will be presented.

Figure 1 shows one student's correct solution for the nonlinear missing value problem, where each student provided correct answers.

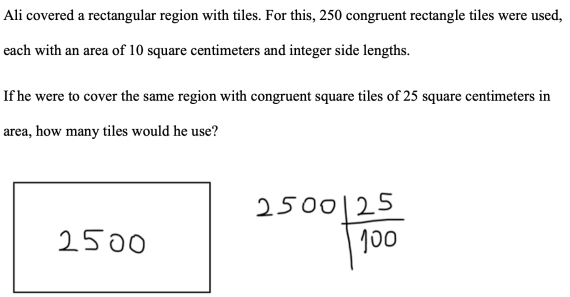

Figure 1: Zenia's correct solution for the nonlinear missing value problem

Zenia: I multiplied 250 by 10 to find the total area. Then I divide 2500 square centimeters by 25 square centimeters; it becomes 100. Therefore, he needs to use 100 of the tiles.

As shown in Figure 1 and supported by the interview excerpt, the student found the total area correctly by multiplying the number of tiles and the area of each tile. Afterward, she divided the total area by the area of the new tiles and accurately found the number of tiles.

Moreover, one of the correct answers to the nonlinear numerical comparison problem, which is presented in the methods, is given in Figure 2.

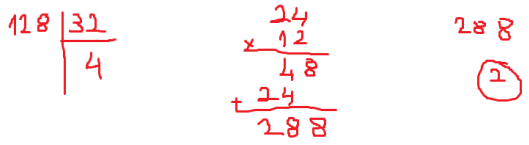

Figure 2: Andrew's correct solution for the nonlinear numerical comparison problem

Andrew: The first photo is enlarged more. First, I multiplied 4 and 8 and got 32. Then, when I divided 128 to 32, the quotient is 4. Afterward, I multiplied 12 and 24 and got 288. When I divided 576 to 288, I got 2. Since the result I obtained in the enlargement ratio of the first photo was larger, the first photo was enlarged more.

In this problem, first, the student found the area of both photographs' original and enlarged versions. Then, he identified the scale factors as 4 and 2. Afterward, he determined that the enlargement ratio of the first photo was larger because its scale factor was larger, and he achieved the correct response.

The Possible Reasons for Gifted Students' Incorrect Responses

In addition to correct responses, analyses of students' answers uncovered incorrect responses as well. The analysis revealed four incorrect answers. When these incorrect answers were examined, it was observed that students' incorrect answers were caused by contextual and conceptual reasons. More specifically, three of them were due to contextual misinterpretation, where the context was scale, and one was due to conceptual confusion. Examples of incorrect answers resulting from each of these two reasons are given below.

The student had a fallacy in interpreting the quotient in the scale context while solving the linear numerical comparison problem, which is presented in the methods.

Andrew: On the map, the actual distance between Ankara and Bursa is 388. When it is divided by 2, I got 194. On the other hand, the actual length is 582 on another map. When I divided 582 by 5, a bigger number, I got something less than 194. Thus, the map showing the distance between Aksaray and Adıyaman is on a smaller scale.

The interview excerpt indicated that the student could not associate the results he arrived at by comparing the divisors in the division process with the scale context. More specifically, although the student correctly calculated the ratio of the actual distance to the length measured on the map, he could not identify which results belonged to a smaller scale. Thus, the student gave an incorrect response stemming from contextual misinterpretation.

In addition to the contextual reason, the conceptual reason, namely conceptual confusion, led one student to provide an incorrect response for a nonlinear qualitative problem (see Figure 3).

When two rectangular prisms, tanks A and B, were filled with equal amounts of water, it was observed that the height of the water in tank A was higher than the height of the water in tank B. The water in the tank has been drained.

Then, these tanks were filled with a certain amount of water again, and it was seen that the height of the water in the two tanks was equal.

In the last case, which tank has the largest volume of water? Explain your reasoning.

Figure 3: Nonlinear qualitative problem

Zenia: I think there is more water in tank A. When an equal amount of water is put into Tank A and Tank B, it looks like there is a lot of water in Tank A. I thought that B was longer and thinner than tank A. When we fill an equal amount of water from here, a larger amount reaches A because it has more depth.

Since the student was confused about the area of base and height, she could not accurately compare the volumes of Tank A and Tank B. In other words, her wrong answer was due to her lack of relational understanding of geometric concepts.

Discussion

The present study aimed to investigate the performance of 7th-grade gifted students in alternative types of proportional reasoning problems and the underlying reasons for those students' incorrect responses. One of the most striking findings of this study was that gifted students had not experienced difficulties reported in prior studies. Specifically, the existing body of research (e.g., Ayan-Civak et al., 2024; De Bock et al., 2007) noted frequent difficulties among middle school students, such as the inability to distinguish additive and multiplicative situations and proportional and nonproportional situations. In contrast, in our study, although gifted students did not know that these problems were proportional reasoning problems, none used additive strategies; instead, they distinguished multiplicative situations correctly.

Moreover, the other compelling result of the present study was that although there was a nonlinear relationship between the attributes, such as side lengths and area in nonlinear problems, none of the students tended to an illusion of linearity because students compared areas with areas and lengths with lengths. This finding implies that gifted students in the present study showed a clear understanding and awareness of the attribute they were coordinating. Gifted students' metacognitive skills might contribute to this awareness. To be more precise, as gifted students know what they know and how to utilize what they know, and they are capable of distinguishing between relevant and irrelevant information (Shore & Kanevsky, 1993), they might be attentive to the specific attributes. Consequently, since the gifted students in this study did not experience the difficulties reported in the literature, it can be concluded that they were capable of identifying and expressing the relationship between quantities. This finding indicated that gifted students in the present study reflect the emergence of algebraic thinking, which might influence their proportional reasoning performance. Therefore, the present study's findings suggest that the unique characteristics of gifted students had an essential role in their proportional reasoning performance.

The other prominent finding was that gifted students' performances differ in alternative types of proportional reasoning problems. Expressly, within the context of the present study, the problem type on which they performed best was the missing value problem. This finding aligned with the findings

of prior studies (e.g., Ben-Chaim et al., 1998) conducted by middle school students. On the other hand, gifted students exhibited the poorest performance on qualitative problems. The reason for this difference in students' performance may be that missing value problems are more common in textbooks than in other problem types (Özgün–Koca & Kayhan–Altay, 2009). This result emphasized the necessity for including qualitative proportional reasoning problems in the mathematics curriculum in Türkiye. Besides, two out of three students had difficulty with linear problems. This might be because students might not make sense of the context of the linear problems, which causes them a *contextual misinterpretation*. This supports that the context of problems affects students' performance (Tourniaire & Pulos, 1985; Özgün-Koca & Altay, 2009) and might explain why they have lower performance in linear problems. Therefore, mathematics teachers should pay particular attention to interpreting the context in teaching and learning proportional reasoning to cultivate the effectiveness of learning for the learners.

Furthermore, the present study's findings revealed that in addition to context, *conceptual reasons* might also have a role in students' performance. Specifically, one student had difficulty understanding and visualizing height despite knowing the volume formula. The reason behind this difficulty may be that the student was exposed to procedural knowledge of the volume formula and/or did not conceptualize the elements of a rectangular prism. This finding underscores the necessity for teachers to prioritize conceptualizing the concept and connecting different branches of mathematics while teaching proportional reasoning.

Based on the valuable findings discussed, the present study highlights the need for differentiation of teaching and learning proportional reasoning tailored to gifted students' unique strengths and difficulties. Moreover, by stressing the disparities between the proportional reasoning performance of gifted and nongifted students, this study might pave the way for future studies to focus extensively on the underlying reasons for these disparities.

Despite the valuable insights and implications the present study offered, it has some limitations. More precisely, since this study aimed to examine gifted students' proportional reasoning performances in-depth, the number of participants was limited. Thus, the findings of the present study illustrated the thought processes of the three participants and shed light on the qualitative facets of problem-solving in this setting, but they were not generalizable. If the findings of this study are desired to be generalized, a quantitative study can be conducted with larger samples to confirm and expand the insights the present study offered.

Experts' structuring processes of equations that can be solved with varying efficiency: An analysis of gaze paths with eye-tracking

Christof Weber[1], Georg Bruckmaier[2] and Markus Vogel[3]

[1]Lucerne University of Teacher Education, Switzerland; christof.weber@phlu.ch

[2]Northwestern Switzerland University of Applied Sciences, Windisch, Switzerland

[3]University of Education, Heidelberg, Germany

Solving equations is fundamental to algebra yet remains a persistent challenge in mathematics teaching and learning. Drawing on a semiotic-pragmatic framework, we argue that algebraic equations lack inherent structure; instead, solvers must actively impose their own personal structure, a process known as 'structuring'. Using eye-tracking, we analysed gaze patterns of student teachers solving equations with varying efficiency. Adaptive experts showed global relating, characterised by rapid transitions between subexpressions of both sides of the equation, and hierarchical structuring, enabling faster solutions. In contrast, routine experts exhibited local relating, marked by sequential processing, longer fixations and increased cognitive load, leading to slower and less accurate performance. These findings provide insights into the cognitive strategies of equation solving and offer implications for instructional approaches that promote more effective equation solving.

Keywords: Equations, structuring processes, solving strategies, adaptive expertise, eye-tracking.

Introduction

This paper presents an ongoing study focusing on how experts' reading of algebraic equations is reflected in their gaze patterns. Adopting a semiotic-pragmatic approach, we contend that equations do not inherently possess an (objective) structure that be directly "read off." Instead, equations are strings of symbols devoid of meaning. To make meaning of an equation, we have actively to "read" a structure "into" it—essentially, impose a structure upon it. This process, known as *structuring*, involves identifying subexpressions and relate them to one other (e.g., Rüede, 2013).

Consider the equation $x - 3(x + 1) = 7 - 3(x + 1)$ (based on Hämmerle et al., 2018). It can be solved using two distinct solution strategies: (A) expanding $3(1 + x)$ on both sides and then simplifying the equation, or (B) adding $3(1 + x)$ to both sides. These strategies differ in two significant ways: First, strategy (B) is more *efficient*, requiring fewer computational steps. Second, the process of *cognitive structuring*—the mental framing before beginning to solve the equation—varies between the two strategies: Using the standard strategy (A) requires structuring the equation as $\{x\} - \{3\}\{(1 + x)\} = \{7\} - \{3\}\{(1 + x)\}$, relating the number $\{3\}$ to the subexpression $\{(1 + x)\}$ twice. In contrast, applying the more efficient strategy (B) involves structuring the equation as $\{x\} - \{3(1 + x)\} = \{7\} - \{3(1 + x)\}$, relating the left and right subexpressions $\{3(1 + x)\}$ to each other. Depending on which structuring the solver imposes, the solution will be correct and achieved with varying levels of efficiency.

In this context, the question arises of how structuring processes differ between experts who solve equations with varying efficiency, namely *routine experts* and *adaptive experts* (Baroody, 2003). Routine experts tend to rely on standard solution strategies, whereas adaptive experts apply more

innovative and efficient approaches. This classification is fluid, as individuals may switch categories depending on task-specific factors that influence strategy selection. The present study addresses this question by capturing and analysing the gaze paths of both expert types using eye-tracking methods. Our objective is to reconstruct *ideal-typical gaze patterns* of routine and adaptive experts during equation solving and explore their implications for instruction (e.g., Bikner-Ahsbahs, 2015).

Theoretical Framework

Structuring an equation: A necessary condition to solve the equation

Algebraic expressions and equations are symbol strings requiring interpretation according to established rules. For instance, one rule permits omission of the multiplication sign, while another mandates that multiplication takes precedence over addition. Consider the expression $x - 3(1 + x)$ which, from a mathematical perspective, must be interpreted as $x - \{3 \cdot (1 + x)\}$. However, in algebra education, it is widely acknowledged that algebraic expressions and equations are less self-explanatory than they may initially seem. Much like interpreting mathematical visualisations, reading algebraic equations involves an active interpretative process. Hefendehl-Hebeker and Schwank (2023) describe this as the "dynamic interplay of reading off and reading into" (p. 109). This dynamic implies that a student might interpret the expression $x - 3(1 + x)$ from an entirely different—and incorrect—structural perspective, such as $(x - 3) \cdot (1 + x)$. In this interpretation, the subtraction between x and 3 is prioritised before relating 3 to the subexpression $(1 + x)$, resulting in an alternative structure.

Each way a person relates parts of an expression represents an interpretative achievement of the person. To highlight this process, we use the term 'structuring' to describe how an individual creates an *idiosyncratic structure* for an expression (Rüede, 2013). This cognitive act shapes how the person subsequently manipulates and transforms the expression (Radford, 2010). For instance, a student who perceives the structure $\{x - 3\} \cdot \{1 + x\}$ is more likely to multiply the term. Mastering algebra, therefore, requires students to address two critical questions (Malle, 1993): *What possible idiosyncratic structuring does an algebraic expression allow, and which align with mathematical rules?* And: *Which of these structures is most advantageous for further manipulation?*

Eye-tracking analyses, particularly in the domain of equation solving, offer a promising method for uncovering these cognitive processes (see Strohmaier et al., 2020, for an overview).

Gaze patterns of experts when solving an equation: The eye-tracking approach

The study of eye movements in mathematical activities has gained prominence in recent years through eye-tracking technology (e.g., Lilienthal & Schindler, 2019). Research spans topics like arithmetic, algebra, and geometry, focusing on activities such as proof and problem-solving. Eye-tracking excels at correlating gaze location with overt attention, though the reliability of this correlation with cognitive processing remains debated (Strohmaier et al., 2020).

Few studies examine eye movements during the reading of algebraic expressions and equations. In one expert-novice study, university students rearranged simple equations like $x \cdot a = b$ or $x/a = b$ to solve for x (Susac et al., 2014). Results showed a positive correlation between the number of fixations and the ratio of reaction time to response accuracy. Experts demonstrated fewer fixations—consistent with earlier studies—meaning that experts "knew where to look" (Susac et al., 2014, p. 567). Another

study (Kohlhase & Fürsich, 2016) found that experts located the equals sign in simple linear equations before shifting to operational symbols. Novices, however, often processed equations from the center or, with longer, more complex equations (such as integral equations), from left to right, mirroring text reading. A follow-up study (Kohlhase et al., 2017) showed that experts navigated complex equations by following their expression trees in depth first traversal of the hierarchical structure.

Moreover, eye-tracking has identified ideal-typical procedures in pattern completion tasks (Schwank, 2001) and revealed common erroneous strategies in, e.g., reasoning with tree diagrams and 2×2 tables (Bruckmaier et al., 2019). Eye-tracking highlights task areas that capture attention and maps decision-making and problem-solving processes. Depending on the research focus, data can be distilled into ideal types through typifying content analysis or used to validate and refine existing ideal types.

The current study

Our study explores how eye-tracking can help to reconstruct solving strategies, an approach employed in previous research. We aim to understanding the mental actions taken when routine and adaptive experts encounter an equation that can be solved with varying efficiency. To observe their structuring process, we focus on their gaze paths, and address the following research questions: *Where is the initial gaze directed? Which elements—such as subexpressions, operations, brackets, or the equals sign—are scrutinised more closely* (indicating perceived importance)? *Between which subexpressions does the gaze shift* (suggesting the establishment of relations)? *Which areas does the gaze focus on, and where is it absent?*

Hypotheses

Aligned with our theoretical framework and the overarching research questions, our hypotheses of the current study explore how participants' eye movements—indicative of varying levels of expertise—differ when solving equations of varying levels of efficiency:

- *Adaptive experts*, who solve equations efficiently after an initial scan, will structure the equation following a top-down approach in the corresponding expression tree (see above). They will focus selectively on areas deemed relevant by the expression tree, demonstrating targeted and efficient "initial scanning" within these critical areas.
- *Routine experts*, following a standard strategy, will distribute their attention more broadly across the task areas. Their gaze will follow a more linear, left-to-right pattern, with a particular emphasis on areas that support the standard solution approach.

While eye-tracking studies typically include both qualitative and quantitative measures—such as fixation count or saccade length—our analysis in this report prioritises qualitative aspects. However, in line with the *information reduction hypothesis*, we anticipate that adaptive experts will exhibit fewer fixations compared to routine experts, as they reduce attention to redundant areas and concentrate on task-relevant information. Additionally, we expect adaptive experts to solve the equation more quickly than routine experts, who may take longer to complete the standard procedure.

Method

Sample

Seven student teachers in their early years of teacher education participated in the study. All had completed upper-secondary education and had achieved very good grades in mathematics in their Matura certificate. Their educational background indicates a solid foundation in algebra, making them well-suited for tasks involving equation solving. We could therefore reasonably expect that all participants possessed, at a minimum, the requisite knowledge to solve basic equations correctly and within a reasonable time frame, reflecting a baseline level of mathematical expertise.

Materials

The task set consisted of five equations—both linear and quadratic—selected based on prior studies. Each equation could be solved using either a standard method (e.g., expansion or quadratic formula) or a more efficient strategy. Examples include the linear equation $x - 3(1 + x) = 7 - 3(1 + x)$ (see above), as well as the quadratic equations $(x - 3)(x + 5) = 0$ and $(x - 1)(x - 2) = x - 1$. This task design allowed for variation in strategy use and corresponding gaze behaviour across participants.

Procedure

Eye movements were recorded using an SR Research EyeLink 1000 system (500 Hz sampling rate) with a tripod-mounted camera, offering a spatial resolution of 0.01°. The system tracked a 32° horizontal and 25° vertical range on a screen with a 1920 × 1080 resolution. Participants were seated approximately 55 cm from the screen to ensure consistent tracking.

After receiving instructions and an illustrative example, participants were asked to solve the equations mentally, without external tools or time constraints. As soon as they had found a solution, they were instructed to say "finish" and then state it aloud. At this point, the display and eye-tracking were paused, and participants explained their approach, which was audio-recorded. The full session—including calibration, task performance and interviews—lasted approximately 30 minutes.

Initial Observations

We focused on participants' solution strategies and their gaze patterns (i.e., scan paths). For example, in solving $x - 3(1 + x) = 7 - 3(1 + x)$, adaptive experts showed gaze transitions between x (on the very left side of the equation) and 7 (after the equals sign), indicating efforts to identify structural similarities and apply an innovative strategy. Routine experts, by contrast, exhibited more linear, left-to-right gaze paths, focusing on expanding the expression $-3(1 + x)$ on both sides, consistent with a standard strategy approach. Preliminary findings suggest routine and adaptive experts display divergent gaze patterns, both qualitatively and quantitatively, such as their time progression and focus intensity. These distinctions informed the hypotheses underlying our current study.

Analysis

Traditional heatmaps and gaze plots struggle to capture both fixation locations and order, particularly for linearly structured stimuli like equations, which are read bidirectionally. To address this limitation, we employ *fixation sequence diagrams* (also known as *sequence charts*), mapping fixation order on the x-axis and fixation position on the y-axis.

We began by combining eye-tracking data and interviews to identify participants with consistent strategies for solving $x-3(x+1)=7-3(x+1)$. For instance, *Claudia* consistently employed a shortcut strategy, recognising the identical terms $3(x + 1)$ on both sides of the equation. This adaptive use of her knowledge led us to classify her as an adaptive expert. In contrast, *Indira* adhered to the standard strategy of expanding and simplifying the expressions on both sides. Her consistent use of the standard method across all equations made her gaze patterns a representative for a routine expert.

To explore how solution strategies manifest in gaze macrostructures, we analysed the gaze paths of both participants. By incorporating interview data and existing literature, we reconstructed two ideal-typical gaze patterns: one representing adaptive experts and another for routine experts. However, the extent to which these ideal-typical gaze patterns can be generalised beyond the specific characteristics of Claudia and Indira remains an open question.

Findings

In the following section, we continue to focus on Claudia and Indira, illustrating and contrasting their gaze paths as the solve the previously introduced equation $x - 3(x + 1) = 7 - 3(x + 1)$. This analysis serves to represent broader patterns across equations involving different solution strategies and to address our two hypotheses.

Ideal-typical gaze paths of adaptive experts: The case of Claudia

Claudia solved the equation correctly in just over six seconds, explaining her strategy during the subsequent interview: "*I just saw, on the left and right, there is exactly the same term being subtracted. So there's 7 left over.*" In other words, she structures the equation as $A - C = B - C$, identifying and matching the term C. Claudia not only recognised this peculiarity but also used it purposefully, employing the innovative method by adding C (or $3(x + 1)$, respectively) to both sides, instead of following the standard algebraic strategy.

Claudia's gaze path comprised 39 fixations, each lasting between 50 and 350 milliseconds, amounting to approximately 6 seconds in total (see Figure 1 for her fixation sequence diagram). Her visual attention initially focused on the left side of the equation before shifting to the right. Further analysis revealed approximately a consistent gaze transition between the two sides—roughly one per second—resulting in seven transitions during her solution process. Early in her gaze path, she concentrated on the left-hand side, attending specially to the operators '–', '·' (or '(', respectively), and '+', in this exact order. Notably, her gaze showed no saccades between equivalent symbols on either side of the equals sign, challenging common assumptions about the gaze strategies of adaptive experts.

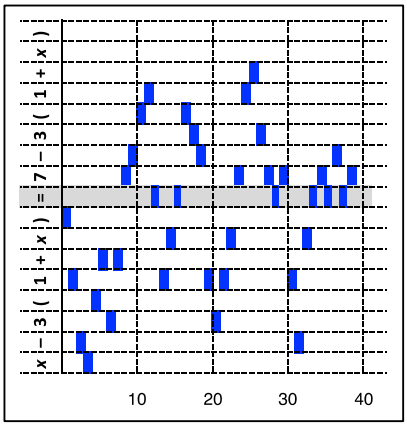

Figure 1: Fixation Sequence Diagram of Claudia (*x*-axis: fixation order)

We interpret these observations as follows: *Adaptive experts* construct relationships that extend beyond the equals sign, relate subexpressions on the left side of the equation to those on the right in

a process we term *global relating*. For these experts, the equals sign does not merely separate the equation into two isolated components; instead, they perceive the equation as a cohesive whole. This integrative perspective allows them to relate partial terms effectively, allowing for remarkably rapid equation-solving. The sequence in which they examine the operators aligns not only with their left-to-right arrangement but also reflects a systematic, top-down traversal of the hierarchical structure within the expression tree of $x - 3(x + 1)$ (Kohlhase et al., 2017). When this expression is written in functional notation—such as $-(x, \cdot(3, +(x, 1)))$— it becomes evident that these experts approach the problem "outside in" (Rüede 2013, p. 402). This way of processing expressions, aligning with our first hypothesis, appears to be a defining characteristic of adaptive experts.

Ideal-typical gaze paths of routine experts: The case of Indira

Indira took 63 seconds to solve the equation, ultimately arriving at the (incorrect) solution $x = {}^{4}/_{5}$. During the interview, she explained her approach: "*I applied the typical math rule. First, I looked at the 3, then at the bracket, and resolved it. After that, I worked it out by hand. Because I didn't have a notepad, it was a bit difficult to remember the numbers. [...] So first the left part and then the same on the right side, and yes, afterwards I looked at both together.*" Her strategy revolved around identifying expressions in the form $A(B + C)$, which led her to follow the standard strategy: distributing, simplifying expressions, and isolating variables sequentially on each side of the equation sequentially before comparing them.

Indira's gaze path (see Figure 2) comprised 150 fixations, ranging from 50 milliseconds to over 2 seconds, totaling approximately 63 seconds. Her visual attention unfolded in four phases: initial focus on the left (~15 s), followed by the right (~14 s), returning to the left (~12 s), and a final revisit to the right (~22 s). Throughout this process, she exhibited minimal gaze alternation between the two sides, with only three transitions across the entire 63-second period. Indira consistently fixated on both operands and operators for extended durations, a pattern observed across all four phases.

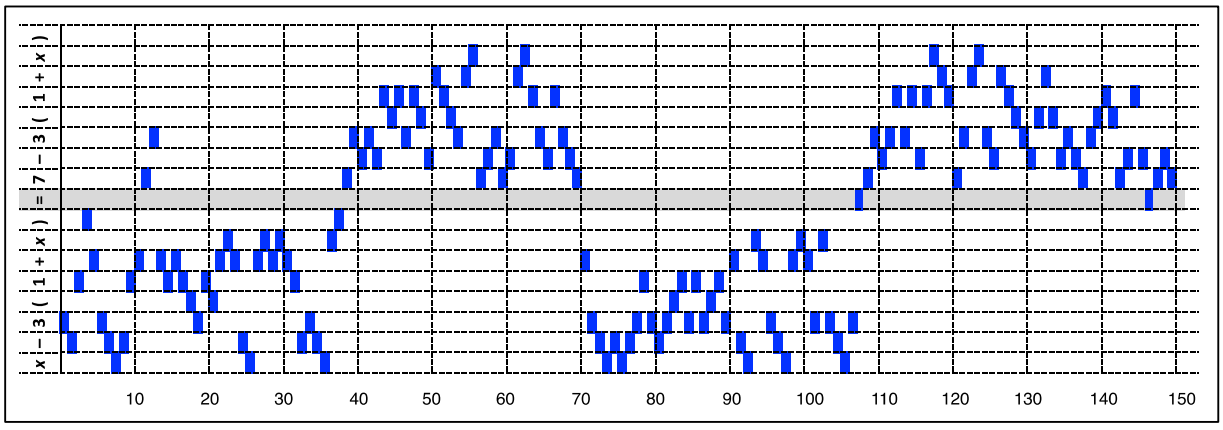

Figure 2: Fixation Sequence Diagram of Indira (*x*-axis: fixation order)

These observations align with our second hypothesis: *routine experts* primarily engage in *local relating*, linking subexpressions mainly within the same side of the equation. They tend to process each side of the equation in isolation, conceptualising the equals sign as a cognitive boundary. This

approach imposes a substantial cognitive load, particularly when mental manipulations are required. Consequently, routine experts must sustain a high level of concentration, investing significant time and cognitive resources to solve the problem. While their strategical approach can handle equations, it also heightens the risk of errors due to prolonged cognitive strain and accumulating inaccuracies.

Discussion and Outlook

The contrasting gaze patterns between Claudia and Indira illustrate distinct cognitive strategies in equation solving. Adaptive experts like Claudia demonstrate *global relating*, rapidly integrating information across the equation through hierarchical processing. In contrast, routine experts such as Indira engage in *local relating*, sequentially focusing on isolated segments with greater cognitive effort, resulting in longer solution times and more fixations. This segmented approach, combined with increased working memory demands, may elevate the risk of errors under cognitive strain.

These findings highlight the importance of structuring in equation solving—an often overlooked aspect of algebra instruction. As Malle (1993) observes, "Many teachers are not even aware that the manipulation of algebraic expressions relies on the recognition of structure [i.e., structuring, C.W.]. As a result, they often focus on 'endless' manipulation practice without addressing this foundational step" (p. 254). Without targeted attention to structuring processes, instruction risks defaulting to procedural practice, with limited development of conceptual understanding.

Furthermore, fixation sequence diagrams offer a promising analytic lens. By visualizing how students structure equations, these diagrams can reveal whether learners adopt globally integrative or locally fragmented strategies. This distinction not only echoes recent work by Schreiter and Vogel (2024) but also aligns with broader expertise literature: adaptive experts draw on flexible pattern recognition, while routine experts tend to follow procedural, step-by-step routines. Our preliminary findings suggest that gaze patterns may serve as predictive indicators of students' solution strategies. As Solstad et al. (2025) note, "eye-tracking can contribute to inferences about mathematical thought processes" (p. 1), though they caution that such interpretations require contextual support and awareness of the limitations of the eye-mind hypothesis. Nonetheless, the integration of eye-tracking into algebra education holds promise for diagnosing and fostering more effective problem-solving strategies.

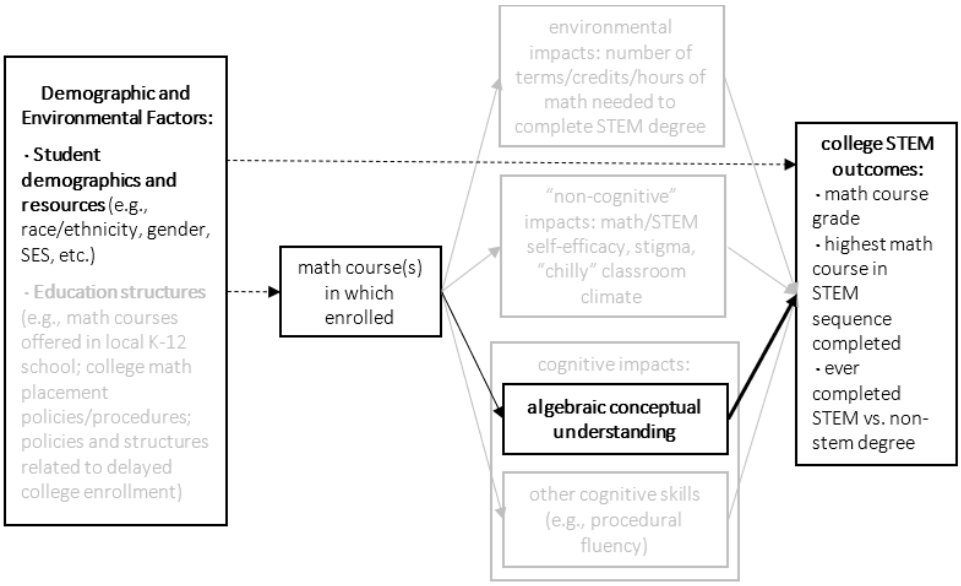
Predictive validity of the algebra concept inventory

Claire Wladis[1,2], Eileen Murray[2] and Geillan Aly[2]

[1]BMCC at the City University of New York, USA; cwladis@bmcc.cuny.edu

[2]The Graduate Center at the City University of New York, USA



We explore whether outcomes in tertiary mathematics courses and STEM (science, technology, engineering and mathematics) degrees can be predicted by scores on the previously-validated Algebra Concept Inventory (ACI). We also explore whether ACI scores explain gaps in outcomes by race/ethnicity and gender. This research explores a dataset of 6,582 students enrolled at the City University of New York, a diverse, urban, public university in the U.S. Results suggest that ACI scores can significantly predict tertiary math and STEM outcomes, above and beyond math course grades.

Keywords: Algebra, conceptual understanding, tertiary students, STEM majors, equity.

Various research has explored which factors predict student outcomes in tertiary mathematics courses as well as success in pursuing and completed tertiary STEM (science, technology, engineering and mathematics) degrees. Existing literature has explored how various factors predict these outcomes, including: K-12 mathematics preparation (e.g., Cohen & Kelly, 2020) post-secondary school performance (e.g., Chen & Soldner, 2013), or more diffuse assessments of general knowledge, such as GPA (grade point average) or standardized test scores (e.g., Gipson, 2016). Algebra in particular has been recognized as both a barrier to degree completion (e.g., Bailey et al., 2010) and a requirement for earning a STEM degree (e.g., Sithole et al., 2017); however, existing research tends to analyze correlations between grades or levels of algebra completed in secondary school and tertiary outcomes, rather than measuring algebra knowledge directly as a predictor of success in math and STEM in the tertiary context. In particular, no existing larger-scale studies have explored the relationship between higher-level reasoning skills such as algebraic conceptual understanding, and successful math and STEM outcomes in the tertiary context. This research attempts to address this gap.

While conceptual understanding is crucial in mathematics (Richland et al., 2012), it is frequently neglected in algebra instruction (e.g., Hodara, 2011). It is especially important for STEM students, who should be able to flexibly apply their algebraic knowledge in unfamiliar situations (e.g., Quarles & Davis, 2017). Models of tertiary STEM degree attainment have explored various predictors, including environmental impacts from course sequences (e.g., Ryu et al., 2022), placement policies (e.g., Ngo et al., 2018), and general cognitive skills (e.g., Chen & Soldner, 2013). However, there is limited exploration of specific measures of conceptual understanding predicting STEM outcomes, and models that include completion of specific math courses as predictors often obscure the separate impact of different correlated factors related to the course in which a student enrolls (e.g., Quarles & Davis, 2017). Here we adapt and expand existing models by including algebraic conceptual understanding as a core factor (Figure 1). We then use scores on the validated Algebra Concept Inventory (ACI; Wladis et al., 2024b) to explore the extent to which ACI scores can predict students' grades in current mathematics courses; whether they ever completed certain core STEM major mathematics courses; or whether they obtained a STEM vs. non-STEM degree. We also explore the

extent to which ACI score can explain differences in these outcomes by race/ethnicity and gender.

Notes: Grey arrows represent relationships that have been tested in other research. Thick black arrow at far right represents main relationship tested in this research. Thin black arrow represents fixed effects by course (controlled for in all analyses). Dotted black arrows represent control variables included in analyses that use controls.

Figure 1: STEM major access and retention model

Further, there are racial/ethnic inequities in access to high quality K-12 mathematics instruction (e.g., NCES, 2024; Schoenfeld, 2022), which may impact students' opportunities to develop conceptual understanding before tertiary entry. Racial/ethnic minorities are more likely to leave STEM degrees, both because of inequitable access to K-12 mathematics instruction and because of hostile climate in STEM fields (e.g., Riegle-Crumb, et al., 2019). Historically marginalized students often encounter mathematics instruction that provides fewer opportunities to develop higher-level reasoning skills such as conceptual understanding (e.g., Schoenfeld, 2022) and are also more likely to be placed into lower-level mathematics courses in college (e.g., Chen, 2016) where instruction tends to focus more on rote procedures without sensemaking (e.g., Hodara, 2011). This may negatively impact STEM degree progression and completion for traditionally marginalized groups, and thus partially explain inequities in STEM degree outcomes. Yet, this relationship has not been explored in prior research.

Algebraic conceptual understanding

The ACI defines algebraic conceptual understanding as understanding of mathematical concepts, which includes mathematical reasoning and provides the foundation for algebraic thinking. Algebraic thinking is the human activity of recognizing, expressing, and reasoning about generalizations, which serves as the foundation for algebra (Hodgen et al., 2018). Algebraic thinking includes creating expressions and equations to generalize patterns or relationships, manipulating symbols to transform expressions, and using algebra as a tool for analyzing structures or relationships. These activities enable students to engage deeply with mathematical concepts and apply them in real-world and abstract situations. For the ACI, concepts are defined as well-defined mathematical processes, objects, or ideas accepted by the mathematical community (Sfard, 1991). The ACI emphasizes concepts accessible to students in a first-year secondary algebra course (or its equivalent) such as

equivalence, syntactic structure, algebraic properties, functions/variation, and variable. Conceptual understanding is operationalized on the ACI as follows: an item was conceptualized as testing conceptual understanding if it is necessary to use logical reasoning (grounded in mathematical definitions) to answer correctly, and it is not possible to arrive at a correct response solely by restating memorized facts or implementing a rote sequence of actions that could be memorized and correctly applied irrespective of deeper understanding of the mathematical justification. As an illustration of concepts and conceptual understanding, we present two ACI items (see Figure 2[1]).

Item 1. *In the expression* $-7x^3 + 1$ *, which part is being cubed (or raised to the third power)?*

a. $-7x$
b. $7x$
c. x

Item 2. *When solving an equation that contains an* x*, a student gets the answer* $8 = 8$*. This means that:*

a. This could only happen if the student made a mistake somewhere.
b. Every possible value of x *is a solution to the original equation.*
c. There is no solution to the original equation.
d. The solution to the original equation is $x = 8$*.*

Figure 2: ACI example items

For Item 1, students conceptualizing the normative structure of the syntax of the expression would typically choose C. Students who choose A or B typically extract the structure of the syntax from non-mathematically salient features drawn from instructional experiences and may conceptualize the meaning and structure of algebraic syntax differently than those who link it to normative operational precedence (e.g., Wladis et al., 2025). For Item 2, students who understand both that valid transformations preserve the solution of an equation and that all values of x would make the equation $8 = 8$ true typically choose B. Students who choose A, C, and D often have alternative conceptions about what it means to solve an equation or for an equation to have a solution; for example, some students who choose D conceptualize solving an equation as a process of performing allowed procedures to get a numerical value as a final result, in a way that is unlinked from the standard definition of a solution of an equation (Wladis et al., 2024c). Both of these items are conceptualized as measuring conceptual understanding because neither can be answered solely by restating memorized facts or performing a rote procedure without understanding its justification.

The ACI is the first large-scale assessment to undergo mixed-methods validation for measuring algebraic conceptual understanding in tertiary students, particularly for all algebra course levels (Wladis, et al, 2024b). Here we use previously-collected ACI scores to explore the relationship between algebraic conceptual understanding and tertiary outcomes such as mathematics course grade, completion of STEM-major mathematics courses, and STEM vs. non-STEM degree completion.

Method

The dataset used for this study included students in mathematics courses at the largest community college at the City University of New York (CUNY) between spring 2019 and summer 2023. This included a wide range of courses, from elementary algebra (focused on objects similar to a first-year secondary algebra course) to more advanced courses such as calculus, linear algebra, and differential equations. We combined institutional records with an existing ACI dataset to explore relationships

[1] For the purposes of test security, numbers and answer option order have been altered.

between students' algebraic conceptual understanding and academic outcomes. This included 6,582 students. The independent variable was a student's score on the ACI that came from various test forms, each of which contain a subset of approximately 25 of the 402 ACI items. The ACI forms used common-item random groups equating design, and analysis has demonstrated excellent reliability and validity for the inventory (Wladis et al., 2024b). ACI scores represent how many standard deviations a student's performance was above or below the mean compared to others in the sample. Dependent variables included: mathematics course grade (0-4.0 scale), successful course completion (grade of C or better), and STEM or non-STEM degree attainment during the study period. "Base" models did not include controls; "full" models used control variables: GPA, prior credits earned, race/ethnicity, gender, age, median household income of zip code, and instructor. Missing data were minimal, affecting less than 2% of the dataset, so we used listwise deletion. Fixed effects were added to relevant models to account for specific course taken, course level/sequence, and instructor.

We used fixed-effects linear/logistic regression models to predict course outcomes and STEM degree attainment. Here we report linear models for easier interpretation. We used the KHB decomposition method (Kohler et al., 2011) for mediation analysis to decompose disparities in ACI scores into "indirect" and "direct" components related to race/ethnicity and gender. Finally, we used entropy balancing (Hainmueller, 2012) to address potential differences between the full population and students with ACI scores; this was used to reweight data and improve covariate balance so that the subset of students with ACI scores matched the larger population on all measured variables.

Results and discussion

Math course and STEM degree completion

ACI scores significantly predicted whether students who attempted, successfully completed, a core STEM major mathematics requirement[2] (Table 1). These differences were not due to correlations between ACI score and current course level because all models included fixed effects for course level (i.e., only compared students enrolled in the same course). Students were 16 percentage points more likely to complete elementary algebra for every 1 SD in ACI score; this was 14, 13, 15, and 11 percentage points for intermediate algebra, precalculus, Calculus I, and Calculus II, respectively.

Table 1: ACI score as predictor of successful completion of STEM major mathematics courses

	Base Models				Full Models			
Ever completed:	**Coeff. (ACI score)**	**SE**	***p***	**Sig.**	**Coeff. (ACI score)**	**SE**	***p***	**Sig.**
Elem. Algebra	0.16	0.04	0.000	***	0.15	0.05	0.001	**
Int. Algebra	0.14	0.02	0.000	***	0.11	0.02	0.000	***
Precalculus	0.13	0.02	0.000	***	0.09	0.02	0.000	***
Calculus I	0.15	0.03	0.000	***	0.09	0.02	0.000	***
Calculus II	0.11	0.02	0.000	***	0.08	0.03	0.008	**
Notes: Linear Probability Multi-Level Weighted Regression: fixed-effects by sequence number of current course, random effects by instructor; *Significance levels:* $*** \alpha = 0.001, ** \alpha = 0.01, * \alpha = 0.05$, $. \alpha = 0.10$								

[2] In the US, as in many parts of Europe, STEM majors are often presumed to begin their studies in Calculus III; however, in reality, many US STEM majors enter college requiring coursework in one or more pre-requisite courses before they can enroll in this course (e.g., Cohen & Kelly, 2020), particularly lower-SES and marginalized students.

ACI scores also significantly predicted whether students who completed a two- or four-year degree during the study period earned a STEM vs. a non-STEM degree. For students in the same level mathematics course when taking the ACI, those with higher ACI scores were significantly more likely to graduate with a STEM degree. ACI score predicted STEM degree completion even more strongly than course grade alone. Students with a 1 SD higher ACI score were 5.1 percentage points more likely to earn a STEM vs. non-STEM degree; accounting for both ACI score and math course grade simultaneously, a 1 SD increase in ACI score corresponded to a 4.0 higher percentage point chance of earning a STEM vs. non-STEM degree for students with the same grades, whereas an increase in one course grade corresponded to only a 1.8 percentage point increase. Thus, ACI scores have predictive power independent of grades, with greater predictive power than math course grades.

ACI score as explaining differential outcomes by race/ethnicity and gender

We also considered whether ACI scores could explain differences in course grades and STEM vs. non-STEM degree completion by race/ethnicity and gender. Critically, we found direct and indirect discrepancies related to course grades highly significant in both base and full models with controls for race/ethnicity (Table 2). In Table 2 we see that ACI score accounts for 13-17% of the difference in course grades by race/ethnicity. For example, URM[3]'s math course grades are on average 0.65 points lower (scale: 1-4), and 0.11 of these points (17%) can be attributed to differences in algebraic conceptual understanding as measured by the ACI (in models without controls). For gender, the pattern is different: while both direct and indirect discrepancies are highly significant in base and full models, they have opposite signs, because women on average earn higher grades in mathematics courses despite having lower ACI scores (a suppressor "effect"). This may be because women on average spend more time on their studies than comparable men (e.g., Wladis et al., 2024a).

Table 2: ACI score as mediator between URM status or gender and mathematics course grade

	Base Models				**Full Models**

Direct discrepancy	0.29	0.04	0.000	***	0.26	0.05	0.000	***
Indirect discrepancy	-0.04	0.01	0.000	***	-0.03	0.01	0.001	**
Notes: Mediation of Relationship Between URM/Gender and Mathematics Course Grade by ACI Score, fixed-effects by course sequence number, clustering by instructor, using KHB Method *Significance levels:* $*** \alpha = 0.001, ** \alpha = 0.01, * \alpha = 0.05, . \alpha = 0.10$								

ACI scores also explained differences in STEM vs. non-STEM degree completion by race/ethnicity (Table 3). Neither the total nor direct discrepancy is significant in base or full models, but the indirect discrepancy is significant, so that after accounting for the indirect relationship of ACI score as an

[3] In tables, we use URM (underrepresented minority) to indicate students of color who have been traditionally underrepresented in STEM fields; this includes Black, Hispanic, and American Indian/Native Alaskan students.

explanatory variable for differences in STEM vs. non-STEM major attainment by race/ethnicity, URM students are ***more*** likely to complete a STEM vs. non-STEM degree (although not statistically significantly so). Thus, ACI score explains 100% of the total discrepancy in STEM vs. non-STEM degree attainment by race/ethnicity. Exploring mediation models for gender shows the total, direct, and indirect discrepancies are all statistically significant, with ACI score explaining about 10% of differences in STEM vs. non-STEM degree attainment by gender.

Table 3: ACI score as mediator between URM status or gender and degree completion

Discussion and conclusion

ACI scores predicted successful completion of core math courses required for STEM majors. ACI scores not only predicted the likelihood that a student would successfully complete tertiary algebra classes if they enrolled in them, but also whether students would complete courses such as Calculus I and II, where algebra is not the main focus of instruction. This suggests that algebraic conceptual understanding may be critical across tertiary mathematical domains, and not just in algebra courses.

ACI scores also predicted whether students earned STEM vs. non-STEM degrees, independent of math course grades. This is particularly striking, since ACI scores were generated from a 25-item test given on a single day and measures general algebraic conceptual knowledge, whereas course grades are based on a term's worth of assessment specific to the particular course. It may be that improving instruction in algebraic conceptual understanding is a critical component of preparing students for STEM degrees and careers—this is a critical area for future research.

ACI scores also explained differences in math grades and STEM vs. non-STEM degree completion by race/ethnicity. ACI score accounted for 13-17% of racial/ethnic math grade differences and 100% of the STEM vs. non-STEM degree completion gap, suggesting that differences in opportunities to develop algebraic conceptual understanding explain a significant proportion tertiary outcome differences by race/ethnicity. Thus, improving access to substantial opportunities to develop algebraic conceptual understanding in mathematics courses may be particularly critical to addressing racial/ethnic inequities in tertiary outcomes—this is a critical area for future research.

Women on average earned higher grades in math courses despite having lower ACI scores. This may be because women on average spend more time on their studies than comparable men (e.g., Wladis

et al., 2024a), and therefore may earn higher grades because of the added time spent studying. More research is needed to better understand this trend. At the same time, differences in ACI scores explained 10% of the gender gap in STEM vs. non-STEM degree completion. Thus, it may be important to ensure that women receive equal opportunities to develop algebraic conceptual understanding in mathematics courses. This may be related to marginalized experiences that women and girls have in mathematics classes (e.g., Reinholz, 2022), which may negatively impact their opportunities to develop conceptual understanding. Future research that investigates the relationship between equitable learning opportunities in the classroom and subsequent development or improvement or conceptual understanding could be an important area for future research.

Prior studies have identified various factors that impact STEM major enrollment and completion, particularly for marginalized groups, including: K-12 mathematics preparation (e.g., Cohen & Kelly, 2020), postsecondary and tertiary grades (e.g., Chen & Soldner, 2013), standardized test scores (e.g., Gipson, 2016), and experiences in tertiary STEM classes (e.g., Riegle-Crumb, et al., 2019). This study provides evidence of an additional factor that has not been directly measured as a predictor of STEM outcomes in prior studies: algebraic conceptual understanding as measured by the ACI. The ACI measures just one conceptualization of algebraic conceptual understanding; there are likely other conceptualizations, as well as other types of mathematical skills and reasoning that are not measured by the ACI, but which could be measured through other instruments or methods. This study illustrates the potential of exploring the relationship between different types of mathematical skills, reasoning, and knowledge and tertiary STEM outcomes, which could be expanded and built on in future studies.

Comparison of structural sense in limit tasks between first and final year engineering students

Gloria Cancec Murillo[1], Pablo Flores Martínez[1] and Teresa Rojano Ceballos[2]

[1]University of Granada, Spain; gloriacancec@correo.ugr.es; [2]CINVESTAV, Mexico

Keywords: Algebraic sense, structural sense, algebraic errors, algebraic manipulation, higher education.

Introduction

Differential and integral calculus presents difficulties for learners, especially in regard to tasks such as limits, which require factoring skills as well as rationalization and simplification of algebraic fractions. These problems arise due to errors or lack of maturity in algebraic management, which leads to the need to develop or reinforce the structural sense, understood as the ability to perceive the structures of algebraic objects (Rojano, 2022).

Theoretical framework

Authors such as Hoch and Dreyfus (2006) identify three skills for structural sense: recognising basic structures, treating complex terms as single entities, and choosing appropriate manipulations to best utilise algebraic structures. Vega-Castro (2013) extends these skills by adding the ability to distinguish substructures, anticipate the effects of transformations, and extract relevant information from an algebraic expression. Muñoz-Porras (2015) introduces the auxiliary variable technique, a useful tool for recognizing and manipulating structures in algebraic expressions. Descriptors as indicated by these authors have yielded the selection of eight key components: (C1) recognize a familiar structure in its simplest form; (C2) identify substructures within an expression and treat them as a single entity when transforming the expression; (C3) deal with a compound term as a single entity by recognizing a familiar structure in a more complex form; (C4) choose appropriate manipulations to optimally make use of a structure; (C5) distinguish substructures within an entity and recognize relationships between them; (C6) apply substitution, either internally or explicitly; (C7) recognize equality relations in structure of present expressions; y (C8) extract relevant information from the external structure of an expression, relative to the object it represents or to its internal structure. A study by Ruiz-Hidalgo and Fernández-Plaza (2013) on limit solving using algebraic fractions concluded that structural sense is related to analytical complexity and the probability of making errors. In this way, Rojano (2022) highlights the usefulness of applying structural sense in calculus tasks. Therefore, the aim of this study is to compare the structural sense between first and final-year engineering students in limit tasks, a relevant dimension that is absent in previous studies.

Methodology

For this purpose, a content analysis Krippendorff (2019) was carried out with a sample of 16 final-year students and 15 first-year students from a Chilean Higher Technical-Professional Education (TP) institution. The questionnaire used considers 10 items in terms of four parts: A) factorization, B) completion of equivalent expressions, C) equations and D) limits of a function at a point. We analyzed

part D, which includes four items that refer to an algebraic fraction ($\lim_{x\to 2}\frac{x^3-8}{x^2-5x+6}$), rationalization ($\lim_{x\to 3}\frac{x-3}{\sqrt{x+1}-2}$), a trigonometric function ($\lim_{x\to 0}\frac{2sin(3x)}{5x}$) and a contextualized situation (The average revenue for article x in a company is $I=\frac{x}{200x-0,2x^2}$, what will happen if the number of articles is reduced to zero?)

Results

The items most answered by both groups of students were on algebraic fractions and rationalization. In algebraic fractions, both groups recognize numerator and denominator in its simple form (C1), but when simplifying (C5), the senior group had better results. In rationalization, both identify the complex structure (C3), but when simplifying (C5), the first-year group achieved a better result by obtaining an equivalent expression (C7). In the trigonometric limit items and contextualized situation, there was minimal participation, though the senior group responded more.

Conclusions

When comparing both groups, a greater development of structural sense was expected in the senior students, but the results show that, although they answered more questions, this does not necessarily reflect a better understanding of the structure. In mathematics education it appears necessary to enhance the application of structural sense in other contexts than algebra, to be successful in areas such as calculus and modelling, key skills for engineers and researchers.

Strategies used by students with autism to complete repeating patterns

Juncal Goñi-Cervera[1], Irene Polo-Blanco[1], Maria Chimoni[2] and Demetra Pitta-Pantazi[2]

[1]Universidad de Cantabria, Spain; juncal.goni@unican.es

[2]University of Cyprus, Cyprus

Keywords: Repeating patterns, algebraic thinking, autistic students, early algebra.

In kindergarten, children start working with patterns. Patterns are defined as any replicable regularity (Papic et al., 2011). One type of pattern that children engage with is repeating patterns, characterized by a cyclic structure created by the repetition of a smaller segment, known as the unit of repeat (Papic et al., 2011). Generalization occurs as soon as the child recognizes that the structure of the unit of repeat remains the same across the pattern. This kind of generalization appears to provide the basis for structural awareness and, consequently, the ground for the development of early algebraic thinking (Papic et al., 2011). This research study focuses on the strategies that students with autism (ASD) use when engaged with repeating pattern tasks. The identification of ASD students' strengths and challenges in this area is considered essential for better understanding how neurodiverse learners process patterns, and for supporting educators' efforts to develop tailored instructional methods that enhance inclusion and improve learning outcomes. Previous studies on early algebraic thinking of ASD students have shown a tendency towards recursive strategies and difficulties with generalization (Goñi-Cervera et al., 2022), which could possibly be related to certain characteristics of the disorder, such as the concrete thinking style and difficulties with abstraction. However, the studies addressing this student profile are scarce, and those that do exist mainly examined strategies used to solve growing pattern tasks within a functional context (e.g., Goñi-Cervera et al., 2022). The current study focuses on ASD students at the beginning of their mathematical learning, aiming to understand their thinking about fundamental mathematical concepts and procedures, as well as the strategies that they employ when engaged with basic maths tasks, such as repeating patterns.

The theoretical framework is based on previous studies with typically developing students, which provides a foundation for understanding how different strategies affect the identification of near and far terms in sequences (Papic et al., 2011). The participants of the present study were 3 Spanish autistic children, aged 6 years old, who were enrolled in different inclusive schools. Data were collected through a questionnaire that included four tasks involving repeating patterns with two different attributes: colour and shape. Tasks 1 and 3 involved an AB pattern, task 2 involved an AAB pattern, and task 4 involved an ABB pattern. Each task included three similar questions related to identifying terms in the sequence. The first question (Q1) asked the participants to find near terms by completing the gaps at the end of the pattern in tasks 1 and 2, and at the beginning of the pattern in tasks 3 and 4. The subsequent two questions addressed far terms for each task. For example, the questions for task 1 were: (Q2) "If the pattern continues, what figure will be in position 14? Explain how you found your answer", and (Q3) "If the pattern continues, what figure will be in position 21? Explain how you reached your answer". To analyse the responses, we adapted the classification from Papic et al. (2011), taking into account strategies used in tasks similar to those presented in this work. Specifically, we considered the following categories: *Random arrangement* (*RAS*): When students

place items in a random fashion; *Alternation (AS):* When students focus on successive items regardless of the complexity of the unit of repeat; *Basic unit of repeat (URS):* When students identify the unit of repeat and use it to complete the pattern. A category named *No evidence (N)* was used for providing no explanation. The following table shows the strategies applied by the three participants in the different questions and tasks. Answers marked with an '*' indicate incorrect responses.

Table 1: Strategies used by the participants in questions 1, 2, and 3

	Task 1 (AB _)			Task 2 (AAB _)			Task 3 (_ AB)			Task 4 (_ ABB)		
	Q1	Q2	Q3	Q1	Q2	Q3	Q1	Q2	Q3	Q1	Q2	Q3
Student 1	AS*	AS*	AS*	AS*	AS*	AS*	AS*	AS*	AS*	AS	AS*	AS*
Student 2	AS	AS*	AS*	AS	AS*	AS*	AS*	AS*	AS*	AS*	URS*	URS
Student 3	AS	AS*	AS*	AS	URS	AS*	AS	URS	N	AS*	AS*	AS*

As shown in Table 1, the AS occurs more frequently than strategies which involve the unit of repeat. Strategies of alternation only resulted in correct answers for finding near terms in the sequences. In contrast, URS led to correctly identifying far terms in three cases. Errors with this strategy were often due to participants losing count while repeating the basic unit. This finding aligns with studies involving TD students engaged with similar tasks (Papic et al., 2011). Although the small sample size limits generalization, our results highlight a type of visual approach, a common strength among ASD individuals and has previously been evidenced in problem-solving and algebraic thinking, often through strategies based on drawings (Polo-Blanco et al., 2024; Goñi-Cervera et al., 2022).

The findings highlight the predominant use of strategies of alternation by ASD students when engaging with repeating pattern tasks, emphasizing their effectiveness for near-term identification but limitations for far-term accuracy. By recognizing these diverse strengths and challenges of ASD students, instruction can be modified to involve differentiation, such as the support of their visual thinking to move from focusing on successive terms to grasping the structure of the pattern.

[5]Charles University, Faculty of Education, Prague, Czech Republic

The Thematic Working Group 4 (TWG4) at CERME14 brought together 30 researchers from 12 countries who presented 20 papers and 2 posters, reflecting an acceptance rate of 75%. These contributions spanned various educational levels and showcased a wide range of methodological and theoretical approaches. The work was organised across five themed sessions—General Perspectives and Conceptual Approaches, Curriculum and Task Design, Use of Tools (Physical and Digital), Teachers and Teacher Education, and Advanced Topics and Young Learners, as well as two sessions of group discussions. These sessions enabled focused discussions and also included time for synthesis and collaborative reflection, reinforcing the interdisciplinary and integrative spirit of the group.

Diversity in Research and Mathematical Focus

The TWG4 papers showcased a broad and evolving spectrum of research interests. Examples include argumentation and reasoning, teacher geometry knowledge, analysis and assessment of students' spatial abilities and geometric knowledge, and the use of 3D printing and computer modelling. The mathematical content explored in these contributions also demonstrated considerable diversity. Examples included learning and teaching projective geometry, properties of solids, symmetry, classification of quadrilaterals, and trigonometry, illustrating the wide spectrum of geometrical themes. Applications were distributed across educational levels and often intersected with technological tools and embodied practices, underscoring TWG4's distinctive focus on integrating cognitive, representational, and instructional dimensions of geometry learning. Researchers such as Antunović examined students' transitions between figural and conceptual reasoning using Duval's framework and echoing insights from Fischbein's theory of figural concepts (Fischbein, 1993), while Büttner and Viola explored conceptual breaks in trigonometric contexts, highlighting the interpretive challenges when switching between multiple representations.

This thematic richness reflects the group's commitment to linking foundational geometric knowledge with contemporary educational demands, especially those brought on by technological and epistemological developments.

Tools, Representations, and Their Integration in Learning Environments

The integration of tools—both physical and digital—was a significant focus in TWG4. Rather than treating them as external enhancements, many contributions demonstrated how tools shape the structure, representation, and semiotic richness of geometry learning. Surynková examined the

affordances of 3D printed models in enhancing spatial visualisation and projections. Brunheira analised the contributions to students' spatial reasoning and knowledge about rotation and its relation to the design of the interdisciplinary tasks between visual arts and geometry. Fujita et al. analysed how multiple theoretical perspectives can guide the intentional integration of both physical and digital tools to support reasoning. Okumus and Hollebrands analyzed how teachers use dynamic geometry software (DGS) to focus students' attention on geometric properties in 3D contexts, contrasting the affordances of static drawings and dynamic constructions.

Del Zozzo illustrated how dynamic tools like GeoGebra, when paired with historical texts, can mediate perceptual and semiotic shifts in learners' understanding. Huang and Fujita introduced virtual reality to extend spatial experience in 3D geometry tasks, while Sauerwein introduced a non-digital yet underutilised construction tool that enabled students to explore geometric loci and develop mathematical language in alignment with Van Hiele levels. Together, these contributions reinforce the view that in geometry, the medium itself—whether physical or virtual—modulates what and how learners see, construct, and argue. In line with Duval (2017), these tools engage different modalities of apprehension and require coordinated interpretation across representations. This shift from using tools to designing with them underscores TWG4's evolving vision of geometry pedagogy. The embodied, representational, and semiotic potentials of tools also set the stage for a broader examination of geometry as a multimodal practice—an idea taken up in the following discussions on embodiment and multimodality.

Geometry Through Embodiment and Multimodality

The exploration of embodied cognition took a prominent place in this year's discussions. Palatnik et al. studied a collaborative task involving a life-sized icosahedron, capturing how gestures and bodily orientation were instrumental in constructing geometric arguments. Their use of eye-tracking and multimodal transcription highlighted the emergence of embodied argumentation and its potential to redefine how we understand proof in educational contexts.

Obayashi and Fujita also contributed significantly to this strand by analysing primary school students' reasoning processes during symmetry tasks. Their analysis, grounded in Duval's framework of figural apprehension, illustrated how students progressed from visual intuition to discursive justification, often through teacher mediation.

These and several other contributions—including those by Del Zozzo, Surynková, and the posters by Maschietto and Battilani and Alstad and Berre—suggest exploring how argumentation in geometry is no longer confined to linguistic expression or formal deduction but extends into the perceptual, physical, and gestural domains.

Task Design and Curricular Articulation

The interplay between task structure, medium, and learning outcome was a recurring concern. Multiple studies investigated how tasks designed around digital tools (e.g., dynamic geometry software) or physical artefacts (e.g., printed manipulatives) could support different cognitive pathways. Bímová et al. explored function plotting using both tangible and digital representations, demonstrating how shifting between tools affects students' interpretative strategies. İmamoğlu et al.

examined how DGE-based problem-solving activities can influence students' mathematical performance and thinking strategies, highlighting the importance of adaptive task design. Vízek and Samková developed a framework for analyzing students' conceptual knowledge of quadrilaterals based on dynamic constructions, capturing distinctions among classification, structural relations, and principled reasoning.

Haj-Yahya et al., in their work with prospective teachers, examined how mathematical events could foster an understanding of inclusion relationships among quadrilaterals. They showed that well-designed interventions helped students move beyond prototype-based reasoning to a more definition-oriented understanding. Similarly, Tortorelli and Tortoriello addressed conceptual gaps between learners' figural impressions and formal definitions, highlighting the utility of structured card-based tasks to prompt reflective dialogue without oversimplifying geometric definitions or reducing them to fixed prototypes. In contrast to these classroom-oriented interventions, Miyakawa and Su conducted a comparative curriculum analysis of junior high school geometry in Japan and Taiwan. Using the Anthropological Theory of the Didactic, they revealed how institutional contexts shape both the organisation of mathematical content and the nature of reasoning in varying national settings.

These studies collectively point to a growing sophistication in task design, with careful attention paid to the sequencing of tasks, selection of representational media, and the scaffolding needed to bridge intuitive and formal knowledge. This multi-dimensionality of task design was further captured in a diagram discussed in the group's final session. The diagram highlighted five interconnected aspects: the structure of the task (from activity to objective), the medium used (digital or physical), the source of the task (ranging from historical texts to everyday contexts), necessary modifications (to accommodate learners' needs), and the overall conceptual aim. It reinforced the idea that in geometry, tasks are shaped as much by their design and origins as by the environments and representational tools through which they are enacted.

Insights into Teacher Education

Contributions focusing on teacher education revealed both challenges and opportunities. Pirklová et al. provided a diagnostic framework for categorising pre-service teachers' errors and understanding where instructional gaps occur. Kovalčíková and Semanišinová analyzed teacher responses to geometric problem-solving, underscoring the difficulty of bridging theoretical knowledge with pedagogical practice.

Several papers, such as those by Halverscheid and Harland, focused on how teacher trainers initiate argumentation and proof processes in geometry instruction. Their qualitative study highlighted how subjective theories influence the choice of proving strategies, particularly in the context of classical geometric theorems. Other studies emphasised that strengthening geometry teacher education requires a blend of deep content knowledge, didactical sensibility, and familiarity with both traditional and novel tools. Danişman and Arabacı explored the challenges preservice teachers face in constructing geometric arguments and aligning their teaching practices with curricular goals, offering insight into the need for more balanced teacher education programmes across countries. Notably, embodied approaches and tool-mediated experiences (e.g., Palatnik et al., Surynková) were seen as potential enhancers of preservice teachers' geometrical insight and adaptability.

Theoretical Approaches and Conceptual Frameworks

Across the group, there was a shared recognition of the importance of theoretical clarity and diversity. Haj-Yahya et al. addressed learners' concept images and definitions through tasks involving both prototypical and non-prototypical shapes. Tortorelli et al. contributed to this theme through a card-based task bridging intuitive and formal understandings of quadrilaterals, based on the idea concept image and definition (Tall & Vinner, 1981). Sauerwein built on the Van Hiele model and Winter's Workshop Language to analyse how students' language and geometric understanding co-develop through construction tasks. Vízek and Samková offered a dimensional approach to conceptual knowledge—covering classification, structure, and principles—assessed through dynamic quadrilateral constructions. Del Zozzo applied the Theory of Objectification both globally and locally, emphasising sensuous cognition and semiotic activity. Palatnik et al. extended embodied learning theory to argumentation, highlighting the interpretive role of movement and perception in reasoning (Radford, 2009). These theoretical contributions offered layered insights into how students perceive, construct, and justify geometric ideas, reinforcing a shared orientation toward theory-informed practice that shaped discussions of task design, teacher preparation, and student learning.

Conclusion and Outlook

The 2025 contributions to TWG4 demonstrate a growing coherence in how geometry education research integrates technological tools, theoretical models, and cognitive perspectives. While spatial reasoning, visualisation, and argumentation remain longstanding concerns, their framing has become more nuanced and inclusive of embodied, multimodal, and socially situated approaches.

The group's discussions suggested several future directions: increased exploration of neurocognitive data collection methods (such as eye-tracking), more longitudinal studies on how learners' geometric reasoning develops across media and contexts, and continued theorisation of how physical and digital tool use can converge in meaningful ways within curricula.

As TWG4 evolves, it continues to affirm its role as a forum for theoretically grounded, empirically rich, and pedagogically responsive research on geometry teaching and learning in the 21st century.

Applying Duval's Teaching Sequence to 7th-Grade Geometry: A Case Study on the Area of a Disc

Branka Antunović

Juraj Dobrila University of Pula, Faculty of Educational Sciences, Pula, Croatia;
bantunovic@unipu.hr

This study investigates the application of Duval's teaching sequences within a geometry classroom, with a particular focus on developing 7th-grade students' conceptual understanding of the area of a disc. By engaging students in tasks that bridge perceptual and mathematical comprehension, this research illustrates how Duval's theoretical framework supports cognitive processes in geometry education. Through classroom observations and analysis of student-teacher interactions, the study assesses the impact of Duval's approach on facilitating cognitive apprehension in learning geometric concepts. The findings emphasize the role of structured teaching sequences that guide students in visualizing, deconstructing, and reconstructing geometric figures, alongside verbal articulation, to build a solid foundation for advanced mathematical reasoning.

Keywords: geometry teaching, cognitive apprehension, area of the disc

Introduction and Theoretical Background

Understanding geometry extends beyond simple shape recognition; it requires a cognitive shift from perceptual awareness to formal mathematical interpretation. Duval (2017) observes that students often struggle to transition from initial perceptual impressions to grasping the deeper mathematical properties embedded within visual representations, particularly in tasks involving decomposition and reconfiguration of geometric figures (Duval, 2014).

Teaching geometry, therefore, involves guiding students from basic visual perception to a more sophisticated mathematical interpretation. Effective geometry education supports this cognitive shift through activities that engage students in both physical and mental manipulation of figures. Duval's structured teaching sequences (2017) facilitate this process, focusing on visualization and cognitive processes over measurements and progressing through stages designed to build conceptual understanding of geometry, particularly for complex concepts like the area of a disc[1]. In the first stage, students manipulate physical objects such as 2D and 3D figures by folding, rotating, or overlapping them. This hands-on approach emphasizes exploring geometric properties without relying on calculations or measurements. In the second stage, students analyse 2D or 3D representations to identify figural units such as points and lines and understand their relationships within larger configurations. This stage fosters abstract thinking by enabling students to view complex shapes as assemblies of simpler components. Finally, in the third stage, students articulate geometric relationships using formal language and technical vocabulary, reinforcing their understanding and linking earlier visual and physical observations to mathematical concepts.

[1] The term "disc" means the part of the plane bounded by a circle (Kislev, 2006, p.9).

This structured progression helps students transition from informal exploration to formal mathematical understanding by integrating verbalization with technical language. Central to this approach is the development of various forms of cognitive apprehension, each playing a unique role in understanding geometric concepts (Duval, 1995). Perceptual apprehension (PA) allows students to recognize and identify geometric figures based on visual attributes. Sequential apprehension (SA) involves understanding and describing the step-by-step construction of a geometric figure. Discursive apprehension (DA) encompasses logical deductions and inferences based on given information, theorems, and definitions. Operative apprehension (OA) enables the manipulation or reconfiguration of geometric figures to solve problems or explore proofs.

For a drawing to function as a true geometric figure, it must evoke PA alongside at least one other type, as PA alone is insufficient for mathematical reasoning (Duval, 1995, p. 143). Incorporating activities that engage and integrate these forms of cognitive apprehension enhances students' ability to think geometrically (e.g., Bernabeu et al., 2021). Teachers play a crucial role in designing tasks that promote visualization, decomposition, construction, reconfiguration, and articulation of geometric concepts. These activities provide a strong foundation for understanding formulas, including the formula for the area of a disc.

Significance of the Study

Although many studies have examined Duval's framework of cognitive apprehension (Duval, 1995, 2017) with students across various educational levels (e.g., Michael-Chrysanthou et al., 2024) or focused on pre-service and in-service teachers (e.g., Llinares & Clemente, 2014), there is, to our knowledge, no research on familiarizing teachers with Duval's framework and its integration into the facilitation of geometric concepts in primary education. This gap is particularly significant in the context of developing students' understanding of the area of a disc. As part of a broader collaborative action research project between a teacher and a researcher exploring Duval's framework of cognitive apprehension in classroom settings, this paper focuses on activities aligned with Duval's teaching sequence. These activities, designed by the teacher, aim to guide students toward deriving the formula for the area of a disc. By analyzing these structured classroom activities, the study seeks to provide insights into how teachers can enhance students' geometric understanding using a structured cognitive approach.

Research Question

This study addresses the following research question: How do teachers use Duval's teaching sequence to guide students in connecting figural transformations with the formal mathematical expression of the area of a disc, by coordinating cognitive apprehensions throughout the instructional stages?

Method

Participants

This study is part of a broader doctoral research (Antunović, 2024), designed as collaborative action research focusing on development of geometrical thinking which involved four in-service mathematics teachers and four 7th-grade classes (ages 12–13) from urban schools in County Istria,

Croatia. The experimental group teacher participated in the Development of Geometrical Thinking (DGT) program, which focused on Duval's framework and its application to geometric content, including polygons, circles, and discs. This paper focuses on one lesson designed and conducted by the experimental group teacher with 24 students from the experimental group, integrating Duval's framework to enhance conceptual understanding.

Data Collection and Analysis

As a part of a broader project which employed mixed methods (Ivankova & Wingo, 2018, p. 9) to assess the DGT program's impact on students' geometrical thinking and cognitive apprehension (quantitative data were gathered through pre- and post-tests, while qualitative data derived from teacher questionnaires, interviews, and classroom observations), this paper focuses on qualitative data from classroom observations, analyzed via Duval's framework on teaching sequences and cognitive apprehension. Data sources included researcher notes, transcripts, and observations, with reliability ensured through triangulation using research diaries, student notebooks, photographs, and video recordings.

Thematic coding was applied to identify cognitive processes in line with Duval's four types of cognitive apprehension: PA - recognizing geometric figures or parts of figures; SA - following step-by-step procedures to construct or describe and analyse geometric objects, OA - physically or mentally manipulating geometric objects; DA - articulating geometric relationships and reasoning.

The analysis focused on how these cognitive apprehensions unfolded in the classroom, highlighting the teacher's role in guiding students. Key themes included:

- Transition from Perceptual to Mathematical Understanding: Moving from visual recognition to mathematical interpretation.
- SA and OA: Cognitive processes in deconstructing and reconstructing figures.
- DA and the Role of Language: The shift from non-verbal manipulation to verbal articulation of geometric concepts.

Classroom Activities

Here we present a detailed lesson on the area of a disc, focusing on activities designed by the teacher. To protect the privacy of students' conversations and interactions, fictitious names such as 'Ivona,' 'Lara,' and 'Borna' were used. The term ET refers to the teacher of the experimental group, and ES refers to the students.

Activity 1: From Description to Construction: Creating Inscribed Regular Polygons

Each student brings a disc to class, a 5 cm radius model cut from colored paper. The students work in groups of four.

ET: Choose a regular polygon that you like.

The teacher walks around the class and asks the group representatives about the polygons they chose.

ET: Tell me which regular polygon you chose and what you know about it.

ES: We chose an equilateral triangle. It is a triangle with all sides the same length and all angles the same, each measuring 60°.

ET: And how will you construct your triangle?

ES: I will first construct the central angle.

ET: Great. And then what happens when you construct that angle?

ES: The arms of the angle intersect the circle at two points. I will use a compass to transfer that distance, and each time it will intersect the circle at one point.

ET: And then?
ES: I will connect these points.
ET: So, you will draw the chords, and these chords are the sides of your triangle.

The teacher continues to guide the students through the process of constructing quadrilaterals, pentagons, hexagons, octagons, and dodecagons. Below, we present part of the discussion regarding the octagon and pentagon:

ET: And who chose the octagon? Ana, please tell us something about the octagon.
ES (Ana): It is a regular polygon with eight congruent sides and all interior angles congruent. The measure of the central angle of the characteristic triangle is 360° divided by 8, which is 45°. So, we need to construct a 45° angle and, as we explained before, divide the circle into congruent parts.
ET: Please, Lara, can you continue Ana's explanation?
ES (Lara): Now, we need to connect every two consecutive points of the circle, which represent the sides of our octagon.
ET: And now, we are left with a pentagon. How will you construct your pentagon?
ES: First, we determine the size of the central angle, which is 360° divided by 5. Then we draw that angle using a protractor and transfer the length of the circular arc along the circle.
ET: Which circular arc?
ES: The arc bounded by the points where the arms of the central angle intersect the circle.
ET: Correct, but we transfer the chord, which represents the side of the polygon.
ET: Let's conclude. Borna, can you describe the construction process of a regular polygon if the radius of the circumscribed circle is given?
ES (Borna): The construction starts with the characteristic triangle of the regular polygon. This means we begin by constructing or drawing the central angle and then transferring the length of the corresponding chord along the circle. Now, we construct the points that are the vertices of the polygon. By drawing the chord that connects two consecutive points, we will finally construct our regular polygon.
ET: Great. So, when the circle is divided into congruent parts, i.e., arcs, the sides of a regular polygon can be considered congruent chords of the same circle. Now, you may begin your constructions.

The students construct the inscribed regular polygons on their discs (using the construction method for regular polygons with a given radius and central angle).

Activity 2: Reconfiguring the Disc to Approximate Different Geometric Shapes

ET: Now, let's move on. Please, look at your disc with the inscribed polygon. Divide your regular polygon into characteristic triangles. What do you need to draw with your regular polygons?
ES: We draw the radius, connecting the centre of the circle to the vertex of the polygon, which also lies on the circle.
ET: Excellent. Now, let's look at your discs. What happened to your disc?
ES: We divided it into parts.
ET: Yes, and what do we call those parts?
ES: Circular sectors.
ET: What is a circular sector?
ES: It's a part of a disc bounded by two radii and a corresponding circular arc.
ET: Can you connect a circular sector and a characteristic triangle? What are their similarities and differences?
ES: Well, both are bounded by two radii and have the same central angle. The difference is that the sector is bounded by a circular arc, while the characteristic triangle is bounded by a line segment, which is a side of the polygon.
ET: Exactly. So, if we divide the inscribed regular polygon into characteristic triangles, the disc will be divided into corresponding circular sectors.

The teacher instructs the students to cut the disc into the marked sectors, like a pie, and then reassemble the sectors by swapping them with their peers, ensuring that the pieces

align along the radius and alternate in colour. After rearranging the sectors, students paste them into their notebooks.

Activity 3: Transitioning from Concrete Models to Imagined Configurations

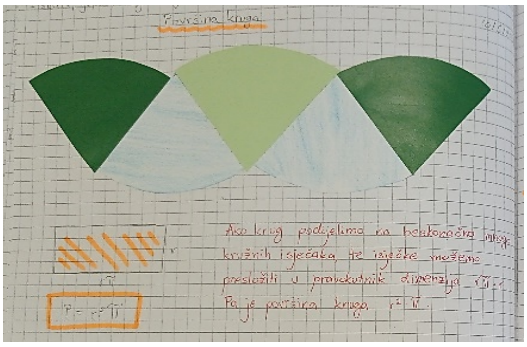
The teacher calls a representative from each group to the front of the class, where they present their work, arranged according to the type of polygon constructed, starting with the triangle. The class then observes and discusses the results. (see Figure 1.a).

ET: Please take a good look at each of the obtained figures and tell me what you notice. What do these figures remind you of? Which geometric shapes do they resemble?
ES: Lara's figure looks like a parallelogram, as does Ivona's.
ET: And what can you tell me about Sara's figure?
ES: It looks like a trapezium.
ET: Great, and the last two?
ES: The same, they look like parallelograms.
ES: But Borna's looks like a rectangle.
ET: Great. And what do you notice when the number of sectors increases?
ES: The figure starts to look like a trapezium or parallelogram.
ES: Or a rectangle.
ET: Excellent. Now, imagine we construct an inscribed regular polygon with 20 sides, or 35 or more, for example 360 sides, and then reconfigure the disc. Can you visualize this in your mind?
ES: Yes.
ET: What geometric figure does this new figure resemble in your mind?
ES: To me, it looks like a rectangle.
ET: Great, but can you explain why?
ES: Well, the sectors look like isosceles triangles.
ET: Do other students understand Karlo? Please look at Borna's figure. These sectors look like the characteristic triangle of a regular polygon. When we inscribe a regular polygon with 20, 36, or more sides in the circle, the base of the characteristic triangle gets closer and closer to the corresponding circular arc. And what happens with the arms of the characteristic triangle?
ES: They are the same, they are the radii of the disc.
ET: Now we can conclude. If the disc is divided into an infinite number of congruent sectors, we can rearrange these sectors into a rectangle.

Activity 4: Verbalizing and Deriving the Area Formula for the Disc

The teacher sketches a rectangle on the board and divides it into many small triangles.

ET: What are the dimensions of this rectangle?
ES: One side is the radius.
ET: Yes, the width is the radius. And what is the length of this rectangle?



The teacher labels one side of the rectangle as r.

ET: Now, let's look at your work. Look at the boundary of each of your figures. Borna's figure is the clearest example.
ES: It's the perimeter of the disc.
ET: Please explain.
ES: If we look at the boundaries, the upper and lower parts are made of circular arcs, which together form the circle.
ET: Great. So, our reconfigured disc is now a new figure bounded by two radii and congruent circular arcs, which together form the circle. What is the length of the upper or lower boundary of Borna's figure?
ES: I think it's half the circumference, half of the perimeter of the disc.
ET: Correct, it's half of the circumference. Now, let's return to our rectangle. Comparing it with Borna's figure, what is the width of our rectangle?
ES: It's the perimeter divided by 2.
ET: And that is...?
ES: It's $r\pi$.

ET: Great.
The teacher is labelling the width of the sketched rectangle rπ.
ET: And finally, now you can tell me what the area of sketch rectangle is.
ES: Area is r multiplying rπ.
ET: Yes. And how do we write r· r which means multiplying a number by itself?
ES: r squared.
ET: Great
The teacher is writing on the board: $P= r^2\pi$.
ET: So, what can you tell me as conclusion?
ES: If the disc is divided into an infinite number of congruent sectors, we can rearrange these sectors into a rectangle with its dimensions r and rπ, so the area of disc is r2π.
ET: Great, that is exactly what this formula is "saying". Please write this in your notebooks (Figure 1.b). Now you can determine the area of your starting disc.

a) Activity 3

b) Students note

Figure 1: Activities of Lesson Area of disc

Findings

This study explores how Duval's teaching sequence helps students connect figural transformations to the formal mathematical expression of the area of a disc. It focuses on how students navigate cognitive apprehensions throughout different instructional stages. The analysis of each activity underscores the teacher's pivotal role in guiding students from perceptual understanding to formal mathematical reasoning.

In this *Activity1*, students construct polygons, progressing from visual recognition to a deeper understanding of geometric properties. They begin by selecting a polygon, describing its features, and then engaging in construction using tools like compasses and protractors. The teacher prompts students to explain their reasoning, helping them move from visual recognition to articulating geometric concepts such as central angles, chords, i.e. from dimensional deconstruction to reconstruction. Through this process, students break down the figure into components and reassemble it, reinforcing their conceptual understanding. The teacher's support encourages students to focus on the ordered steps of the construction, reinforcing their understanding of the step-by-step nature of geometric constructions while enhancing their sequential reasoning and verbal articulation of geometric relationships. One student even generalizes the construction method, deepening their understanding. The dominant cognitive focus in this activity is SA, as students concentrate on the step-by-step construction of the inscribed regular polygon.

In *Activity 2* students begin to view the disc as composed of smaller parts. By reconfiguring sectors to approximate different geometric shapes, such as parallelograms and trapezoids, they move from

visual recognition to interpreting the disc's mathematical properties. This activity emphasizes OA as students divide the disc into congruent sectors and rearrange them, learning how smaller parts combine to form a whole. The physical manipulation of the disc—cutting sectors and reassembling them—reinforces spatial understanding and supports students in grasping geometric transformations. Throughout the activity, the teacher prompts students to articulate their observations and make connections between the geometric shapes they are forming and the disc's properties. This enhances the students' ability to express mathematical concepts verbally and deepens their understanding of the transformations occurring in the disc.

Activity 3 challenges students to move beyond hands-on manipulation and visualize how the disc would appear if divided into more sectors. This shift from concrete manipulation to mental imagery signals a transition towards mathematical abstraction. Students are asked to mentally follow the process of dividing the disc into an increasing number of sectors, engaging in abstract sequential reasoning. As they visualize the transformation (OA), they gain an understanding of its implications. Mental manipulation of images further supports the development of operative reasoning, as students mentally reconstruct the figure and comprehend the changes involved. The teacher encourages students to verbalize these mental images, helping them formalize their thought processes using geometric language (DA). In this activity, the interplay between OA and DA is key, as students move from concrete, physical actions to abstract mental processes, which they then express verbally.

Finally, in *Activity 4* students connect their earlier transformations of the disc to the formal area formula, completing the transition from perceptual understanding to formal mathematical abstraction. This activity involves sequential reasoning as students follow logical progression from visualizing the rearranged sectors to recognizing the rectangle that they approximate. As they apply their earlier physical manipulations to derive the area formula, students engage in symbolic reasoning, transitioning from concrete models to abstract mathematical thought. The teacher prompts students to use formal mathematical language to describe the components of the area formula, reinforcing the connection between geometric properties and formal mathematical expressions. DA dominates this activity, as students verbalize and formalize their understanding of the area of the disc, concluding with the formula $P = r^2\pi$.

In summary, Duval's teaching sequence supports a progressive, multi-stage approach to learning, where PA, SA, OA and DA are woven together to build a deeper understanding of geometry. Students' progress from engaging in hands-on activities (Activities 1 and 2) with concrete models, to developing mental visualization by recognizing figural units within configurations (Activity 3), and finally to achieving a formal understanding of geometric concepts through verbalization and symbolic expression of the area formula of a disc (Activity 4). The teacher plays an essential role in facilitating these transitions, helping students articulate their understanding and move from concrete models to symbolic reasoning. Each activity within the sequence emphasizes different cognitive apprehensions, ensuring that students develop a well-rounded understanding of geometric concepts and their formal representations.

Discussion and Conclusion

This study explores a geometry lesson on the area of a disc, taught by a DGT-trained teacher. It investigates the effectiveness of Duval's framework in structuring lessons to support the development

of geometrical thinking. The findings demonstrate how Duval's teaching sequence helps students transition from perceptual and visual understanding to formal mathematical reasoning. By systematically engaging students in the coordination of cognitive apprehensions, teachers can foster a deeper understanding of geometric concepts, such as the area of a disc and its formula.

A key finding highlights the critical role of teacher guidance in helping students navigate these processes. Through well-planned activities aligned with teaching stages and emphasizing the coordination of cognitive apprehensions, teachers can facilitate transitions from concrete models to abstract reasoning. Strategic questioning further supports this process, underscoring the need for adequate teacher preparation when implementing Duval's framework.

While the research focuses on the area of a disc, Duval's framework applies broadly to other geometric topics, such as axial symmetry (Duval, 2017), and to understanding and deriving various mathematical formulas. This adaptability invites future research to explore its impact across different mathematical contexts and educational levels. Further studies could quantitatively assess this approach across diverse student populations and mathematical topics, providing deeper insights into its effectiveness and applicability.

Generating 3D virtual models of straight-line helicoids in GeoGebra by animations

Daniela Bímová[1], Jiří Břehovský[1] and Petra Pirklová[1]

[1]Technical University of Liberec, Faculty of Science, Humanities and Education, Liberec, Czech Republic; daniela.bimova@tul.cz

In the paper, we present the results of a study that relates to comparing the level of spatial visualization of students of the 3rd year of the bachelor's cycle of the Mathematics study program with a focus on Education at the FP TUL with their abilities to create 3D virtual models (3DVMs) of straight-line helicoids (S-LHs) in the open-source software GeoGebra using animations. The main goals were to find out, using quantitative and qualitative analyses of students' work and subsequent directed interviews with them, to what extent a lower level of spatial visualization involves their success in solving tasks in a dynamic geometry environment. The next main goal was also to verify what specific possibilities the dynamic software has, according to the students, to increase their spatial visualization.

Keywords: GeoGebra, 3D virtual models, straight-line helicoids, animation, visuospatial abilities.

Introduction

Many studies (e.g., Fitriyani, 2018) highlight the importance of incorporating geometry into the educational content at all levels of schools. One of the goals of teaching geometry is to develop students' geometric thinking. Enhancing the level of geometric thinking contributes to improving students' proficiency in other mathematical skills, which are crucial, for instance, in problem-solving (Clements & Sarama, 2007). Geometric thinking has a significant impact on the correct representation of the magnitude of a number and the understanding of numerical relationships (Geary, 2007) and supports arithmetic transformations (Hubbard et al., 2005). Despite these facts, a considerable number of students and teachers still face challenges in mastering geometry (Seah & Horne, 2020). Another task of geometry is to develop students' spatial visualization. It is clear that acquiring skills in areas such as spatial perception, visualization, and the ability to use positional relationships is not only useful for correctly solving a few problems related to school geometry. It has been shown to be of fundamental importance in many areas of human activity, including scientific thinking, numeracy, arithmetic, and algebraic skills (Castro-Alonso & Uttal, 2019; Georges et al., 2019). Visuospatial abilities also play a crucial role in many aspects of thinking, and it has been shown that their level can be purposefully enhanced (Gilligan et al., 2020).

Spatial visualization and spatial cognition

The description and characterization of spatial visualization have been the subject of many studies, which highlight its important components. E.g., McGee (1985), Carroll (1993), and Gardner (2011) pointed out that the ability to mentally manipulate, rotate, bend, or flip a visualized object is one of the key aspects of human intelligence. An important categorization of students' spatial abilities was published by Maier (1994), who described five fundamental aspects of visuospatial abilities: spatial perception, spatial visualization, mental rotation, spatial relation, and spatial orientation. Each of these components plays an important role in the development and use of an individual's spatial visualization. Mulligan (2015) defined spatial reasoning or spatial intelligence as the ability to recognize and mentally manipulate the spatial properties of objects and the spatial relationships between these objects. One way to enhance students' visuospatial abilities is through the

use of dynamic software for teaching geometry. Baki et al. (2011) highlighted its considerable effectiveness and impact on a deeper understanding of geometry.

Solving spatial tasks, students rely on spatial cognition. Behrmann and Shomstein (2009) understand spatial cognition as a complex, multifaceted set of processes that deal with a wide range of tasks, including, i.e., mental rotation, spatial navigation, and spatial working memory. Gabbard (2015) mentions that spatial cognition does not include one, but many specific abilities. He also adds that these spatial abilities can be applied to the mental representation (imagining) of objects as well as to acting on external stimuli.

Aim of the study and research questions

The aim of this study is to present partial results from comparing the level of spatial visualization of third-year students of the bachelor's cycle of the Mathematics study program with a focus on Education, it means future mathematics teachers for elementary or secondary schools, with their abilities to create 3DVMs of S-LHs in the open-source software GeoGebra using animations. This study seeks to answer the following research questions: "To what extent are students with an average or below-average level of spatial visualization able to independently create 3DVMs of S-LHs in GeoGebra using animations?" If students make errors while creating 3DVMs of S-LHs, we ask: "In the creation of which types of S-LHs do they make the most errors, and what are the primary reasons for these errors?"

Research method

To answer the research questions, we conducted a case study involving 20 third-year students of the bachelor's cycle of the Mathematics study program, focusing on education, over two consecutive academic years. First, each student's level of spatial visualization was assessed using a tool developed by Stolínová (2020). Then, students were tasked with creating 3DVMs of four types of S-LHs in GeoGebra. The 3DVMs of S-LHs created by the students were analysed, and the specific errors each student made during the task were clearly identified. The final step was a structured interview with the students, aimed at uncovering the nature and causes of the errors made during the creation of 3DVMs of S-LHs, as well as gathering their perspectives on the impact of using dynamic geometry software in relation to improving their spatial visualization skills. Harris et al. (2024) described a similar method based on completing a geometry test and a spatial visualization test and exploring the influence of spatial visualization, as measured in psychology, and visualization on geometry tasks.

Results and discussions

Students in the third year of the bachelor's cycle of the Mathematics study program with a focus on Education at the Faculty of Science, Humanities and Education of TUL are studying the course Geometry 2 (GE2) in the winter semester and the course Geometric Software (GSW) in the subsequent summer semester. Various topics of spatial geometry are taught in the GE2 course. The students are asked to fill in the specially prepared test to find out the level of their spatial visualization (Stolínová, 2020) at the beginning of studying the course GE2.

The test was piloted in various classes of the second stage at three elementary schools in the Liberec region and at the secondary school in Louny during the research phase of the mentioned diploma thesis (Stolínová, 2020), as well as during a preparatory course organized annually for first-year bachelor’s students of various faculties at TUL. A total of 127 elementary school pupils, 19 secondary school pupils, and 154 university students participated in the pilot testing. We aim to verify the validity of the test by administering it to students in the Mathematics study program with a focus on Education and subsequently comparing each student’s test results with their academic

performance during the course. The spatial visualization test was administered to these students at the beginning of the winter semesters in the last two academic years. The success of students in solving the individual tasks included in the test reflects the level of spatial visualization of the tested students. The results obtained from the university students are consistent with the results of elementary and secondary school students from the pilot tests, indicating that approximately 60% of the tested students have an average or somewhat below-average level of spatial visualization. Specifically, in the academic year 2022-2023, 5 out of 9 students had an average or below-average level of spatial visualization, and in the academic year 2023-2024, the test results indicated an average or below-average level of spatial visualization in 6 out of 11 students. In analysing the 3DVMs of S-LHs, we focused mainly on the models generated by students with an average or below-average level of spatial visualization.

In the course GSW, students are introduced to the user interface and work in GeoGebra. They create dynamic applets for planar and spatial geometry tasks and also learn about the differential geometry of curves and surfaces. Some kinematically generated curves are drawn using animation. Similarly, students are assigned tasks to model 3DVMs of helicoids in the GeoGebra 3D window using animations. Before this activity, students worked on a task presented at the MEDA4 conference (Bímová et al., 2024). This task involved generating 3DVMs of S-LHs based on their parametric equations, making effective use of GeoGebra dynamic tool – the slider – which was used to set variable values for the corresponding parameters. The created models were then gradually converted into *.stl and *.gcode files, and finally, corresponding physical models of S-LHs were 3D printed. This provided students with a clear understanding of what the different types of S-LHs look like and what the process of 3D printing means. Surynková (2023) similarly mentions that the whole process of 3D printing combines the design, 3D computer modeling with CAD or other computer modeling software, and the process of fabrication itself.

The acquired experiences and visualizations of different types of S-LHs were effectively utilized by students when constructing 3DVMs of S-LHs in GeoGebra using animations. To create such 3DVMs, a correct understanding of the basic principles of screw motion and awareness of the position of the generating curve (in our case, a line segment) relative to the axis of the corresponding screw motion is necessary. This can be quite challenging with a lower level of spatial visualization. We will gradually discuss the observed problems that students faced while creating 3DVMs of the various types of S-LHs. Students created 3DVMs of S-LHs individually, each on their own PC. We saw their work by sharing their screens in the GeoGebra Classroom, where we could immediately analyze any errors that occurred.

Out of 20 students observed, 14 struggled to complete the task on their own, failing to do so successfully. Among these 14 students, 11 achieved an average or below-average level of spatial visualization on the test, while 3 students achieved an above-average level. The students correctly determined that it was first necessary to construct a plane perpendicular to the axis of the created helicoid and that a creating line segment needed to be constructed in this plane, with one endpoint being the point on the axis of the helicoid model Three students attempted to fix this point with the axis, although it was not the correct approach. However, they also knew that the other end point of the creating line segment must lie on a circle that is coincident with the constructed perpendicular plane to the axis of the created helicoid and whose centre is also on the axis of the helicoid model. They constructed the creating line segment as the radius of this circle, placing the second endpoint of the creating line segment as a so-called free point on the circle (see Fig. 1a). When the students began the animation of this point and activated the trace display for the creating line segment, they were intrigued to discover that the animation produced a circle instead of the expected 3DVM of the right-angled closed S-LH (see Fig. 1b). The teacher then guided a thoughtful discussion with these three students to explore the outcome:

Teacher: What was the cause of the circle appearing in your solutions instead of the 3DVM of the right-angled closed S-LH?
Student 1: I found it challenging to fully visualize how to set up the animation.
Student 2: In my imagination, I only created an image of the creating line segment rotating around the axis of the helicoid being constructed, but I completely overlooked that this creating line segment should also move along the direction of the axis.
Teacher: Correct. How will you ensure that the creating line segment moves along the axis of the right-angled closed S-LH?
Student 2: We need to release the endpoint of the creating line segment that lies on the helicoid's axis.
Teacher: That's right, but that alone isn't enough.
Student 3: To make the creating line segment move along the axis of the helicoid, we need to activate the animation for its second endpoint as well, which lies on the axis of the helicoid.
Teacher: Good, then try to correct your solutions according to what you have just mentioned.
…
Student 2: Great, it looks like the 3DVM of the corresponding helicoid is now generated correctly (see Fig. 1c).

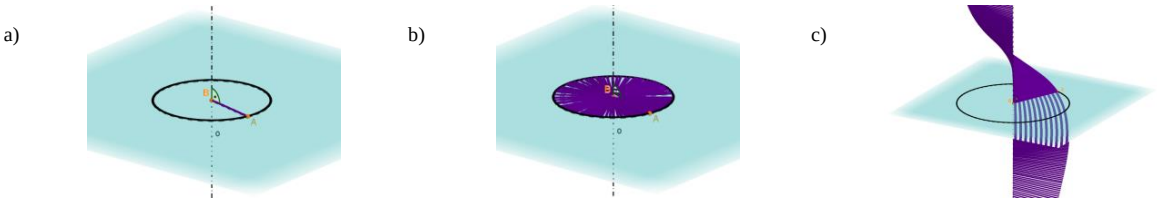

Figure 1: Creation of the circle and 3DVM of the right-angled closed S-LH

The six students mentioned above worked with animations of one or both endpoints of the appropriately positioned creating line segment. They relied on the basic principles of screw motion, which means a uniform motion resulting from the simultaneous combination of translational movement along a given axis and rotational movement around the same axis. They did not consider the curve along which the endpoint of the line segment, not located on the axis of the constructed helicoid model, moves. The remaining eight students revisited the task from the previous lesson and applied the "Curve(<Expression>, <Expression>, <Expression>, <Variable Parameter>, <Start Value>, <End Value>)" command in GeoGebra to generate the helix for the endpoint of the creating line segment that doesn't lie on the axis of the constructed helicoid model. While they made significant progress in comparison with the previously three mentioned students, they did not manage to solve the problem completely successfully. One student displayed only the helix of the considered endpoint but nothing else. Another student displayed the helix of the endpoint of the creating line segment that does not lie on the axis of the constructed helicoid model. This endpoint was inserted on the helix, but no other object was constructed (see Fig. 2a). Four students also placed a free point on the helix and placed an arbitrary point on the axis of the constructed helicoid model, which they fixed. They then constructed a line segment with endpoints at these mentioned points. After that, they started the animation of the endpoint of the creating line segment lying on the helix. Because the second endpoint of the creating line segment was fixed, the animation did not generate the 3DVM of the right-angled closed S-LH as expected. (see Fig. 2c). These four students had initially tried to set the creating line segment so that it was perpendicular to the axis of the created helicoid (see Fig. 2b). The teacher had the following conversation with these four students:

Teacher: Why was the 3DVM of the right-angled closed S-LH not created correctly?
Student 7: I envisioned one endpoint of the creating line segment moving along the helix, but overlooked that the other endpoint must follow its curve. Upon starting the animation, I noticed the line segment's incorrect movement.

Teacher: Constructing the helix for one of the endpoints of the creating line segment of the 3DVM of the right-angled closed S-LH and placing this point on the helix (as a free point) leads to the correct solution. What else must you consider when you know that the final model should be a right-angled closed S-LH?
Student 7: The second endpoint of the creating line segment must lie on the axis of the constructed helicoid.
Teacher: Very good. And what else must be true?
Student 8: For a right-angled S-LH, the creating line or segment must be perpendicular to the axis of the constructed helicoid.
Teacher: Excellent. And how do you ensure that these two conditions are met?
Student 9: We construct a perpendicular line to the axis of the helicoid passing through the chosen point on the helix.
Teacher: Good, but that's not entirely accurate. There are infinitely many perpendicular lines to the axis of the helicoid model that can be constructed by passing through a point on the helix.
Student 9: Ah, so how do we select the correct line?
Teacher: Consider what all such perpendicular lines create.
Student 7: A plane.
Teacher: Correct. And what kind of plane?
Student 10: A plane that passes through the chosen point on the helix and is perpendicular to the axis of the constructed helicoid.
Teacher: Excellent. So how do you obtain the second endpoint of the creating line segment?
Student 8: We get it as the intersection of the constructed plane with the axis of the helicoid.
Teacher: Perfect. What remains to be done?
Student 7: Activate the trace for the creating line segment and set the animations for its endpoints.
Teacher: Yes, that's exactly right. Try solving the task as you've described.

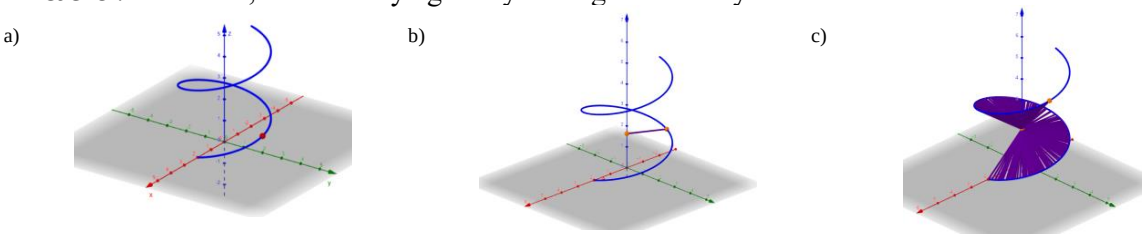

Figure 2: Wrong creation of the 3DVM of the right-angled closed S-LH

Rendering a 3DVM of an oblique closed S-LH using animations initially posed difficulties for all students in both academic years. Students were inspired by the solution to the previous task. They first placed free points representing the endpoints of the creating line segment, both on the generated helix and on the axis of the constructed helicoid model. They then connected these points with a line segment. They activated the trace for the creating line segment and started the animation for both endpoints of this line segment. Even though the speeds of movement for both points were set to the same value and their animations were started simultaneously, the point on the axis of the constructed helicoid model moved faster, especially when approaching the edges of the clipping box in the 3D window of the software, compared to the other endpoint moving along the helix. The result was a model of a surface shown in Fig. 3a). However, this does not represent a 3DVM of an oblique closed S-LH. Consequently, the teacher decided to conduct interviews with all students from both groups. Below, we present a guided interview with students from the academic year 2023-2024.

Teacher: What problem do you see when observing the animation of the creation of the 3DVM of the helicoid as you set it up?
Student 10: I think the problem is that the creating line segment changes its length during its movement.
Teacher: Yes, that's a great observation. Why did the error you made occur?
Student 11: I've didn't realize the importance of visualizing how to position the generating line segment to ensure it maintains a fixed length.

Teacher: How can you ensure the creating line segment's length remains constant during the screw motion?
Student 10: Choose an appropriate plane in which the creating line segment will lie.
Teacher: How would you construct such a plane?
Student 12: One point will be the endpoint of the creating line segment that lies on the generated helix. The other two points will be any two points in space.
Teacher: And how would you obtain the second endpoint of the creating line segment?
Student 13: I believe it would be as the intersection of the constructed plane with the axis of the constructed helicoid model (see Fig. 3b).
Teacher: Honestly, I don't think that is the correct solution. What might be the problem?
Student 13: I can't imagine how the objects will behave once the animation starts.
Student 12: Unfortunately, I can't see it either; I don't understand it.
Student 14: I'm in the same situation; I have no idea what will be rendered during the animation.

The teacher then asked the students to construct their described solution so that they could see the result of their proposed solution in the 3D window and thus gain a clearer understanding of the spatial situation. The resulting model of the surface is shown in Fig. 3c).

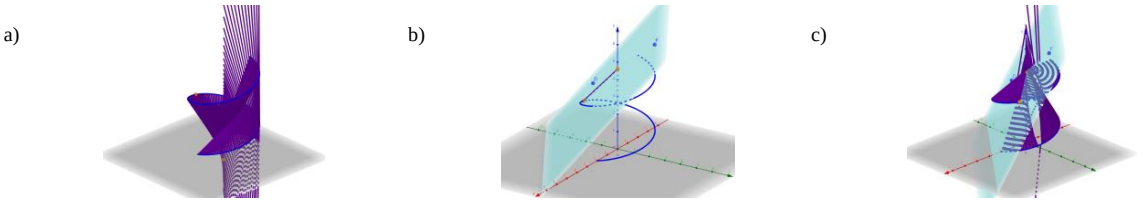

Figure 3: Wrongly created 3DVMs of the oblique closed S-LH

When rendering the 3DVM of the right-angled open S-LH using animation, students made almost no mistakes in either academic year. Based on previous experiences, they generated the helix of one (e.g., point *A*) of the endpoints of the creating line segment *AB* using the special command. Then, they constructed a circle along which point *A* rotates during the screw motion around and in the direction of the axis of the constructed helicoid model. This circle lies in a plane passing through point *A* and perpendicular to the axis of the constructed helicoid model. The second endpoint *B* of the creating line segment *AB* was constructed as the intersection of a spherical surface centred at point *A* with a chosen radius and the circle passing through point *A* (see Fig. 4a). They enabled the trace for both endpoints *A* and *B* as well as the creating line segment *AB*, and started the animation of point *A*. The 3DVM of the right-angled open S-LH began to render (see Fig. 4b). Individual guided interviews between the teacher and students were not necessary in either of the two academic years. Only one student made a mistake in this task by enabling not only the trace of the creating line segment and its endpoints but also the trace of the circle passing through point *A* (see Fig. 4c). This mistake was immediately noticed after starting the animation, and the student promptly turned off the trace of the circle.

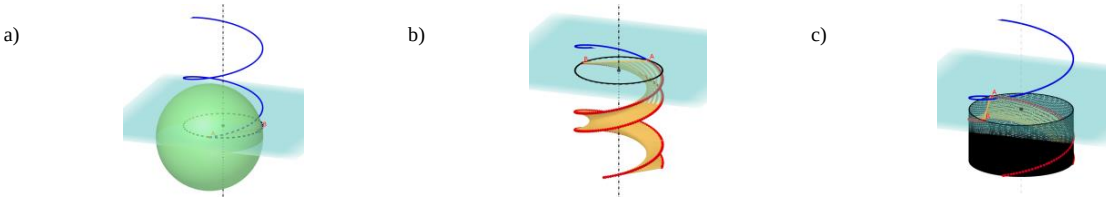

Figure 4: Creation of the 3DVM of the right-angled open S-LH

On the other hand, when generating the 3DVM of the oblique open S-LH, almost all students in both academic years made the same mistake regarding the creation of the second endpoint of the creating line segment. They

tried to create it analogously to the method used for creating the 3DVM of the oblique closed S-LH, specifically by using a spherical surface. The students chose an arbitrary point on the spherical surface centred at point *A* and labelled it *B* (see Fig. 5a). Then, they constructed the creating line segment *AB*. They enabled the trace for both endpoints *A* and *B* as well as creating line segment *AB* and started the animation of point *A* (see Fig. 5b). Initially, they believed that the 3DVM of the oblique open S-LH was rendering correctly. However, the teacher disproved their assumption. The following is the conversation between the teacher and the students:

Teacher:	Look at the created 3DVM from a perpendicular top point of view. What do you see? (Fig. 5c)
Student 4:	A top point of view of the constructed surface.
Teacher:	Yes, that's correct. But do you think this is really a 3DVM of the oblique open S-LH?
Student 2:	I don't see any mistake.
Teacher:	However, there is a mistake.
Student 2:	I can't imagine that the surface should look different!
Teacher:	Try to visualize how the 3DVM of the oblique open S-LH should look from a perpendicular top point of view, or what should be different.
Student 3:	The constructed 3DVM of the helicoid is not symmetrical according to the axis of the screw motion in a perpendicular top point of view onto it.
Teacher:	Yes, that's right. You correctly constructed the creating line segment so that it is non-parallel to the axis of the screw motion. But is there another condition for the path of point *B*? Do you have any idea what it might be?
Student 5:	It is necessary for point *B* to also move along a helicoid whose axis aligns with the axis of the screw motion. In our case, this is not true.
Student 2:	We could achieve this by generating a suitable helix for point *B* as well (Fig. 6a). If point *B* moves along it during the given screw motion, then the 3DVM of the oblique open S-LH should render correctly.
Student 4:	I've tried it this way, and it really works (Fig. 6b).
Teacher:	Look at how skilled you are; you discovered the correct setup of the basic objects and their animations. What geometric object is now displayed in the perpendicular top point of view onto the created 3DVM of the oblique open S-LH?
Student 6:	It is an annulus (Fig.6c).
Teacher:	Yes, very correct. You have successfully created all four types of S-LHs using animations.

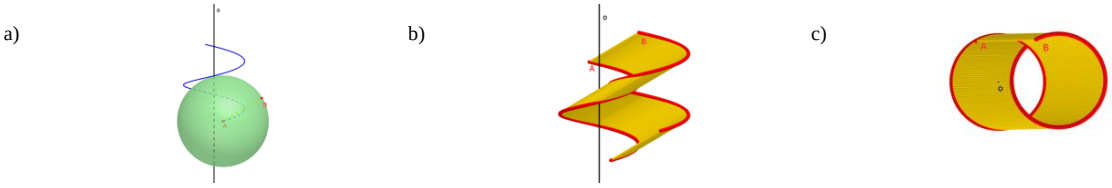

Figure 5: Wrongly created 3DVM of the oblique open S-LH

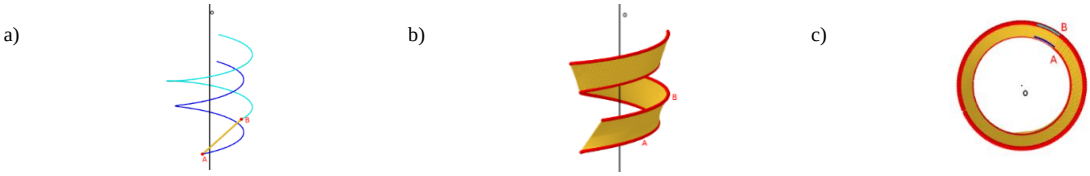

Figure 8: Creation of the 3DVM of the oblique open S-LH

Conclusion

All students with average to below-average visuospatial skills made significant errors when creating 3DVMs of S-LHs. None of these students managed to create an animation that accurately depicted the corresponding S-LH model on their first attempt in GeoGebra. We sought the reasons for these errors through guided interviews with the students. The errors varied, but the origin mentioned by the students was the same for all. Students encountered challenges in fully grasping the concept of the S-LH or in accurately rendering it,

but their efforts to understand and represent it demonstrated engagement and curiosity. All struggled with mentally manipulating the given geometric object, particularly when it was necessary to consider multiple properties and parameters occurring simultaneously. We also asked students whether and how virtual models help improve their visuospatial skills. The responses indicated that visible animation and immediate feedback were helpful. Essentially, all students realized where they had made errors after viewing the animation and were able to describe their errors. The error rate for the first task was the highest among all four tasks assigned. This was due to the fact that it was the first task of this type that the students encountered. In solving the remaining three tasks, students avoided similar errors, although other problematic steps and mistakes emerged, they were discussed in the text. The results of the analysis will enable us to focus on problem areas in teaching and contribute more effectively to improving the visuospatial skills of future mathematics teachers.

Designing tasks to connect geometry and art – developing spatial reasoning using tilling

Lina Brunheira and Cristina Loureiro

Higher School of Education of Lisbon, CI&DEI, Polytechnic Institute of Lisbon, Portugal;

lbrunheira@eselx.ipl.pt

This paper reports a classroom experience in 3rd grade using Portuguese traditional tilling. Our goal is to discuss the contributions to students' spatial reasoning and knowledge about rotation and its relation to the design of the interdisciplinary tasks between visual arts and geometry. Data were collected through observation, audio records of the classroom interactions and students' records. The results show the tasks were meaningful for the students, who learned about rotation and mobilized spatial reasoning. Imagination has an important role for both areas of the curriculum and the tasks should foster that skill, supported by the adequate materials.

Keywords: Geometry, Visual Arts, Interdisciplinary, Spatial reasoning, Task design.

Introduction

In the past two decades there has been a growing interest in spatial reasoning (SR), both as a curricular orientation (NCTM, 2000) and a research field (Davis et al., 2015). Despite some difficulties regarding language in the literature and different perspectives and methods from psychology and mathematics education, there is some consensus about the relevance of SR. For instance, Whiteley et al. (2015) refer that people with strong spatial skills are generally successful at mathematics, that SR supports mathematical understanding and problem solving, it is important in a large range of jobs and daily activities "as the interfaces used to access and manipulate that information are shifting away from the alphanumeric toward the spatial" (p. 9). Regarding specifically mental rotation–a component of SR commonly considered–, as Bruce et al. (2015) state, research shows that people who perform well "also tend to perform well across a range of mathematical tasks, including arithmetic, algebra, calculus, geometry, and word problems" (p. 96).

Concerning the curriculum, SR relevance it is often ignored as a goal and "learning activities for young children that foster spatial reasoning are sorely lacking" (Bruce et al., 2015, p. 85). Another big challenge of education, according to Morin (2002), is to overcome the separation of disciplinary boundaries of knowledge and encourage effective connection, moving towards a unifying approach that understands phenomena in their multidimensionality. Also, Niss (2002) highlights the need to build curricula focused on the meaningful use of mathematical content, seeking to create diverse situations in which mathematics can play a significant role.

Regarding Mathematics and Visual Arts, history has revealed several examples of their fertile interaction, like Leonardo Da Vinci's Treatise on Painting, published in 1651, but this interest has no significant correspondence in the classroom. Despite this, some experiences with children from the age of 4 (Loureiro, 2018) "show a strong potential in visual arts activities for the development of geometric and spatial reasoning and an added value for students to attribute meaning to geometry activities" (p. 572).

In this paper, we will address a classroom experience in 3rd grade using Portuguese traditional tilling to work on mental rotation. Our goal is to discuss: a) What are the contributions to students SR and knowledge about rotation that emerge from the task? b) Which aspects of the design of the interdisciplinary tasks between visual arts and geometry favour students learning?

Conceptual framework

Spatial reasoning and the role of rotation

For Davis et al. (2015), SR cannot be understood simply by reducing it to its components and these should not be considered in isolation. Nevertheless, the authors list a non-exhaustive set of categories, each involving several components, that show critical qualities of the SR. These categories (*interpreting, (de)constructing, altering, moving, situating, sensating*) are presented in a diagram that preferably associates each one with the activity of *understanding* (more "mental") or *transforming* (more "physical") (Davis et al., 2015). In the category *moving*, associated to *transforming*, we find the isometries, in particular *rotating* which, as we mentioned, seems to have an important role:

> What explains the relationship between mental rotation skills and mathematics performance? What are the pedagogical implications of this relationship? We believe that the answer to both of these questions is in part linked to the role of the imagination. In performing mathematics and mental rotations, we must use our imagination to mentally manipulate information . . . In terms of pedagogical implications, we believe that increased efforts are needed to explicitly engage the "mathematical imaginations" of young children. (Bruce et al., 2015, p. 96)

These authors suggest that a curricula that engages children in developing their mental rotation skills promotes a more dynamic and imaginative approach to early geometry instruction and learning. The examples of vignettes they present share some orientations worth noting: they push the boundaries of typical geometry curricula; "they oscillate between and among working with concrete materials, the imagination, and considering abstract ideas in playful contexts for young children" (p. 86); and there is an explicit attention on how multitouch technologies and mathematics tools, which are meant to support the actions of SR, a deeper understanding of spatial ideas, and a more precise discourse.

Interdisciplinary activities of Geometry and Visual Arts

In Portugal, the MARTE1618 project (Loureiro, 2018; Regatão & Loureiro, 2019) has developed several interdisciplinary activities between Mathematics and Visual Arts, with children ages 4 to 6, which highlight the development of distinct aspects, such as knowledge of concepts and procedures, SR and other capabilities that are implicated in two areas. Focusing only on Mathematics, and regarding knowledge, the learning of symmetry "in its wider meaning and with all its richness" (Loureiro, 2023, p. 52) is an example, as well as distinct forms of representation of 3D objects in the plane–two examples with large tradition in art. SR emerges significantly, namely implying the spatial structuring of 3D objects, in which the same object can assume different forms of structuring. Some of these objects may be simple solids such as parallelepiped or solids of revolution, possible to materialize in artistic objects like pop-up books, leading the children "to develop a mathematical view of real objects" (Loureiro, 2023, p. 69). The link between Mathematics and Visual Arts may still be a vehicle for developing transverse skills such as visual communication. As Loureiro argues, "artists

and visual communication experts are the ones who best create and design attractive and meaningful visual contexts . . . they resort to series of organized forms very rich from a mathematical point of view" (2023, p. 63). Regatão and Loureiro (2019) also refer the development of imagination, creativity, aesthetic sensitivity and the ability to solve problems.

Methods

The work we present in this text corresponds to a preliminary stage of the Project IMAVIS. This project aims to promote interdisciplinarity between Mathematics and Visual Arts in Elementary school (Grades 1-6), through collaborative work between higher education teachers and teachers at these levels of education. The main objective is to investigate the design and experimentation of interdisciplinary tasks, falling within the scope of didactic engineering, understood as an empirical science of the didactic phenomena in which empirical validation of outcomes is key (Barquero & Bosch, 2021). These authors focus on the central role of the "situation" and present the four-stage model followed by this researcher: 1) Preliminary analyses, when "the content to be taught and learned is questioned, usually considering different kinds of hypothetical didactic phenomena involved" (p. 251); 2) Design and *a priori* analysis, leading to the characterization of the content and the formulation of problematic questions within a sequence of concrete situations; 3) Implementation, observation and data collection; and 4) A posteriori analysis, validation and development culminates the DE process. In our research, we respect these four working stages, but with small adjustments, particularly in the first one: 1) Characterization of an interdisciplinary situation with the respective epistemological questioning of mathematical knowledge and of knowledge of visual arts.

In stage 3, the implementation of the tasks was carried out in two 3rd grade classes, each one having 21 students. Each class had an experienced teacher with no significant knowledge of interdisciplinary work between Mathematics and Visual arts. Data from classroom experiences was collected through observation, audio records of the classroom interactions and students' records. Concerning SR, we used the framework of Davis et al. (2015), particularly the categories *moving* (which includes *rotating*), situating (which includes *locating*) and *sensating* (which includes *visualising, imagining*).

Results

We organise this section considering stages 1, 2 and 4 of the model previously presented, although in this paper we focus mainly on the geometrical learning.

Characterization of the interdisciplinary situation

Portugal has an important tradition in the art of tiling that goes back to the 15th century and continues to this day, going through different phases, styles and functions. In addition to the functional aspect of covering a surface, this art form has been used to adorn buildings since the mid-19th century. Today, we can still find many examples of this tradition in old buildings, especially in the old parts of major cities such as Lisbon and Oporto (for examples, consult https://azulejosporto.pt/). From an artistic point of view, tiles are particularly rich in their use of colour and the composition of elements that allow them to form captivating patterns. From a geometrical point of view, a typical tile is constructed using a square forming tile panels rich in symmetry. Additionally, when we look at the way of constructing the panel, starting from one tile, other aspects emerge like rotation and

translation. Also, we may classify all tiles in one of three cases (Figure 1): A is invariant under any rotation; B assumes a different orientation[1] if it rotates 90º (or 270º); C has a different orientation if it rotates 90º, 180º and 270º. These three cases lead to different situations when constructing a panel: tile A forms a unique panel, while B and C form many different panels.

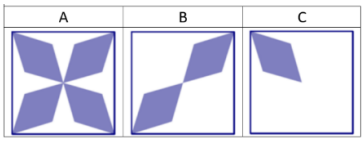

Figure 1: Types of tiles considering variation under rotation

In this analysis, we highlight that the construction of a panel has no relation to reflexion because the back of the tiles is not decorated. Thus, all SR is restricted to rotation and translation.

The recent Portuguese curriculum suggest that, in 3rd grade, students should learn to produce the image of a simple plane figure by rotation, with an amplitude of 90º or 180º, clockwise or anticlockwise. This way, the context of tiling seems to be an interesting and suitable situation to foster geometrical and artistic learning using an interdisciplinary approach.

Design and *a priori* analysis

Figure 2 presents the sequence of interdisciplinary tasks designed. Previously, the teachers presented rotation using a representation of a flag, and students constructed the images corresponding to a rotation of 90º, 180º and 270º, using the base of the flag as its centre.

1. Go to https://azulejosporto.pt/ . There you'll find lots of tiles on the front of buildings in the city of Oporto. Explore the website and see how beautiful the patterns are.
2. In the website, select the tile here presented (AP_20210816_36) and look at the panel. Explain how the tile was rotated to form the panel.

3. Search the website for other examples where rotation was used to create the panels and record their number.
4. Joana has created a tile to make a panel using the same technique. Draw how the set of four tiles will look.

5. Look at the panel formed by the white and blue tile (AP 20160622_08). Rotation was not used in this panel. Using this tile, build a panel in which you use rotation. Record it and explain how you used rotation.

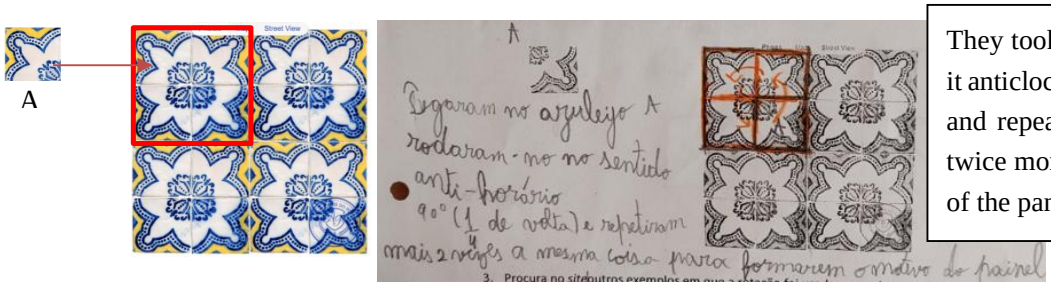
Figure 2: The sequence of interdisciplinary tasks using tiles

[1] To simplify the language, we'll use the term orientation to compare the position of the original figure and its image in relation to the parallelism/perpendicularity of its sides.

The main goal of task 1 was to immerse students into the situation and let them enjoy. While observing the tiles, they could notice the use of abstract forms, the way they were organised in the square and the use of colours, without a necessary attention to the geometrical aspects.

Task 2 focuses on rotation and the formal language (centre, amplitude and direction). The students had to visualise that using 90º turns (clockwise or anticlockwise) around a particular vertex creates a set of four tiles. This new set formed a motif that is repeated in the panel using translation.

Task 3 is interdisciplinary focused, because its purpose is to find how geometry is used to form the panels, how it influences its esthetical dimension, and value this relationship. Students had to develop a mathematical view or, as Fujita and Jones refer, a "geometrical eye" (2002). In fact, the website has many examples of tiles type A, B and C. In the first case, the tile corresponds to the motif, so the panel may be constructed using only translation. Tile in task 2 is type C, as most tiles on the website.



Task 4 was designed to challenge students SR. The sun, star, moon and heart were conceived and placed to allow different levels of difficulty. The star and the sun should be easier because of its rotational symmetry. The moon and the heart will have four different orientations, but we expected that the further away from the centre of rotation, the more difficult it is to anticipate the result of the transformation. Students who showed significant difficulties could use tracing paper and, in the end, the class could confront the drawings with the dynamic construction using GeoGebra (see here).

Finally, task 5 is also interdisciplinary focused, because students should use their geometrical knowledge about rotation to create new panels, using creativity, and communicate their creations. The tile is very suitable for that purpose because. In fact, it is a historical motif, studied in the 18th century by the French monks Truchet and Douat, and allows for the construction of beautiful patterns.

A posteriori analysis, validation and development

In this section, we discuss mainly tasks 4 and 5, based on records and episodes of both classes where the students worked in pairs or small groups. Regarding the other tasks, we will comment briefly.

First, in both classes, the students had a very nice reaction when they observed the tiles and the panels on the website. They made many comments comparing them, inviting their colleagues and teacher to look at a particular one they found especially beautiful, setting the mood for the next tasks. For the next one, it was necessary to give an additional explanation to understand our intention. The teacher asked the class which motif was repeated on the panel and the students identified the four tiles marked (Figure 3a). She then superimposed tile A on the panel and asked how that tile generates the motif, and the students identified the use of 90º turns (Figure 3b).

They took the tile and turned it anticlockwise 90º (1/4 turn) and repeated the same thing twice more to form the motif of the panel.

Figure 3a and 3b: Identification of the motif and the use of rotations

In task 3, the majority of students identified correctly panels that necessarily used rotation, except for one case (see here), a mistake that may be due to its particular configuration.

In task 4, there were mainly three types of responses, illustrated by Figures 4a, 4b and 4c.

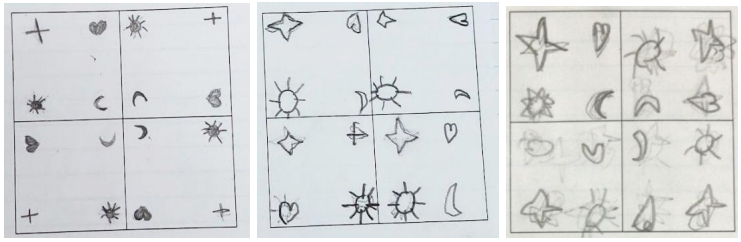


Figure 4a, 4b and 4c: Construction of the motif

Figure 4a shows a right solution. The students were able to *locate* each of the elements in the right place for each of the tiles and also position the heart and the moon with the right orientation, understanding that these two elements would be different when they turned 90º degrees. Considering they solve this question without any tool, this means they *visualise* correctly the movement of the figures when they *rotate* repeatedly 90º. So, these students showed significant skills concerning SR.

Figure 4b was unexpected to us. Considering both the heart and the moon, three of the tiles have these elements with the right orientation if they were to perform 90º turns anticlockwise, although they are not placed correctly in the corner of the tiles. In the fourth tile, it seems the students got lost because there is even no moon. So, this solution may signify that there is some success in *visualising* the rotation of the figures, at least *imagining* its orientation. Concerning *locating*, this solution evidence many mistakes. Again, there are three tiles that are consistent: the elements don't change their position. A possible explanation is that students were considering a path like  instead of a rotating and got lost in the last tile. Despite the explanation, there is evidence of mobilising SR.

Figure 4c shows the right solution, but clearly after many trials and errors. These students used tracing paper because they were really struggling *visualising* the solution, both the individual *rotation* of each element and its *location* in the tiles. So, this shows how important was the use of the physical tool for these students.

In task 5, the choice of the tile led to different panels, always using rotation. Many of the proposals followed the same construction method as before (Figures 5b and 5c), but there were some surprises.

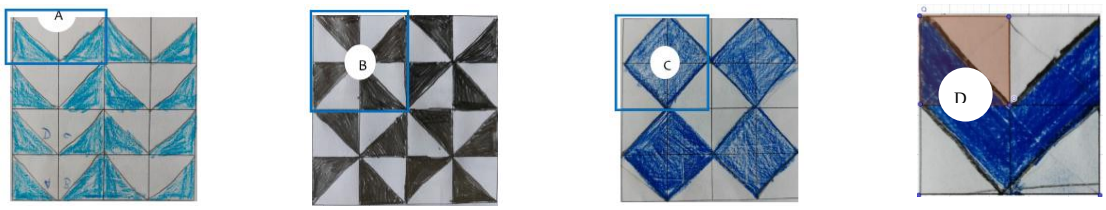

Figure 5a, 5b 5c and 5d: Panels created by the students

The observation of the students' records by the teacher showed the need for synthesis of the elements needed to define a rotation: centre, amplitude and direction. To do this, the teacher selected four of

the motifs constructed by the students (Figures 5a to 5d) and named points A, B and C to facilitate communication and add rigour to it. She also gave each student paper tiles so that they reproduce on the table each motif projected on the board, and moved on to a collective discussion in which the students indicated the centre, the amplitude and the direction of the angle of rotation of the tile.

The fourth motif selected by the teacher (Figure 5d) was surprising, since the centre of rotation of the first tile was not on one of the vertices of the square, but rather the midpoint of one of the sides. One of the students who built this motif came to the board and explained to her classmates the rotations.

Teacher:	Maria, how did you build this one?
Maria:	We took the tile and turned it.
Teacher:	But how?
Maria:	If I put my finger here and turn it anticlockwise, it looks like this. [Without hesitating, points her finger to the midpoint of the side (D) and rotated it].
Teacher:	How much did you rotate?
Maria:	180 degrees.
Teacher:	Notice that Maria didn't rotate from one of the vertices of the square as she did in the other motifs, she fixed a point in the middle of the side of the square. Now, how do you move on to the third tile?
Maria:	I need one more point to rotate it.
Teacher:	Where do you want me to mark the point?
Maria:	Here, at the junction of the four squares.
Teacher:	So, when we explain the rotation of a figure, we always have to refer to what?
Samuel:	How much the figure moves.
Teacher:	I didn't quite understand.
Maria:	If it's 90 degrees, 180...
Teacher:	You're talking about the measure of the angle. What else?
Maria:	We also have to say where the point of rotation is and the direction.

This episode shows how well Maria understands rotation, dominates its aspects and, mostly, how SR supports her knowledge and performance. Naturally, this differs from student to student. Nevertheless, considering the students' records and our observations, it seems that the sequence of tasks helped the students to construct their knowledge about rotation (what it means, how is defined), including the language associated with this transformation. Also the tasks enhance their SR, as they had to *visualise* the image of a figure after rotating 90º turns (task 4) and, on the contrary, identify which rotation would produce a motif they created (task 5). In this case, that implies *locating* the centre of rotation and *imagining* the angle.

Conclusion

Considering the design process, some aspects emerge from this experience. Firstly, as Bruce et al. (2015) point out, it's important to push the boundaries of typical geometry curricula and the interdisciplinarity between maths and visual arts seems to do this, motivating students and favouring the meaningful use of mathematics (Niss, 2002). To do this, the right choice of the interdisciplinary situation is fundamental. It must be powerful from a mathematical and artistic point of view, and students must be able to relate to it. Secondly, we want to notice is the role of imagination, which is present both in the mathematical dimension and in the artistic one. Imagination supports the process of creating and operating with mental images and is at the core of rotation, a transformation frequently used in the construction of panels of tiles, but also necessary to interpret these artistic objects, contributing to developing the "geometrical eye" (Fujita & Jones, 2012) and SR. But imagination is

also an important part of creativity, necessary to the creation of artistic objects. In this experience, students seem to value this aspect and a certain liberty associated with it, which was express when one of the classes suggested the used of the patterns they created to make a gift for mother's day. Finally, we highlight the use of manipulative tools in support of the mental process, also referred to by Bruce at al. (2015), which favour the creation and experimentation, but also the analysis.

Insights into conceptual breaks of individual sine concepts

Maximilian Büttner[1] and Giada Viola[2]

[2]University of Ferrara, Department of Mathematics and Computer Science, Ferrara, Italy

This research aimed to investigate students' difficulties in using different representations in trigonometry. For this reason, we classified three types of conceptual breaks based on Tall and Vinner's theory of concept image and concept definition. Analyzing the results of a questionnaire, that aims to investigate individual trigonometric concepts and representations answered by university students, seems to confirm the presence of this classification. Furthermore, we proposed possible implications for teaching that could facilitate overcoming these breaks.

Keywords: Trigonometry, concept image, concept definition, conceptual breaks, sine

Introduction

Trigonometry is a topic in mathematics education in which representations from different content areas interconnect: Right triangles and the unit circle as geometric objects, the Cartesian coordinate system for visualizing trigonometric function curves, and algebraic equations for describing trigonometric relations. A typical task in trigonometry is the calculation of unknown side lengths or angles. Students often memorize the formulas required for these calculations, but their meanings cannot be interpreted (Kendal & Stacey, 1998; Yiğit Koyunkaya, 2016). The graphical representations mentioned are used by students for visualization, but in many cases, they cannot be linked together or do not correspond to mathematically appropriate representations (Brown, 2005). In fact, the lack of linkage goes so far that some researchers speak of *trigonometries* that are perceived as separate from one another, e.g. a right triangle trigonometry and a periodic function graph trigonometry (Chin, 2013). Our study is consistent with this area of research and specifically, aims to investigate students' conceptual breaks within one trigonometric concept. To achieve this, we asked them to complete a questionnaire focused on the definition and representations of sine, and we analyzed the students' answers using the concept image and concept definition theory of Tall and Vinner (1981), identifying three different conceptual breaks.

Theoretical framework

We illustrate the concept image theory which we used to describe individual concepts and we show how conceptual breaks can be seen within this theoretical framework. We also show the results of other research to highlight why a study of conceptual breaks within trigonometry education might be interesting.

Concept Image and Concept Definition Theory

The Concept Image and Concept Definition Theory formulated by Tall and Vinner (1981) provides a theoretical framework to describe individual concepts. In their theory, a *concept image* comprises the "total cognitive structure that is associated with the concept, which includes all the mental pictures

and associated properties and processes. It is built up over the years through experiences of all kinds, changing as the individual meets new stimuli and matures." (Tall & Vinner, 1981, p. 152). Thus, the concept image includes all mental visualizations of graphic or iconic representations, tables, coordinate systems, but also symbolic expressions. These can be both conscious and unconscious. The concept image does not have to form a coherent unit – individual components of the concept image can contradict each other, whereby a mental conflict only arises if these two components are activated simultaneously. The part of the concept image that is activated at a certain time is called the *evoked concept image*.

The *concept definition* is another important element in this theory. It is a verbalized form of a mathematical concept and is distinguished from the concept image. It can correspond to the general mathematical definition or can be an individual description that is based on the concept image and may deviate from an appropriate mathematical formulation. Mental images are also generated when the concept definition is used. These concept definition related images are called *concept definition images* and are part of the concept image.

We use the concept image theory for two reasons: First, in trigonometry, there exist many different graphical representations that have a particular influence on mental images. Thus, it makes sense to use a theoretical framework that focuses on mental images. Secondly, other research about trigonometry is already based on the concept image theory. Thus, our results can be better linked to these results.

Concept Image Theory related research on trigonometry

Trigonometric concepts, their interpretation, and their use by students and prospective teachers have been the subject of several studies. Kendall and Stacey (1998) investigated whether students are more successful in solving trigonometry problems if they use right triangles or the unit circle. Although the group using right triangles performed better in this study, Weber (2005) came to the contrary conclusion in another study: In his case, the students who used the unit circle performed better. Weber (2005) argues that it is not primarily the concrete representation in trigonometry lessons that matters, but how the concept behind the individual representations is understood. The fact that students show low conceptual knowledge of trigonometry has also been the subject of other studies (Chin, 2013; Martín-Fernández et al., 2019). The use of mnemonics to memorize trigonometric ratios (Engl.: SOH-CAH-TOA, whereby sine (S), cosine (C), tangent (T), opposite (O), ankathete (A), hypotenuse (H)) was also associated with procedural understanding in other studies (Brown, 2005; Kendal & Stacey, 1998; Yiğit Koyunkaya, 2016). Based on these studies, there is a call for a stronger focus on conceptual considerations in teaching trigonometry.

Yiğit Koyunkaya (2016) used concept image theory to investigate mathematical educational graduate student's understanding of the relationships between sine and cosine in a right triangle. The right triangles and the unit circle were identified as the students' concept images. The SOH-CAH-TOA mnemonic was identified as the concept definition. Other research work also provides information on the concept image of secondary school students: In addition, to right triangles and the unit circle, students also use coordinates and directed line lengths (in the unit circle) and the periodic function

curve when working on tasks, which means that these can be assigned to their concept image (Brown, 2005; Martín-Fernández et al., 2019).

Description of conceptual breaks within the concept image theory

In this article, an individual concept for trigonometry is understood as the union of concept image and concept definition. A trigonometry-related concept image includes the individually formed graphical representations (right triangle, unit circle, and sinusoid), but also the symbolic functional equations. A concept definition is seen as a verbal explanation of the question 'What is sine?'. The term *representation* is used in a broader sense: Not only graphical representations are meant here but also equations and verbal sentences. Within the concept image theory, we distinguish between different conceptual breaks (Table 1).

Table 1: Different types of Conceptual breaks within the Concept Image Theory

Type	Description	Example
A conceptual break within an evoked concept image	A certain individual representation does not correspond to the appropriate representation.	A student does not center the unit circle in the coordinate origin.
A conceptual break within the concept image	There are linking difficulties between different representations.	It cannot be explained what the representation of the unit circle has to do with the sinusoids.
A conceptual break between concept image and concept definition	There are linking difficulties between individual images and the verbal definitions.	A student defines sin(x) as a ratio of side lengths in a right triangle but uses the periodic function curve to visualize it.

Trigonometry related research about conceptual breaks

In an empirical study (Chin, 2013), student teachers distinguished three separate *trigonometries*: Triangle trigonometry, unit circle trigonometry and analytical trigonometry (series representation). This was made explicit by the fact that most student teachers had difficulties shifting between these *trigonometries* and answering questions in multiple *trigonometries*. These findings indicate a conceptual break within the concept image of trigonometry. In another study (Brown, 2005), conceptual breaks were also observed within evoked concept images. The conceptual difficulties occurred when working with right triangles, the unit circle, and periodic functions.

The following research question arise for us: What conceptual breaks can be identified in university students' concept of sine? We want to answer this question applying a qualitative analysis. We also want to discuss how these conceptual breaks can be addressed in the classroom.

Methods

A questionnaire was designed to investigate students' definitions of a mathematical concept and its representations. The questionnaire consisted of three questions, among others. We only provide an insight into these three questions, as they were the most relevant for answering our research questions during the analysis:

1. Give a definition of sin(x).
2. Provide a representation of sin(x).
3. What does the sin(x) represent in the right triangle?

The questions were designed to explore students' ability to connect different images and the definition of the same mathematical concept (sine). In particular, the first question concerns the definition of the concept. The answers to this question are traded as the students' concept definition or their concept definition images if their answers contain images. The second question aims to find out something about the concept image. There are two reasons why we ask about the representation of the right triangle in the third question: First, we want to further investigate the presence of the misconception based on the identification of the sine as the cathetus of a right triangle (Martín-Fernández, 2019) which would indicate a conceptual break within an evoked concept image based on our definition. Second, this question aims to explore conceptual breaks within the concept image and between the concept image and the concept definition.

The experiment was conducted with 94 freshmen from an Italian university, specifically 68 from the faculty of Architecture, and 26 from the faculty of Engineering. The study took place during the first semester, while the students were attending a Calculus course after the trigonometry review and participated voluntarily in the experiment. Specifically, trigonometry is a topic that they studied during secondary school (present in every Italian high school curriculum) and is revisited by university teachers during Calculus courses. This justifies the selection of these participants. Students had 20 minutes to respond to the questions and we collected their written answers. We conducted a qualitative analysis of the students' responses, focusing on the presence of three conceptual breaks (Table 1). To identify the three different types of conceptual breaks in the students' answers, we analyzed their answers to the different questions in relation to the description in table 1.

Analysis

In a qualitative study, we focused our attention on three cases (students A, B and C) that illustrate the three different breaks (conceptual breaks in the evoked concept image, conceptual break within the concept image and break between concept image and concept definition).

Example of a conceptual break within an evoked concept image (student A)

In Figure 1a, the student A answered question 1 and Figure 1b contains the answer to question 3 (*What does the sin(x) represent in the right triangle?*). A coordinate system, a circle, and an inscribed right triangle can be seen, whereby the angle between the cartesian axes in the first quadrant is the right angle of the right triangle. Next to the drawing, the student wrote, "*The sine in a right triangle represents one of the two catheti forming the angle* α".

The unit circle drawn in Figure 1b contains some specifics that indicate conceptual breaks in the evoked concept image: The position of the inscribed right triangle is at the wrong position and the right angle is labeled by α. The intersection points of the circle with the axes were marked counterclockwise with $0, \pi/2, \pi, 3\pi/2$, which indicate a rotation conception. The x- and y-axis have been swapped. The catheti are labeled with $\sin\alpha$ and $\cos\beta$. These characteristics do not correspond to an appropriate representation of a unit circle which is why a conceptual break within an evoked concept image is identified (Table 1).

a) "$y = \sin(x): \mathbb{R} \to [-1,1]$

$$\sin(x) = \frac{opposite\ cathetus}{hypothenuse}"$$

b)

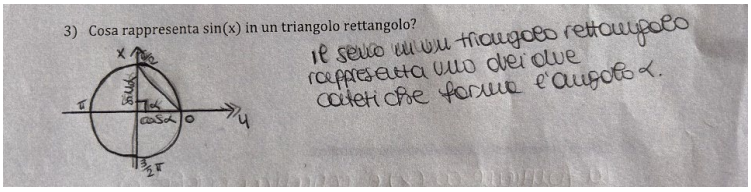

Figure 1: a) definition given by the student to question 1; b) Student's answer to question 3

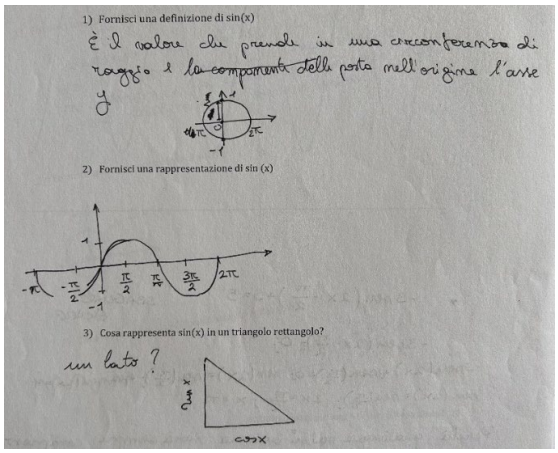
Additionally, in Figure 1a, it is possible to see that the student A uses another definition, highlighting the difficulty in evoking correlated images. This example can be interpreted as an attempt to relate the right triangle and the unit circumference.

In fact, individual components of the appropriate image are present (circle, coordinate system, right triangle), but they have not been positioned in such a way that they can be used to illustrate trigonometric relations. As a result, no practical problems can be solved with the help of this concept image.

Example of a conceptual break within the concept image (student B)

In Figure 2, we can see the answers of a student B to all three questions. In the first question, the student's answer was "*It's the value that a circle of radius 1 takes on the y-axis."*, additionally the unit circle was drawn. In the second question, the student B drew a sinusoid, and in the third question a right triangle, identifying sin(x) as a cathetus.



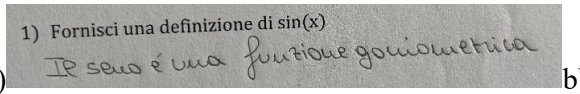


Figure 2: Answers of a student to all questions

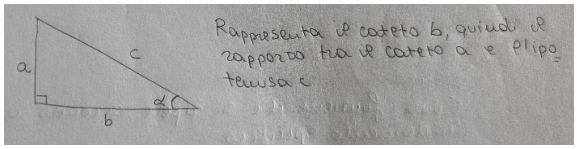
Although only task 3 asks for a specific representation, other representations are used to answer the other two questions. In this case, the unit circle is part of the concept definition image, whereas the sinusoid and the right triangle are evoked concept images for the following questions. Especially the use of the unit circle in question 1 and the sinusoid in question 2 could indicate linking difficulties between these two representations which is why we identified a conceptual break within the concept image (Table 1). However, further tasks would have to show whether student B is actually unable to switch between these representations or not.

We interpret the identification of the length of a cathetus with sin(x) as an overgeneralization of the right triangle from the unit circle. This interpretation is also supported by the status of the unit circle as a concept image definition, as well as by the results of other studies (Martín-Fernández, 2019).

Example of a conceptual break between concept image and concept definition (student C)

Sttudent C answered the first question (Figure 3a): "*sin(x) is a trigonometric function*". In Figure 3b, we can see that student C drew a right triangle and wrote: "*Represents the cathetus b, then the ratio of the cathetus a to the hypotenuse c*".

a) 



b) 

Figure 3: Student's answer to question 1 and 3

The use of the word "then" is very interesting. We see in it a certain dominant position of the interpretation of sine as a length of a cathetus, while the interpretation as a ratio has a lesser significance. However, the drawing, which represents a part of the concept definition image, only corresponds to the interpretation as a ratio and not to the interpretation as a length of a cathetus or as a trigonometric function. These are indications of linking difficulties between the image and the definition which is why we identified a conceptual break between concept image and concept definition (Table 1). This interpretation supports the hypotheses of other research studies that describe the presence of different *trigonometries* in students' minds (Chin, 2013). However, the concept definition used in task 1 may also have been provoked by the use of "sin(x)" in the task. This notation has a stronger connection to the interpretation as a function and could have provoked a second concept definition.

Discussion

The cases illustrate conceptual breaks by students and thus confirm findings from existing research. We want to discuss potential reasons behind these conceptual breaks as well as present teaching measures that counteract these breaks. It is hoped that the separation into different conceptual breaks will lead to a more differentiated discussion.

Possible reasons for conceptual breaks

The consideration of different types of conceptual breaks (Table 1) enables a differentiated consideration of possible causes.

In the case of conceptual breaks within the evoked concept image, the representations shown do not correspond to the mathematically appropriate representations (Figure 1). This could be due to a lack of prior knowledge: Conceptual difficulties with circles or triangles could be transferred to the concept image of the unit circle. It is also conceivable that only parts from school lessons, and not the whole concept, were understood. For example, the circle and the right triangle are recognized as important components of the unit circle representation, but the incorrect positioning of the triangle (Figure 1) shows the impossibility of representing trigonometric relations and thus an inadequate conceptualization. Thus, a lack of conceptual considerations in teaching in the introductory phase on the topic of trigonometry favors the emergence of such conceptual breaks. Too great a focus on calculus-oriented tasks in lessons could further reinforce existing conceptual breaks.

In the case of conceptual breaks within the concept image, different representations are not adequately interlinked (Figure 2). If the conceptual links between trigonometry on the unit circle, right triangles, and sinusoids are not made transparent in class, the representations cannot be linked together. As a result, separate trigonometries are formed, as already described in the literature (Chin, 2013).

Conceptual breaks between concept definition and concept image could also be demonstrated in this study, but they differed from those already known from the literature: While in Anglo-American studies mnemonics formed the concept definition, in this study the definition of the sine as a function or as the y-coordinate of the unit circle was predominant. On the one hand, the lack of such a mnemonic in Italian could be responsible for this difference, but on the other hand, the illustrations and definitions presented in class could also significantly influence the concept image and the concept definition. The fact that there is no match between concept image and concept definition in the illustrated case (Figure 3) could be due to a lack of support for representation linking in class.

Implications for teaching

The following points should be considered in lessons in order to counteract conceptual breaks at an early stage: 1. Conceptual considerations should be strengthened, especially in the introductory phase of this topic. 2. Linking different concepts and representations of trigonometry should be supported in lessons.

Teaching implementations for the first point are currently being researched within a design research project (Büttner & Erath, 2023b). The developed learning design focuses on the assignment of angles to trigonometric ratios within the context of slopes. This is intended to counteract a conceptual break between trigonometry on right triangles and sinusoids at an early stage.

The link between representations on the right-angled triangle and the unit circle can be supported in class with the help of GeoGebra applets (Figure 4). In the applet shown, the unit circle and sinusoids are shown side by side. By varying the angle using the slider, the corresponding point on the unit circle and the point in the Cartesian coordinate system are moved at the same time. The activated track mode makes the sinusoid visible in the coordinate system. The connections between the two representations can be recognized through the simultaneous dynamics, which support a representation linkage.

First graders' conceptions and linguistic descriptions of geometric shapes

Şahin Danişman[1] and Duygu Arabacı[1]

[1]Düzce University, Faculty of Education, Düzce, Türkiye; sahin.danisman@gmail.com

This research aims to examine children's conceptions about identification and properties of geometric shapes. This descriptive research was carried out on a research sample consisting of 27 first graders. The data were collected using a printed handout that illustrated models and non-models of planar geometric shapes. The students were expected to identify triangles, squares, rectangles, and circles among the given set of shapes. The findings suggest that the students' preferences were mostly prototypical shapes, and shapes with curved corners or edges that resemble the prototype were also marked. This shows that students refer to the similarity to the original shape, ignore the fact that the edges should be straight line segments, and some students think in three dimensions and mark curved edges as models. The fact that the shape is small, pressed or rotated prevented the correct identification of the shapes.

Keywords: Geometric shapes, conceptions, prototypes.

Introduction

The current state of research demonstrates that the ability to formulate geometric reasoning is closely related to the ability to form mental representations and to manipulate them in the process of reasoning (Pérez et al., 2019). In order to ensure that students are fully able to comprehend abstract geometric concepts, it is necessary to develop both their conceptual knowledge and their language skills, as well as provide hands-on experiences for students as well as clearly define the symbols that correspond to specific terms (Fujita et al., 2020; Leavy et al., 2017). If any of these key elements are neglected in geometry education, then misconceptions will likely develop which may persist throughout the student's mathematical education and make them more difficult to overcome.

Various theories have been proposed for the development of students' concept formation and thinking structures. These theories collectively contribute to our understanding of cognitive development and education, highlighting the interplay between social interaction, language, and structured learning processes. Piaget's Cognitive Development Theory focuses on stages of cognitive development that children go through as they grow. It proposes that children construct knowledge through interactions with their environment, progressing through distinct stages that are age-related. Each stage represents a different way of thinking and understanding the world (Piaget & Inhelder, 1971). Vygotsky disagreed with Piaget's view that the human mind possesses cognitive structures independent of social factors. Vygotsky's Social Development Theory emphasizes the role of social interaction and culture in cognitive development. Language is crucial for the formation of cognitive structures, differing from Piaget's focus on individual cognitive processes. He suggests that learning occurs through social contexts and collaborative dialogue (Vygotsky, 1970). Bruner's Theory of Representations proposes three modes of representation: enactive (action-based), iconic (image-based), and symbolic (language-based). Hence, education of children should progress through these stages to develop symbolic thinking, which is essential for understanding abstract concepts. The theory also highlights

the importance of language in learning and problem-solving, suggesting that different types of representations are necessary for all ages (Bruner, 1966).

Van Hiele's Model of Geometric Thought identifies five levels of geometric understanding, where each level builds on the previous one. It emphasizes that students cannot skip levels; a thorough understanding of one level is necessary to progress to the next. It provides a framework for diagnosing geometric understanding, which can enhance the teaching of geometry (van Hiele, 1986). Knight (2006) summarizes the theory as existence of levels of understanding, properties that are inherent to each level, and occurrence of movement to a level from the previous level. The van Hiele model of geometric thought is a theory that describes how students learn geometry in a hierarchical manner through five distinct levels. These levels are visualization, analysis, informal deduction, deduction, and rigor. In the first level, students recognize shapes and objects based on their appearance. They can identify and name geometric figures but do not understand their properties or relationships. In the second level, students begin to understand the properties of shapes. They can identify and describe the characteristics of geometric figures, such as the number of sides or angles, but they do not yet understand the relationships between these properties. In the third level, students can logically order properties and understand the relationships between them. They can follow informal arguments and understand the significance of definitions and theorems. In the fourth level, students can construct formal proofs and understand the structure of a mathematical system. They can work with axioms, definitions, and theorems in a formal deductive manner. At the highest level, students understand the formal aspects of geometry and can compare different systems of geometry. They can work in abstract and axiomatic systems and understand the role of logic and proof in mathematics. A schematic representation of the van Hiele levels of geometric thought is presented by van de Walle et al. (2013). This representation indicates that the levels are not isolated, but intertwined, and that geometric terms grow in meaning over time.

Understanding geometric shapes is a fundamental aspect of early mathematical education, crucial for developing spatial reasoning and advanced mathematical skills. This research aims to examine children’s conceptions about identification and properties of geometric shapes. In line with this aim, as a part of this study, we are trying to determine the kind of lexical or non-lexical resources the children are using in order to describe the shapes by comparing the children's lingual expression with the geometric terminology used in the shapes.

Methods

This is a descriptive study which seeks for the conceptions of first graders about geometric shapes. The research was carried out on a research sample consisting of 27 first graders. The research was conducted using a printed handout that illustrated models and non-models of planar geometric shapes as a means of illustrating the shapes. These handouts including shape collections were developed by Zilkova et al. (2018). The questions included shapes for identification of triangle, square, rectangle, and circle. Figure in the appendix represents the list shapes among which the requested shapes would be chosen. The students were asked to choose the shapes for triangles, squares, rectangles and circles as shown in the appendix. A researcher guided the students during the implementation. As squares were examined separately and first graders were not expected to know the relationship between a

square and rectangle, correct identification of rectangles included models except squares. All of the choices of the students were coded and frequencies and percentages have been presented separately for each of the shapes examined. Students' choices and discourses for the required shapes were examined altogether for the certain types of shapes. For example, all the data for triangles have been examined synchronously. Pseudonyms (M for males, F for females followed by a participant number) have been assigned for the students.

Findings

The findings have been presented in four sections for each of the shapes.

First graders' conceptions of triangles

Table 1 presents the findings for the conceptions of triangles with descriptive statistics.

Table 1: Descriptive statistics for the conceptions of triangles

Shape	*f*	%	Shape	*f*	%
1e	23	85.2	**2b**	3	11.1
2a	14	51.9	**2d**	2	7.4
3d	10	37.0	**1c**	1	3.7
3e	9	33.3	**2e**	1	3.7
3b	5	18.5	**3a**	1	3.7
3c	5	18.5			

1c, 1e, 2a, 3c, and 3e are correctly drawn figures for the triangle. It is noteworthy that among the triangle models, 1c was marked by only 1 person. This may be due to the fact that the top of the shape is down, and it is a scalene triangle. When asked, a student (F3) stated that it (1c) does not look like the triangles she knows (which are prototypes). 3d and 3b may have been chosen more because they resemble the shape of the prototype triangle. 2b has similar characteristics with these two, but it may have been chosen in smaller numbers due to its outward curvature. Indeed, the dialog with a student (M2) is as follows:

Researcher: What shape do you think this (3e) looks like?
Student: A triangle.
Researcher: Then we will put it on it too. Do you know what a triangle is?
Student: Like this (pointing to 1e).

As seen in the dialog, the fact that the student showed 1e, which represents the most common triangle prototype, may be an indication that they consider prototype shapes when determining shapes.

It was observed that one student marked triangles and all geometric shapes similar to triangles. In the clinical interview with the student, it was determined that the student had partial knowledge about the triangle, but lacked knowledge that the sides of the triangle should be a straight line segment. This situation caused the student to name shapes similar to triangles as triangles. As a matter of fact, when the student was asked about the difference between a triangle and a square, it was seen that he used

the correct mathematical expression that a triangle has 3 vertices, but in the dialog that took place afterwards, it was seen that he named the shapes whose sides are not regular line segments as suppressed triangles. The dialog with the student (M5) is presented below:

Researcher: How do you think a triangle is different from a square?
Student: A square has 4 vertices, a triangle has 3 vertices.
Researcher: Where is the corner?
Student: (Points a corner).
Researcher: Do you think this shape and this shape are the same? (2d-3e) You said the triangle has 3 vertices. Does this figure (2d) have 3 vertices? Can you show me by marking them?
Student: (Points the corners).
Researcher: Here? (concave part)
Student: They pressed it a little bit this way (inward).

First graders' conceptions of squares

Table 2 presents the findings for the conceptions of squares with descriptive statistics.

Table 2: Descriptive statistics for the conceptions of squares

Shape	*f*	*%*	Shape	*f*	*%*
1a	21	77.8	**3b**	2	7.4
3c	14	51.9	**1d**	1	3.7
3e	11	40.7	**2b**	1	3.7
3d	7	25.9	**2d**	1	3.7
1b	6	22.2	**3a**	1	3.7
2a	3	11.1			

1a, 3c, and 3e are correctly drawn figures for the square. The fact that the majority of the students' choices were correct models shows that the students correctly identified and recognized the square. In addition, it can be said that most of the students were aware that the position of the square is not important in determining the geometric shape. As a matter of fact, in the clinical interview with one of the students, although the student was initially undecided about whether 3c was a square or not, she decided that this shape was also a square by associating it with the concrete example she encountered in daily life. The dialog with the student (F6) is as follows:

Student: (Not sure whether 3c is a square or not) I couldn't understand that again.
Researcher: Do you think it is a square or not?
Student: I don't know.
Researcher: What do you think about the characteristics of a square?
Student: (After examining it for a few seconds and deciding to choose a shape). This is a square.
Researcher: Why did you change your mind?
Student: I was turning the pillow and it was like this (3c). Normally my pillow is in the shape of a square, looks like this (prototype).

It is also interesting that students did not mark 3e very much even though it was a prototype they knew. The reason why 3e was chosen less frequently among the correct models may be its small size.

In the clinical interview, when a student who did not mark 3e was asked why it was not a square, the student stated that he was not aware of it and then marked it realizing that it was a square. The students' incorrect choices were mostly rhombus and shapes with rounded corners or curved edges similar to a square.

First graders' conceptions of rectangles

Table 3 presents the findings for the conceptions of rectangles with descriptive statistics.

Table 3: Descriptive statistics for the conceptions of rectangles

Shape	*f*	%	Shape	*f*	%
2b	12	44.4	**1c**	2	7.4
3b	9	33.3	**2a**	2	7.4
1d	6	22.2	**2c**	2	7.4
2e	5	18.5	**2d**	2	7.4
3a	4	14.8	**2f**	2	7.4
1a	4	14.8	**1b**	1	3.7
2g	3	11.1	**3c**	1	3.7

2b, 2g, and 3b are correctly drawn figures for the rectangle. The reason why 2g was chosen less frequently may be that it is quite narrow and looks like a line. In general, it is seen that most of the students were unable to identify the correct models of rectangles. The students' incorrect choices were mostly parallelogram and rectangles with rounded or cut corners. One of the students in the clinical interview considered 2c as a rectangle. The student was asked why this shape was a rectangle since it was a different choice from other marked shapes. The dialog with the student (F2) is as follows:

Researcher: What do you think a rectangle is?
Student: A rectangle is a long thing like this, and this one looks short because it is pressed here (at the corners).
Researcher: What about this one? (3c)
Student: It is also rectangular. They shake it like this (Figure 1), that's how it happens. For example, a napkin is rectangular, when you shake it, it becomes like this (3c).

Figure 1: Images of a student shaking a rectangular piece of paper

When the dialog above is examined, it is understood that the student imagines the rectangle in 3D space and thinks about the image of the rectangle in case it moves. Although it is not appropriate, it is noteworthy that the student imagines the shape in 3D space. In the interviews conducted with the student for other rectangles and other geometric shapes (square, triangle, circle), it was noticed that the student had a similar way of thinking.

First graders' conceptions of circles

Table 4 presents the findings for the conceptions of circles with descriptive statistics.

Table 4: Descriptive statistics for the conceptions of circles

Shape	*f*	%	Shape	*f*	%
3a	23	85.2	**3c**	2	7.4
1c	14	51.9	**3d**	2	7.4
2d	11	40.7	**1b**	1	3.7
2a	6	22.2	**1e**	1	3.7
2c	4	14.8	**2b**	1	3.7
2e	4	14.8	**3b**	1	3.7
1a	2	7.4			

1c, 2d, and 3a are correctly drawn figures for the circle. As with the square model, most of the student choices are correct models for the circle. 2d, the correct model with the lowest proportion, may have been chosen less often due to its small size as in the square. Interestingly, 2a and 2c, which are polygons, are the most marked models among the incorrect choices. This may indicate that students refer to the circle as being "round" and are unaware that a circle has no corners. During the interviews, when a student (F2) was asked what a circle was, she defined a circle as "A circle, round." On the other hand, when the student was asked about the two non-circle geometric shapes chosen by the student during the clinical interview, it was determined that although the student had the correct knowledge about the circle, she also marked different shapes because she thought about the movement of the circle by thinking in 3D as in her previous statements.

Conclusion

Students correctly identified triangle and circle shapes with the highest percentage. The rate of identifying the square is also quite high and the lowest percentage of success belongs to rectangles. The students' preferences were mostly prototypical shapes, and shapes with curved corners or edges that resemble the prototype were also marked. This shows that students refer to the similarity to the original shape, ignore the fact that the edges should be straight line segments, and some students think in three dimensions and mark curved edges as models. The fact that the shape is small, pressed or rotated prevented the correct identification of the shapes.

As the literature suggests students commonly fail to correctly define angles and triangles, often due to errors in concept images and reasoning (Kusno & Sutarto, 2022). Young children (5-6 years old) can identify prototypical triangles but struggle with different types, sizes, and orientations, relying heavily on visual prototypes (Dağlı & Halat, 2016). Preschool children also struggle to identify squares in rotated directions and smaller sizes, indicating a lack of flexibility in their geometric understanding (Halat & Dağlı, 2016). Learner-generated examples reveal that prospective teachers often have a limited understanding of what constitutes a proper mathematical definition of a square,

highlighting the need for better pedagogical strategies (Zazkis & Leikin, 2008). Geometric knowledge about squares is developed more through experiential learning rather than developmental stages, suggesting that hands-on activities and real-life applications are effective in teaching this concept (Seah et al., 2016). Many students believe that rectangles must always be regularly shaped and do not recognize irregularly shaped rectangles (Guncaga & Zilkova, 2019; Ningrum et al., 2018). Students' conceptions of circles are often fraught with misconceptions and cognitive challenges.

Research indicates that early and varied exposure to geometric shapes, combined with effective teaching strategies and materials, significantly enhances students' understanding of geometric concepts. Teachers' professional development and the integration of technology further support this learning process. By addressing these factors, educators can better support students in developing a strong foundation in geometry.

Appendix

Encountering improper points through geogebrization

Agnese Del Zozzo[1]

[1]University of Trento, Trento, Italy; agnese.delzozzo@unitn.it

Using Radford's Theory of Objectification, this study analyses the learning process of two undergraduate students engaging with a geogebrization activity in the realm of projective geometry, focusing on the operation of projection from improper point as a centre.

Keywords: Geogebrization, projective geometry, improper elements, theory of objectification.

Premise and rationale

This paper stems from my doctoral thesis (Del Zozzo, 2024a), which focused on defining a process called *geogebrization* (GGBZ) *of mathematical texts*[1] (Del Zozzo, 2023; 2024b) and studying its potential through a specific case study involving excerpts from Guido Castelnuovo's (1904) didactic treatise on the foundations of synthetic projective geometry. For the experimental phase, I designed an activity that I proposed to four pairs of participants, each representing an expert perspective on relevant aspects of this process. However, none of the eight participants had previously studied projective geometry using Castelnuovo's synthetic approach or utilized GeoGebra to create dynamic and interactive visualizations. This allowed me to gather insights into how such an approach could enhance the understanding of fundamental concepts in projective geometry, such as improper elements and the operations of projection and section. In this paper, I present an example from the work of two undergraduate mathematics students, analysing an emblematic episode involving the graphical management of projection with improper elements, through the lens of Radford's (2021) Theory of Objectification (TO). This study aligns with international research examining the integration of digital technologies and the history of mathematics, particularly in geometry, where dynamic geometry software and (so far mostly) Euclid's *Elements* serve as focal points. For example, Thomsen and Jankvist (2022) demonstrated how GeoGebra-based activities with 7th-grade students fostered mathematical skills, while Prieto and Arredondo (2021) used TO to analyse prospective teachers' learning through construction tasks based on Euclid's propositions.

This paper aims to achieve two objectives: first, to demonstrate the application of TO in a previously unexplored area, and second, to illustrate how GGBZ activities involving historical texts can influence the learning (in Radford's sense) of advanced mathematical objects that participants have partially encountered before.

---

[1] In a few words, it is a process by which one or more learners transform a printed mathematical text into an *appropriate combination of resources* in the GeoGebra Service Platform (GSP, i.e. the website www.geogebra.com). The goal is to create a product made public on the GSP that can be used for communicative, popularization, or educational purposes. By an *appropriate combination of resources*, we mean the set of choices and actions taken by the individuals involved in the GGBZ of the text, who exploit the opportunities provided by the GSP in such a way as to satisfy two requirements: i) unpack and materialize the mathematics embedded in the original mathematical text by leveraging the functionalities of GSP; ii) increase the communicative potential of the original text.

Theoretical framework

The TO is based on the Cultural-Historical Activity Theory and is part of sociocultural theories, which conceive of human beings—what they think, do, feel, imagine, and dream—as deeply interconnected with the culture in which they live (Radford, 2021, in particular p. 17). In TO, mathematical objects are considered to exist as cultural artifacts that are generated and materialized during human activities. Mathematics is consequently conceived as something that is both ideal and material, produced by the activity of teachers and students.

This vision necessitates reconceptualizing, from a cultural-historical perspective, the concepts of *knowledge*—which refers to a general and dynamic entity, a potentiality, the generative capacity to do something or think in a certain way—and *knowing*—which is the actualization and materialization of knowledge through human *activity* into something concrete that can be sensibly perceived. In our case, Castelnuovo (1904) represents a cultural artifact. It is an object in a cultural space-time that actualizes historical knowledge, which is the projective (and analytical) geometry of that period (or at least a part of it).

Such a vision of knowledge and knowing corresponds to (and requires) a particular vision of *learning*. In fact, in TO, the study of learning cannot ignore the specificities of the mathematical knowledge that is learned. Knowledge, as a collective product of previous generations, is something that exists in culture independently of specific individual learning. Therefore, a person can neither build nor possess knowledge. It is something that individuals encounter throughout their lives, and the process of encountering cultural-historical systems of thought is what, in TO, is called the *process of objectification* (Radford, 2021, in particular p. 71). What triggers a process of objectification is human activity—social, intellectual, corporeal, sensorial, and semiotic—during which individuals encounter the cultural object that initially opposes them but which, as the activity proceeds, is increasingly transformed into an object of consciousness.

Within this dynamic framework, noticing occurs through what in TO is called *sensuous cognition*, that is, a broad conception of mind and consciousness which includes not only ideal and mental characteristics but also embodied ones such as perception, feelings, and kinaesthetic activity. Within sensuous cognition, the imaginative, perceptive, and sensorimotor aspects integrate, are produced historically and culturally, and the transformation of consciousness due to the encounter with cultural objects corresponds to (and allows) new ways of perceiving the world. In fact, learning as a process of objectification results in what Radford calls a *domestication of the eye*, a long process that allows individuals—in a cultural-historical activity intertwined with the use of signs and artifacts—to transform the eye (and other senses) into sophisticated theoretical organs capable of becoming aware and giving meaning to the mathematical knowledge encountered through activity.

In the development of the process of objectification, what in TO are called *semiotic means of objectification* are crucial:

> These devices are fundamental to the manner in which things become progressively noticed. These objects, tools, linguistic devices, and signs that individuals intentionally use in social meaning-making processes to achieve a stable form of awareness, to make apparent their intentions, and to

> carry out their actions to attain the goal of their activities, are called *semiotic means of objectification*. They are semiotic in that they are key pieces in the production of meanings embedded in the processes of objectification. (Radford, 2021, p. 100, emphasis in original).

The semiotic means of objectification employed sculpt the forms and modes of activity and are decisive with respect to noticing and the way in which new ways of perceiving the world develop. In general, the role of semiotic means of objectification is so significant that analysing them within the context of the human social activity that gives them meaning allows us to study the objectification process and, therefore, to detect and study learning. The methodological construct that allows us to describe and interpret learning—as a process of objectification mediated by semiotic means—is the *semiotic node* (Radford & Sabena, 2015). A semiotic node is a segment of teaching/learning activity in which a nucleus of the objectification process is identified, evidenced by a rich and complex organization of semiotic means of objectification that allows the emergence of new objects of consciousness. Therefore, the search for semiotic nodes and the analysis of semiotic means of objectification provide important information regarding how learning is taking place (Radford, 2021). The deeper consciousness that subjects acquire in the process of objectification gives rise to a subsequent phenomenon called *semiotic contraction*. Indeed, the process of objectification allows a reorganization of semiotic resources, in which decisions are made about which of them are relevant or irrelevant (Radford, 2021, in particular p. 102). In other words, the process of objectification—evidenced by the semiotic node—occurs through a transformation of the eye with which the mathematical object is perceived, leading to a refinement of the semiotic resources deployed during the semiotic node itself. In TO, semiotic contraction is considered evidence of learning.

Within the framework of the TO, I can now formulate the research question: when engaged in a GGBZ activity involving an excerpt from Castelnuovo's (1904) regarding the operation of projection from a point, how does the domestication of the eye develop if the centre is improper?

Methods

We consider a pair of undergraduate students in Mathematics (LT1 and LT2) engaging with a GGBZ activity structured as a *GeoGebra Book* and delivered via *GeoGebra Classroom*. The activity, described in Del Zozzo (2023, 2024a, and 2024b), was originally in Italian but is available in English at https://www.geogebra.org/m/ksxsjc3v. The entire activity consists in nine problems regarding the basic tenants of projective geometry (improper elements, projections and sections); each problem starts with an excerpt of the original text along with a sequence of related tasks to do. For the sake of clarity in reading what follows, I report in Figure 1 the third problem.

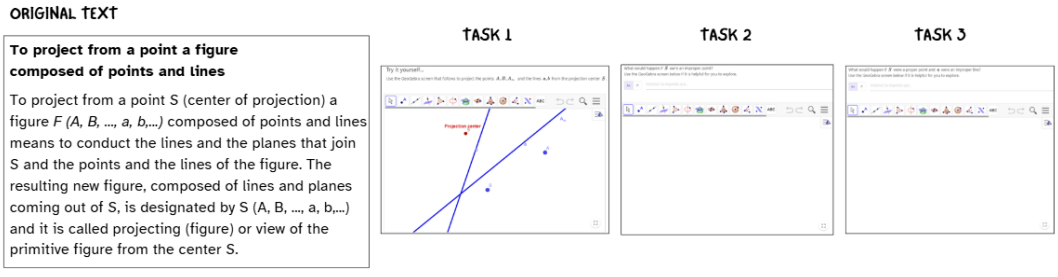

Figure 1: Problem 3 regarding projections from a point

LT1 and LT2 completed the entire activity in four meetings, each lasting between 1 hour and 30 minutes and 2 hours. Each meeting was videotaped from two sources: an external camera and the PC screen used by the participants. The unit of analysis considered is the GGBZ activity segment, and the main research data are the video recordings of the meetings, in a side-by-side edited version, along with all the students working protocols (both digital and material). For the video analysis, I built on Radford and Sabena (2015), and I have outlined an analytical scheme to identify the semiotic nodes: i) Identification of the presence of a conflict that triggers a thoughtful reflection (e.g., silence); ii) detection of an increase in the use of semiotic means of objectification; iii) detection of semiotic contraction indicators. I report in what follow a summary of a semiotic node that illustrates LT1 and LT2's domestication of the eye while managing the operation of projection from an improper centre. For the reader's convenience, I have highlighted specific passages in the transcriptions that are referenced during the analysis.

The encounter with the nature of improper points

In the middle of the first meeting, LT1 and LT2 were engaging with Task 2 of Problem 3 (Figure 1). In this task, building on the situation proposed in Task 1, students are asked to explore the case where the projection centre is an improper point, using an empty GeoGebra screen to perform the construction. To do so, they must manage an improper point as the centre of projection, materializing both the initial construction and the projection of various elements within GeoGebra. In this task, handling the projection of a proper line and another improper point creates a significant conceptual shift from Task 1, representing a conflict between the students' existing knowledge and the one they are encountering. As a first step, LT1 and LT2 construct in the provided GeoGebra screen the initial situation from the one present in Task 1 (two proper points, one improper point, and two proper lines). At this point, they have to insert the centre of projection which, this time, is an improper point:

1 LT1: Ah..now we have to take S which we want a point at infinity that is a line basically [...]

An identification between a point at infinity and a line emerges from LT1's words. They insert a new line into the construction, colour it red, and label it with the letter S (Figure 2).

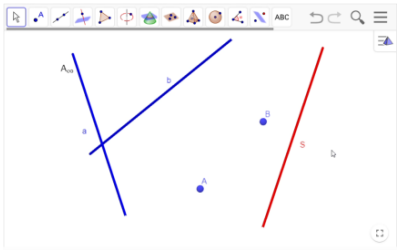

Figure 2: Starting situation

After this, they silently reread the original text (indicator of conflict). After the silent rereading, LT2 opens the conversation and as LT1, she also identifies the improper point with a specific, fixed line. Due to this identification, LT2 share with LT1 her conflict in imagining how to handle the case where the proper line to project is skew with the "line-improper point". Indeed, since it is the projection of a line from a point, one should obtain a plane that contains that point and that line, that results in an impossible operation if the improper point is conceived as a fixed line, which is skew with the proper

line to project. In these first moments, there is an initial increase in gesturing. The discussion continues, and after a while, LT1 again proposes to reread the text but this time does so aloud:

2	LT1:	Let's try to start from here *((places her hand on the printed sheet with the original text that begins Problem 3))* where it tells us... *((starts reading, following the text with her finger))* "to project whatever it is means to draw the lines and planes that join *S* to the points and lines of the figure". So we have *S*, and we take a point—what does it mean to join *S* with a point *((has picked up the mouse and points the cursor at point A on the GeoGebra screen))* ... it means... to draw the parallel line, I'd say.
3	LT2:	Yes
4	LT1:	So you'd have the parallel line like this *((moves the mouse cursor parallel to line S passing through B))* and the parallel line like that... but the points didn't particularly bother us [LT2: Yes]. Now we want the lines, which means *((returns to the text indicating while reading))* […] to draw the plane that joins *S* to the line.

In 2 to 4 new sings appears: verbalizing the words read, paced by the movement of her finger; the subsequent verbal reformulation accompanied by indexical gestures on the screen; and verbalizing the actions that materialize the projection of a proper point from an improper point. The new signs lead to a new perception of the situation, which materializes in the subsequent exchange.

5	LT2:	Yes *((silence))* so we'd want to take a plane that has the same orientation as *S*... but...
6	LT1:	Eh, but *S* is a single direction *((points index finger upward))*; it can't define the orientation of a plane [LT2: Ah, right, true].
7	LT1:	It would mean... drawing the plane that joins... wait *((takes the mouse))* so if with the point we draw the parallel line... with a line *((with the cursor, she points first to point B and then traces the line parallel to S passing through B; then she moves the cursor over line b))*... eh no, but we can't draw the parallel plane *((puts down the mouse))*—the plane parallel to what?
8	LT2:	I mean, the doubt that arises is that *((points to the screen with her hand))* if we could draw a plane that, let's say, contains the plane *((first with a flat hand and then traces S on the screen with her index finger))*—that is parallel to the plane containing *S ((moves her flat hand and then points again to S))*—the intersection *((points to line b))*, let's say *((holds out her flat hand with palm facing upward))*, between the shifted plane *((moves her hand upward continuing to keep the palm facing upward))* toward the other line is a point; that is, if they are not *((flat hand))* parallel, the two lines among themselves *((points on the screen first to line S and then to line b))*, we would have a plane *((flat hand moving as if "slicing" the air))* that intersects *((points to line b))* one of the points of the line.
9	LT1:	Eh, but *((at the PC, moves the mouse cursor along S))* you say the plane that contains *S*, but there are infinite planes that contain *S*, so how do you choose it...? [LT2: Mh] wait *((brings closer the printed sheets related to the problems already solved but doesn't immediately read their content))*.
10	LT2:	I mean, we'd have to choose it based on... no, let's say *((points to the screen))* we choose it by taking a point from the line *((brings her hand closer and points to line b))*, but it seems silly to me *((moves her hand away from the screen and brings it to her chin))*... because obviously, by taking any point on the line, we have a different plane.

We assist here to a new perception of the improper point: between 5 and 9 it is no longer identified with a fixed line but with a *direction*. This shift illustrates the domestication of the eye occurring.

Moreover, in line 7, LT1 seems to act similarly to what was done in line 4, but the phrase she utters presents a substantial difference. Indeed, the case of projecting the points is quickly dismissed in 4, while in line 7, the two situations are related with an "if". LT1's consciousness shifts as she notices the impossibility of drawing a plane with only the condition of parallelism for a line because it's not unique. In line 8, LT2's coordination between the hand gestures and the words "plan" and "plan moved", materializes the possibility of perceiving the situation dynamically. Although the encounter with the cultural object is still partial and in process, the dynamism introduced is refined and clarified in the lines 9 and 10. In fact, responding to LT1's question (line 9), LT2 proposes choosing it "by taking a point from the line", while pointing on the screen to line *b* (10). But she also shows insecurity and after line 10 there is a 13-second silence, which is interrupted by LT1, who again repeats the words describing the type of action required to project a line from a point. From now on, we face a turning point of the activity. LT1 and LT2 then return to their work on previous tasks and problems. In Problem 1 they managed the action of joining an improper point with a proper one (that is conducting a line that passes through the proper point and has the direction indicated by the improper one). In Problem 2 they managed the action of joining an improper line with a proper point (that is conducting a plane that passes through the proper point and has the direction indicated by the improper line). LT1 speaks again:

11	LT1:	Earlier, we were joining a proper point with an improper line...
12	LT2:	While now we are joining... a
13	LT1:	A proper line and a line—and an improper point *((seems to correct herself))*... but if we take a point on a line and we have to join it to the point at infinity as we did here [...] so we make a point [...] *((constructs a point on the proper line))* let's say we fix this point [LT2: Okay], it doesn't matter how we chose it... so we have a proper point; no, here we don't have an improper line—we have an improper point *((had in her hands the printed page related to Problem 2: changes page and takes the one related to Problem 1))* means that we have to... we have an improper point... sorry, uh *((at the PC, scrolls with the mouse wheel to display the instructions of Task 2 and then returns to the GeoGebra screen))* yes, we have an improper point—a point at infinity.

In this passage, the line and the point at infinity are no longer identified: in 13 "a line" is immediately substituted by "a point at infinity" an expression that is retained in the sequel as well, with no longer feeling the need to identify it with a *precise* line. In 13 LT1 is perceiving line *b* in a new way: as *the set of its points*. From now on, the encounter with cultural-historical knowledge related to the operation of projection from an improper point begins to fully take place:

14	LT1:	But here we have the first exercise [LT2: Yes] *((returns again to the original text that begins Problem 1))* "join a proper point with a point at infinity" *((rereads while following the text with her finger))* means drawing the parallel line *((moves her hand, pointing in the air to her left. Then, she takes the mouse back in hand))*.
15	LT2:	Ok
16	LT1:	...So if I choose another... and then it comes out... *((on the GeoGebra screen, she begins to construct the line parallel to S that passes through C, a point on line b to be projected))*.
17	LT2:	It practically results in another line.

18	LT1:	It comes out....*((constructs the black line, see Figure 3a))* yes a pencil of parallel lines because if I now take another point *((constructs a new point she calls D on line b, see Figure 3b))* and....it would come out like this *((constructs the line parallel to S passing through the new point, see Figure 3c))* wait because I perform the magic *((activates the "show trace" command on the parallel line just constructed and begins to drag point D along line b, see Figure 3d))*...show trace…
19	LT2:	Ok
20	LT1:	And I do this *((continues to drag D along b with the trace active on the line, see Figure 3e))* eh yes, [LT2: and so we get] […] an improper pencil of lines […]

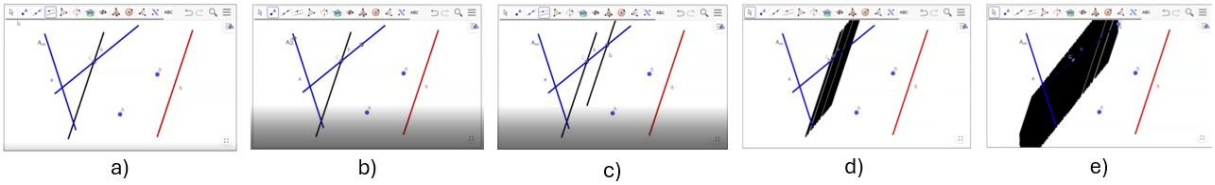

Figure 3: screenshot of lines 18-20, video here https://tinyurl.com/f52224

What happens between lines 14 and 20 is crucial and represents the condensation of everything that has occurred in all the previous activity segments. LT1 is aware that she can choose a point on line *b* to join it with the improper point serving as the projection centre (14); Moreover, perceiving *b* as the set of its points enables LT1 and LT2 to notice in 16 and 17 the possibility of applying the same procedure to another point on *b* generalizing to any other point in 18. Through LT1's interaction with GeoGebra's functionalities described between lines 18 and 20, the process of domesticating the eye becomes completed, and the cultural knowledge materialized by dragging point *D* with the trace active. In conclusion of Task 2, LT1 and LT2 produce a written answer that moves them to a sudden refinement in the semiotic resources used to describe what happens to the operation of projecting a proper line when considering an improper projection centre. We are witnessing a semiotic contraction, evidence of learning, which marks the end of the semiotic node under analysis.

Discussion and conclusion

Through the lens of TO, this study has illustrated how two undergraduate students engaged with the operation of projection from an improper centre in a synthetic approach to projective geometry. The GeoGebra-based activity not only facilitated the students' interaction with historical mathematical texts but also allowed them to actively construct and visualize complex concepts dynamically.

The research question under consideration is: when engaged in a GGBZ activity involving an excerpt from Castelnuovo's (1904) regarding the operation of projection from a point, how does the domestication of the eye develop if the centre is improper? The analysis of the episode shows the students' gradual domestication of the eye, wherein their perception of the improper point shifted from initially identifying it with a precise line, then conceiving it as a direction and finally as the common direction of a pencil of improper line (where we can choose the one we want). This shift occurs within a process of objectification that has been described analysing how the use of semiotic means of objectification develops in the social interaction between LT1 and LT2.

The insights gained from this case study suggest several directions for further research. First, expanding the sample to include a broader range of participants, searching for patterns and invariants. Moreover, it may be argued that GGBZ activity of a historical text on projective geometry could be chosen as an experimental activity to study how learning in this area of geometry develops. Finally, here we are considering only the classical synthetical approach to projective geometry, but it could be interesting to explore a GGBZ activity that includes also a connection with the more modern and analytical-algebraic approach (i.e. homogeneous coordinates).

In teaching geometry, the use of both physical and digital tools has been identified as useful ways to develop students' geometrical reasoning. To gain insight into the effective use of these tools for geometrical reasoning, in this paper we reviewed relevant theories in mathematics education. We considered several different theoretical ideas, such as instrumentation theory, the theory of semiotic mediation, geometrical reasoning, figural concepts, etc. By synthesising and combining these theoretical ideas, we provided examples of questions to critically examine task design and learning processes with both physical and digital tools in the context of geometric reasoning.

Keywords: Theories in mathematics education, task design, the use of physical and digital tools, geometrical reasoning

Introduction

In CERME13, we can observe that many papers reported on the effects and influence of the use of different tools, both physical and digital, in the teaching and learning of geometry, e.g. the use of 3D models and GeoGebra (Bímová, et al., 2023), the use of 3D pens (Palatnik, 2023), and so on. On the other hand, as described by Palatnik et al. (2023), the consensus of the CERME geometry WG members is that we still do not know much about how different tools can be combined, especially physical and digital tools, what learning can be achieved or designed, how learners interact with these different tools and what role teachers would play (see also Nemirovsky & Sinclair, 2020).

In this paper, we will address one of the themes identified in the CERME14 TGW04, namely the interplay between different tools and their effectiveness on students' learning. We focus on this topic as it was stated that "the intertwined use of physical and digital tools is a fruitful research area for exploring ways to enhance students' mathematical learning" (Komatsu and Fujita, 2024, p. 274). We take a theoretical approach as "a need for a more coherent understanding of theories from the community" was recognised in the CERME13 geometry working group (Palatnik, 2023, p. 3), and we will critically review some of the relevant theories related to tools in the teaching and learning of geometry.

The aim of this paper is to provide examples of questions to critically examine task design and learning processes with both physical and digital tools in the context of geometrical reasoning. We focus on the promotion of geometrical reasoning as this was suggested as one of the important tasks in geometry teaching (Jayathirtha, 2018). In particular, we explore our working research question "What questions can be considered to critically examine issues related to task design and learning processes with both physical and digital tools in the context of geometrical reasoning?"

What is a theory in mathematics education?

It is probably not possible to define 'what a theory is' in mathematics education. However, debates about theories have played an important role in mathematics education research, and many ideas have been discussed by many researchers (for more details see Komatsu and Fujita, 2024). For example, Mason & Waywood (1996) refer to the following functions of theories: explanatory ("how or why something happened"), descriptive ("providing a language to frame a way of seeing"), informative (informing "practice by sharpening or heightening sensitivity to notice and act in the future"), and predictive ("what will happen in similar situations by stating necessary or appropriate conditions") (pp. 1060–1). They also state that theory provides a language for formulating questions, specifies a methodology, delineates a coherent and consistent view of the objects of study/the nature and role of data collection and analysis, supports a means of validating findings, and formats the reporting of findings (pp.1061–2). Radford (2008) also identified theory as 'a way of producing understandings and courses of action based on' a system, a methodology and a set of paradigmatic research questions or schemata (p. 320).

In this paper, we focus on the theories related to use of both digital and physical tools in the teaching and learning of geometrical reasoning in order to the complexity of the use of tools and geometrical reasoning. Amongst different strategies to network different theories/theoretical ideas (Prediger et al., 2008), our main strategy is 'combining', i.e. combining various theoretical ideas related to the use of physical and digital tools in mathematics education in general, and geometrical reasoning. In what follows, we will first take some theoretical ideas in relation to the use of physical and digital tools, and then those related to geometrical reasoning. We then consider, by combining different theoretical ideas, examples of questions to critically examine task design and learning processes with the both physical and digital tools in the context of geometrical reasoning.

Theories related to the use of physical and digital tools

In this section, we focus on the use of both digital and physical tools for teaching and learning mathematics. In order to design tasks for students and consider learning processes, we need to consider how these tools can be combined or used effectively. Soury–Lavergne (2013; 2021) used the tool Pascaline to teach base–10 place value notation. She designed both tangible and digital versions of the tool and provided examples of how these tools can be used, considering the similarities and differences between these two tools. Bímová, et al. (2023) used both GeoGebra 3D and tangible models to support students' problem solving with 3D shapes. As a slightly different example, we can also consider the use of digital tools and pen and paper. For example, Komatsu and Jones (2020) investigated how students approached challenging proof problems in geometry through the interplay between digital (GeoGebra) and pen and paper. Although the use of these two tools may sound trivial, the interaction between these tools is not straightforward and careful design and intention was required to support students' mathematical thinking and reasoning.

According to Sinclaire et al. (2023), one of the major theories that have been used in the use of technology in mathematics education is the instrumental approach in didactics. This is rooted "in the work of Piaget and Vergnaud (for the concept of scheme), as well as Vygotsky (for the concepts of mediation, and the social aspects of the instrumentation)" (p. 394). The theory distinguishes between

'artefacts' and 'instruments', and the latter is "a mixed entity that pertains to both the subject and the artefact" (p. 394). The developmental process from artefacts to instruments is called 'instrumental genesis'. In this process, the bilateral relationship between the subject (e.g. learner) and the artefact (e.g. dynamic geometry software) is established. One is *instrumentalization* (from the subject to the artefact), which is described by Artigue (2002) as "it is directed towards the artefact, loading it progressively with potentialities, and eventually transforming it for specific uses" and *instrumentation* (from the artefact to the subject) as "leading to the development or appropriation of schemes of instrumented action which progressively take shape as techniques that permit an effective response to given tasks" (p. 250). This theory has been widely used and influential in mathematics education research. In particular, the focus of the study is centred on 'instrumental genesis', and it gives us a point of reflection as to why some technological tools might be less effective than expected (e.g. this is because the instrumental genesis did not happen), or the particular use of tools and behaviours of students so called action/utilisation schemes, e.g. students use the so–called dragging test to check whether the key properties of shapes constructed with a dynamic geometry software will be retained when one of the points on the shapes is dragged (Arzarello et al., 2002). More recently, Pittalis and Drijvers (2023) extended this idea to capture how utilization schemes can be used to examine students' interplay between embodied dragging and geometrical concepts with multi–touch tablet devices.

When considering the use of both digital and physical tools, the duo–artefacts framework proposed by Maschietto and Soury–Lavergne (2013, see also Soury–Lavergne, 2021) is useful. This idea was rooted in the instrumentation theory as well as didactic situations (Brousseau, 1997). Soury–Lavergne has designed and studied the Pascaline artefacts with two different forms, e.g. tangible and digital Pascaline. In considering the use of both tangible and digital Pascaline, Soury–Lavergne did not consider the instrumentation process separately, but a joint genesis, making explicit the continuity and discontinuity of these two artefacts. In particular, the notion of 'antagonism', "properties or functionalities of one artefact that are inefficient or even divergent from the other" (pp. 6–7), will play an important role in this framework, described as follows. In geometry, Voltolini (2018) used both a ruler/compass and an e–book with a dynamic geometry environment and found that the interaction between these tools in a carefully sequenced lesson developed a new concept of a triangle and a new way of using a compass, contributing to a rich understanding of geometric concepts among primary school students.

Another theoretical idea, the theory of semiotic mediation (TSM), integrates both teaching and learning with particular tools (Bartolini Bussi & Mariotti, 2008). This theory is rooted in Vygotsky as background theory, and concerned with how semiotic meanings emerge in learners through the use of certain tools, and how teachers can organise the learning environment to promote the development of personal meanings into mathematical meanings (Mariotti, 2012, pp. 168–9). In this theory, the notion of semiotic potential is used to consider how we can design a learning environment with artefacts, taking into account how the artefacts can be used by both students and teachers for effective semiotic mediation (ibid., p. 170) with the following three components, namely mathematical content, historical references and utilisation schemes (Bartolini Bussi & Mariotti, 2008; Maschietto, 2015). For example, in order to design and implement learning environments with certain tools, it is useful

to critically examine what mathematical content is represented and how it is mediated by the tools, how the tools were invented and developed historically (e.g., construction tools in dynamic geometry software are rooted in Euclid's *Elements*), and how students will use the tools to achieve given learning goals in their learning.

While instrumentation theory considers the process of instrumental genesis and the learner's scheme of use, TSM considers both students and teachers and how mathematical concepts might be mediated through the use of certain artefacts within communities (of course, instrumentation theory considers the importance of interventions, e.g. instrumental orchestrations). The a–priori analysis is also important to consider the semiotic potential of the tools.

Theories related to geometrical reasoning

In this section we shall focus on theories related to geometrical reasoning. Jones (1998) describes theoretical ideas as "As geometry evolves to encompass the understanding of diverse visual phenomena, it is important to be clear about what is meant by the geometrical reasoning necessary to solve mathematical problems involving visual phenomena, and how such reasoning develops" (p. 29) and listed the van Hiele model of thinking in geometry (e.g. van Hiele, 1986), the theory of figural concepts (Fischbein, 1993) and Duval's cognitive model of geometrical reasoning (Duval, 1998). Similarly, Sinclair et al. (2016) listed the following as 'Theories specifically about the teaching and learning of geometry', the van Hiele model, the theory of theory of figural concepts, theories of figural apprehension and dimensional deconstruction (i.e. Duval), and the theory of spaces for geometric work (Gómez–Chacón & Kuzniak, 2015).

Van Hiele's model has been widely discussed and used in the study of geometric reasoning. Briefly, the theory models the development of geometric reasoning as follows: Visual, Descriptive, Abstract/Relational/Informal Deduction, Formal Deduction and Rigour (van Hiele, 1986). For example, while students at the visual level reason about shapes and their properties according to their concrete examples or visual appearance, students at the abstract level begin to see relationships between shapes and make simple logical deductions.

The theory of figural concepts (Fischbein, 1993, p. 140) is also often referred to when considering the nature of geometric figures, i.e. that geometric figures have both visual and conceptual properties. This notion of figural concept is useful when considering students' geometrical reasoning, for example, how students use their visual or conceptual reasoning when attempting to classify quadrilaterals hierarchically (e.g. Fujita & Jones, 2007).

Duval considered there are at least three cognitive processes, visualisation, construction and reasoning (Duval, 1998). Duval's theory of figural apprehension identifies four types of apprehension: perceptual apprehension, sequential apprehension, discursive apprehension and operative apprehension. 'Apprehension' means "the act of understanding something, or the way that something is understood" (Cambridge Dictionary). These 'apprehensions' are useful to consider students' capabilities to solve various geometrical problems. For example, perceptual apprehension is related to the perception of elements of figures. The operative apprehension might be used by students to manipulate, extract or divide certain elements of the given shapes (which might be represented by diagrams), Michael–Chrysantho et al. (2024) describe, for example, "operative

apprehension becomes a starting point in order to investigate other configurations that can be obtained by visual operations" (p. 4). The sequential apprehension might be utilised when students describe how they construct certain geometrical shapes, e.g. constructing an equilateral triangle by using a ruler and compass, or dynamic geometry tools.

Task design and learning processes with the use of physical and digital tools for developing geometrical reasoning

In this section, we shall provide examples of questions to critically examine task design and learning processes with the both physical and digital tools in the context of geometrical reasoning. A theory can be used to consider language to formulate questions, to specify a methodology, to delineate a coherent and consistent view of the objects of study and role of data collection and analysis, to support a means for validating findings, and to format reporting of findings (Mason & Waywood, 1996; Radford, 2008). Due to the limited space of this paper, we will explore what 'language to formulate research questions' can be considered in terms of task design, combining different aspects and ideas from the theoretical ideas reviewed in the previous sections.

As an example, let us consider a problem how to find the centre of spinners with triangles and quadrilaterals using the case of equilateral triangle.

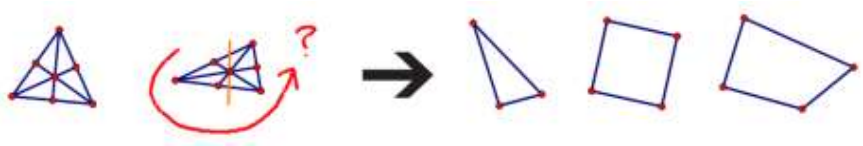

Figure 1: Triangle and Quadrilaterals spinners

Mathematically, a centre of gravity will be an ideal point for spinners and this could be a useful activity as some students may think that a centre of gravity does not exist if a triangle is not equilateral or quadrilateral, relying only on their visual perceptions. Providing a context (spinner) might also encourage students to understand the importance of the centre of gravity from a practical and theoretical perspective. Now suppose we want to design activities and a sequence of these activities to promote, for example, visual to more formal ways of thinking in geometry (van Hiele, 1986). Then, informed by the theoretical ideas reviewed in the previous sections, some questions can be critically explored, which are answers to our working research question as well as our conclusion of this paper.

Task design: when designing tasks from this problem context, we should examine first what semiotic potentials (Bartolini Bussi & Mariotti, 2008) can be considered in order to promote geometrical reasoning by using both physical and digital tools in this particular activities. Historical and cultural contexts might be important as spinners are known as traditional toys in Japan, even though this is not directly related to mathematics. When we consider the different tools to be used, we need to critically examine what 'antagonism' (Maschietto & Soury–Lavergne, 2013, Soury–Lavergne, 2021) between physical and digital tools might be used to promote their conceptual understanding of geometrical figures (Fischbein, 1993) or their geometrical reasoning (van Hiele, 1986). For example, it is possible to physically experiment with physical spinners, but not with digital tools. On the other hand, students can use digital tools to explore various possibilities of the points, and this might

provide some reasoning to explain why a particular point within triangles or quadrilaterals work well as a centre of gravity.

Learning processes: Defining and experimenting with a centre of gravity with/without a dynamic geometry environment could encourage students to use different sequential understandings (Duval, 1998). We can also examine students' use patterns, shaped by the instrumental genesis of the duo–artefact (Artigue, 2002; Soury–Lavergne, 2021), and how these patterns might be observed in their use of conjectures and related to their figural concepts (Fischbein, 1993). For example, some students might assume that an intersection of diagonals could be the centre of quadrilaterals from their visual perceptions (van Hiele, 1986), but dragging one of the vertices might provide opportunities to explore their reasoning further by considering the cases of triangles and the theoretical meaning of the centre of gravity (Figure 2).

Fostering understanding of inclusion relationships through mathematical events

Aehsan Haj-Yahya [1,2], Juhaina Awawdeh Shahbari[1] and Huda Shayeb[1]

[1] Al-Qasemi Academic College of Education, Baqa-El-Gharbia, Israel; aehsanhajyahya@gmail.com

[2] The Arab Academic Institute for Education, Israel

This study examined the impact of analysing mathematical events on prospective teachers' understanding of inclusion relationships among quadrilaterals. Initially, most participants struggled to identify these relationships, relying on prototype examples rather than shape definitions. After an intervention involving mathematical event analysis, participants showed significant improvement in recognising inclusion relationships, using geometrical definitions and critical attributes to explain their responses. This approach enhanced their ability to extend concept images to non-prototypical examples.

Keywords: Mathematical events, inclusion relationships, prototypes, critical attributes.

Introduction

Inclusion relationships among geometric shapes are fundamental to advanced mathematical thinking, as outlined in Van Hiele's (1958) model. At the third level of geometric understanding, mastery of these hierarchical connections is crucial. This comprehension serves as a gateway to higher-order reasoning, particularly in constructing geometric proofs. Without a solid grasp of inclusion relationships, students face significant barriers in progressing to more complex mathematical concepts and problem-solving techniques. Research consistently reveals widespread difficulties in comprehending hierarchical relationships among quadrilaterals. Okazaki and Fujita's (2007) cross-cultural study of Japanese students and Scottish teachers found shared challenges in categorising rectangles as parallelograms and squares as rectangles or rhombuses, with subtle differences between these two populations. Zeybek's (2018) study of pre-service math teachers in the United States revealed initial similar struggles, with improvement following targeted instruction, highlight the pervasive nature of these conceptual challenges across diverse groups.

Numerous studies have highlighted the significant impact of non-critical attributes in prototype examples on students' misidentification of inclusion relationships among geometric shapes (e.g., Okazaki & Fujita, 2007). These non-critical attributes, often characterised by strong visual elements, frequently override formal definitions in students' reasoning processes. The powerful influence of visual factors is exemplified in Haj-Yahya and Hershkowitz's (2013) unexpected finding that 10th-grade students performed better on verbal tasks than on visual ones when identifying inclusion relationships between squares. This counterintuitive result underscores the potent effect of visual cues on geometric reasoning. In a recent study, Haj-Yahya and Hershkowitz (2024) uncovered significant challenges in geometric concept formation among 11th-grade students. Their analysis revealed that many students excessively rely on prototypical examples, a tendency that severely impedes their ability to construct proofs related to the attributes of these concepts. This finding illuminates a

significant shortcoming in geometry education: students' limited ability to extrapolate from specific instances to overarching geometric principles.

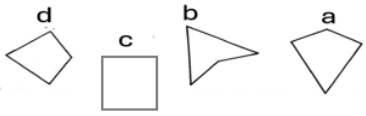
Various interventions, including dynamic geometry software and concept-mapping techniques, have been employed to enhance students' understanding of inclusion relationships in geometry (Haj-Yahya et al., 2024). While these approaches have shown promise, the specific impact of event analysis remains under-explored. Event analysis offers a unique opportunity to deepen students' understanding. By providing students with contextualised scenarios, event analysis can make learning more engaging and meaningful. Additionally, it can encourage students to actively apply their understanding and justify their reasoning, fostering a deeper level of comprehension. Drawing on prior research, the importance of mathematical defining in teacher professional development is well documented. Studies like Kobiela et al. (2023) and Climent et al. (2024) emphasize that developing teachers' knowledge of mathematical defining requires attention to both pedagogical and mathematical aspects, supporting teachers in understanding not only how to teach definitions but also the mathematical principles underlying definitional practices in geometry.

Mathematical events in educational research

Mathematical events are occurrences in mathematics classrooms that present pedagogical challenges requiring teacher intervention (Markovitz, 2003). According to Conner et al. (2011), a mathematical event can emerge from a student's question, an ambiguous textbook statement, or a teacher's comment. Such events create unique opportunities to explore concepts, make mathematical connections, and reinforce learners' developing understanding. These events have become valuable in teacher education and research (e.g., Tirosh et al., 2019). Engaging with mathematical events benefits teachers' professional development by enhancing their awareness of student thinking patterns and appropriate responses (Markovitz, 2003). Stockero et al. (2020) assert that these events provide opportunities to build upon students' mathematical thinking, facilitating a deeper understanding of critical concepts. Through analysing mathematical events from their classrooms, teachers reported deepening their mathematical understanding, as evidenced by their reflections. This process shows promise as an approach to expanding mathematics teaching expertise (Conner et al., 2011). The significance of mathematical events lies in the discourse they generate, fostering a learning community based on argumentative dialogue where participants articulate reasoning, listen actively, and engage constructively with peers' arguments (Toulmin, 2003). This study examines how prospective teachers analyse mathematical events to develop their understanding and justify the inclusion of relationships between quadrilaterals.

Methods

Research participants and context



This study involved 20 prospective teachers who are all the participants of a geometry-teaching course. The participants were pursuing their teaching certification for teaching in first and second grades at a teacher training college of the Arab community in Israel. This course serves as a second course in the mathematics education curriculum, alongside a calculus-teaching course designed for first and second graders. The course content was centered on four areas of geometric thinking:

properties of shapes, spatial relationships, transformations and symmetry, and visualization. The teaching and learning process throughout the course was grounded in discussions during mathematical events. The current research specifically focused on three sessions that emphasized inclusion relationships. The three events in the three sessions, highlighting various ways of thinking and addressing common errors in the selected in inclusion relationships. The mathematical events were developed based on literature and the researchers' experience in teaching geometry (see Figure 1) and were presented for all the class. One of the researchers conducted the course, she presented events that encouraged participants to promote understanding of inclusion relationships. Her role was to facilitate learning and motivate participants to independently promote their understanding while providing opportunities for them to explore methods of justification and engage in discussions. She employed a strategic questioning sequence that transformed students' reasoning from visual to analytical thinking, such as "How about examining which features...", "What else do you see about the diagonals?".

Data sources, procedures, and analyses

The data were collected from three sources. The main and first source was observations of class discussions, which were recorded on video and transcribed verbatim. The second and third were pre- and post-questionnaires, which included verbal and visual tasks related to inclusion relationships among quadrilaterals (e.g., Is a square a kite? Yes/No/Don't know. Explain your answer). The pre- and post-questionnaires were conducted within an interval of three months.

Teacher Samir presented the following definition of the kite to his students: "A quadrilateral with two distinct pairs of adjacent equal sides." Then, he showed the following shapes:

Jamil raised his hand and told the teacher that all the shapes are kites except for shape c.
Teacher: Why, Jamil?
Jamil: Because a kite must have two long sides and two short sides.
Teacher: But the definition of the kite is a quadrilateral with two distinct pairs of adjacent equal sides. Does shape c meet the definition?
Jamil: Yes.
Teacher: Can we call it a kite?
Jamil: This is a square, not a kite. This is a square with all sides equal. But in a kite, there is one pair of long sides and one pair of short sides.

Figure 1: The second mathematical event

Initial information was collected regarding participants' understanding through their responses to the pre-questionnaire, followed by participants' engagement in analysing mathematical events. Finally, the post-questionnaire was administered. The pre-questionnaire and post-questionnaire data were analyzed using thematic content analysis (Braun & Clarke, 2006). The researchers categorized the data based on categories provided by Haj-Yahya and Hershkowitz (2013) and additional categories that emerged during the analysis. The observations were analyzed in two stages. The first was based on Toulmin's (2003) argumentation model, beginning with creating an argument log, that based on

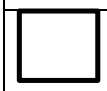
observing all discussions in the classroom and highlighting discussions whenever participants drew conclusions. These conclusions were marked, collected, and organised according to the components of the argument model: data, claim, warrant, backing, rebuttal, and qualifier.

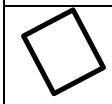
Findings

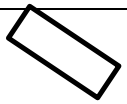
The findings reveal significant shifts in participants' understanding and identification of inclusion relationships among various shapes, particularly squares, rectangles, parallelograms, and kites. This emerged through both verbal and visual tasks administered before and after engagement with mathematical events. The results demonstrate marked improvements in participants' ability to recognize and justify inclusion relationships, moving from narrow, prototypical understandings to broader, more inclusive conceptualisations of geometric shapes. The following sections detail these changes, highlighting the specific improvements in participants' understanding of shape hierarchies and their explanatory abilities.

The findings reveal a significant shift in participants' understanding of inclusion relationships among shapes (see Table 1), moving from misidentification to correct identification. This change is evident in both the participants' responses and reasoning. Participants' judgments were initially based on non-critical attributes exclusive to prototypical examples. However, post-intervention, their reasoning reflects a more sophisticated understanding. Participants began to justify their responses based on formal definitions of the containing group, explicitly explain how one group is included within another, or demonstrate an understanding that the attributes of one shape are fully encompassed within the attributes of another shape.

Table 1: Examples from identification of inclusion relationships - the verbal tasks







Claim	pre		Post	
	Acceptance of the claim	Examples of justification	Acceptance of the claim	Examples of justification
The square is a rectangle.	4	A rectangle differs from a square because one pair of sides is longer than the other.	17	The attributes of a rectangle are included in the attributes of a square.
The rectangle is a parallelogram.	11	The rectangle has all angles equal to 90 degrees, but the parallelogram does not.	17	The rectangle has all the attributes of a parallelogram.
The square is a kite.	2	Kite sides are not of equal length.	14	A square is a kite with all sides of equal length.

We found significant improvements in participants' ability to identify non-prototypical examples such as squares as rectangles, parallelograms, or kites in the visual task, with substantial increases in correct identifications from pre-questionnaire to post-questionnaire. This trend of enhanced recognition extended to the identification of rectangles as parallelograms, mirroring the positive shifts observed in the verbal identification task and indicating a consistent improvement in participants' understanding of shape relationships across different tasks.

Table 2 shows that participants' identification of the square as a rectangle, parallelogram, or kite improved dramatically from the pre-questionnaire to the post-questionnaire. The same direction was observed regarding the identification of a rectangle as a parallelogram. This tendency was in the same

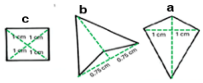
direction as in the visual identification task. Additionally, as seen in Table 2, the participants identified inclusion relationships that were not directly addressed to them through these mathematical events, particularly the inclusion relationship between a square and a parallelogram. The participants also recognised that while every square is a rectangle, the converse is not true.

Table 2: Identification of inclusion relationships - the visual tasks

The shape	Questionnaire	Identified as a square	Identified as a rectangle	Identified as a parallelogram	Identified as a kite
	Pre-questionnaire	20	7	3	0
	Post-questionnaire	20	20	18	19
	Pre-questionnaire	9	2	0	1
	Post-questionnaire	20	20	15	18
	Pre-questionnaire	2	10	7	0
	Post-questionnaire	0	20	19	0
	Pre-questionnaire	2	20	3	0
	Post-questionnaire	0	20	18	0

Identification of inclusion relationships through analysing mathematical events

The findings indicate that by analysing the mathematical events, participants developed their understanding according to the identification and justification of the inclusion relationship. Episode 1 describes the development of the discourse regarding inclusion relations between a square and a kite, especially regarding one of the common features: the main diagonal is perpendicular to the secondary diagonal and bisects it. [Due to space constraints, we choose only one episode, and without sequencing the order of speech turns]



Episode 1: One of the common features of kites and squares

1 Rima: I am sure that form a () is a kite, and b () is also a kite, but I am debating about the square () because its appearance is different.

3 Seaham: I want to draw a straight line on the board between all the parallel vertices, which are the diagonals. I will do it like this; it does not matter if it is out of shape. I want to show you this [Seaham drew the diagonals].

6 Maas: The diagonals are perpendicular to each other.
8 Participants: [drawing the diagonals and checking] Yes. All are perpendicular.
10 Participants: The diagonals are perpendicular in all three.
11 Lecturer: What does it mean that the diagonals are perpendicular?
12 Rima: They form a 90-degree angle.
13 Lecturer: Right, they form an angle of 90 degrees. What else do you see about the diagonals?

14	Dalia:	The diagonals bisect.
16	Dalia:	It means that one of the diagonals bisect the other into two equal lengths.
18	Participants:	The longer diagonal bisects the shorter one. 
19	Seaham:	But I have a question. The kite in the middle is not like the others. In all of them, I can clearly see the lengths of the diagonals. But in this kite, the longer diagonal is not bisected into two parts (even if the parts are not equal).
20	Dalia:	It doesn't matter. Actually, this is what they have in common.
22	Rima:	Since the two diagonals are equal in length, it follows that even after they intersect perpendicularly, all their segments are of equal length. I mean, both bisect each other.
24	Seaham:	The other shapes have diagonals of different lengths, and after the diagonals intersect perpendicularly, the segments are also of different lengths.
28	Sema:	Because originally, the square had equal sides.

During the discussion, two arguments were raised Arguments 1 and 2 below, which are presented in Figures 1 and 2. Regarding the inclusion relationship event about a square and a kite, a claim was made by Maas (see Figure 2).

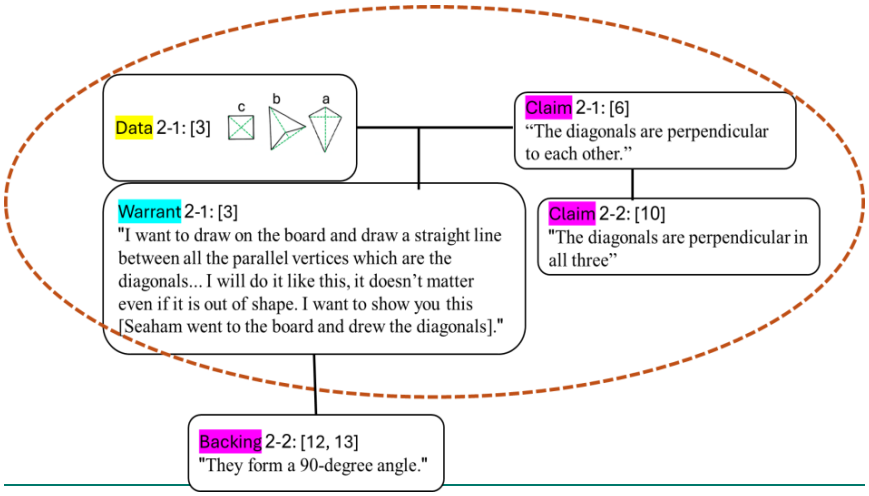


Figure 2: Argument 1- two diagonals are perpendicular to each other

Figure 2 illustrates a process by which the participants identified the critical feature of the perpendicularity of the diagonals in prototypical and non-prototypical kites. By presenting the data, examining it, and concluding that perpendicularity is a property common to the square and the kite, they concluded that it is an important property common to all these shapes.

Figure 3 demonstrates how the participants conclude that one diagonal bisects the other in both the square and the kite. Through the presentation of appropriate data and justifications, they come to the understanding that this is a common and critical feature for all shapes, including the square. Therefore, they conclude that the square has the kite properties. In lines 19 to 23, we see that the prospective teachers discussed what makes a square a special case of a kite, progressing in their understanding of the inclusion relationship between kites and squares. Despite the square being a non-prototypical, the common property that one diagonal bisects another is still present.

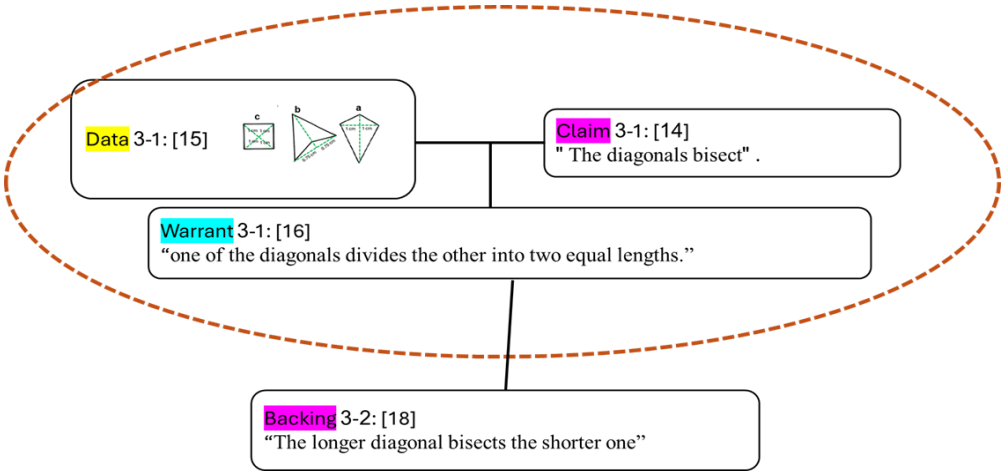

Figure 3: Argument 2- two diagonals, one bisects the other

Discussion

The objective of the current study was to examine how prospective teachers analyse mathematical events to develop their understanding and justify inclusion of relationships between quadrilaterals. The findings indicated that the discussion of mathematical events helped in revealing participants' reliance on non-critical attributes that are exclusive to prototypical examples. Moreover, the need to explain and support their claims led them to use formal definitions or critical attributes, which contributed to them seeing that certain shapes share attributes and belong to broader categories. For example, as presented in Episode 1, the discussion progressed from initial visual uncertainty to a systematic comparison of the properties of a kite and a square, leading participants to identify critical shared attributes and ultimately concluding that a square possesses the properties of a kite. The results that emerged in the current study align with previous studies (e.g., Stockero et al., 2020) that emphasise the effectiveness of engagement with analyses of mathematical events. The application of the Toulmin model effectively highlights how structured reasoning changed, such as presenting warrants and backing in the transition from initial misunderstanding to a more nuanced and accurate grasp of mathematical inclusion relationships between shapes.

Before the intervention, the vast majority of the participants struggled to identify the inclusion relationships between several quadrilaterals in both the visual tasks and verbal tasks. In addition, when they were asked to provide explanations for their responses, the majority of them tended to use the attributes of the prototype examples instead of the definitions of the shapes (see Table 1). In the post-questionnaire, the participants identified the inclusion relationships between the quadrilaterals correctly and provided explanations based on geometrical definitions of the concepts or critical attributes of these concepts. The intervention might have improved their comprehension of inclusion relationships and the development of concept images that are not limited to prototype examples (Haj-Yahya et al., 2024). However, the mathematical events focused on only three inclusion relationships, and not all of the study participants joined the discussion of the mathematical events. The findings revealed improvement in most participants' understanding of inclusion relationships.

Subjective theories of teacher trainers as to how to initiate argumentation and proving processes for geometry in lower secondary school classrooms

Stefan Halverscheid[1] and Marina Harland[2]

[1]Georg-August University Göttingen, Mathematisches Institut, Göttingen, Deutschland
stefan.halverscheid@mathematik.uni-goettingen.de

[2]Hainberg Gymnasium Göttingen, Germany

Two experienced mathematics teacher trainers are interviewed to assess the possibilities of proof activities in lower secondary schools that work in everyday school life. The subjective theories of the teacher trainers on how to make the classical proofs of the sum of angles in triangles and the Pythagorean theorem accessible to all are investigated within the research programme of individual curricula. It is striking that their choices of proof procedures are strongly influenced by heterogeneous classroom situations.

Keywords: Secondary school mathematics, Geometry, Classroom Techniques

Introduction

Starting from Styliandes & Styliandes (2007), many CERME activities have been related to argumentation and proof in the classroom (Mariotti et al. 2018) providing teachers and educators with a wide range of tools (Reid &Vargas 2017). In the field of geometry, proof is a classic, but its implementation in the classroom is complex. A broad approach of empirically based discoveries (Jahnke 2006), argumentation and more formal deductive reasoning eventually leads to proof activities (Herbst et al. 2016).

Proving and argumentation

The relationship between proof and argumentation is important for school mathematics (Pedemonte 2002) because proofs are considered difficult and have many facets (Hannah & Jahnke 1996). The important defining characteristics are the formal deductive aspect and the valid reasoning. This means that proof is a process of reasoning from the general to the specific, following strict logical rules, see for example Müller-Hill (2013).

The aim of proof is to deduce the truth of the proposition to be proved from other true propositions. In the process of proof, the freedom from contradiction of the individual propositions, which are linked together during the proof to form a chain of arguments, is central. One of the central aspects of a proof, which plays a particularly important role in the later consideration of proof and proving at school, is the aspect of formal rigour. Perfect rigour is unattainable and undesirable, since too long chains of reasoning would be incomprehensible to the human recipient (Jahnke et al. 2023).

The concept of argumentation, unlike the concept of proof, plays a role in different scientific disciplines and is defined differently in each of them. A widely used definition for 'argumentation' - beyond mathematics education - has been proposed by Van Eemeren et al. (2013) as a 'verbal and social activity of reason that aims to increase (or decrease) the acceptability of a controversial point

of view for the listener or reader, by presenting a constellation of propositions intended to justify (or refute) the point of view before a rational judge.'" (Van Eemeren et al., 2013, p.5)

Duval (1991) sees proof and argumentation as two different activities in the superordinate category of justification. According to him, argumentation follows implicit rules that arise from the structure of language and the utterances of speakers. An argument can occur as soon as arguments are exchanged with someone else, where an argument can be anything that can be used to justify or refute a claim. Proof, on the other hand, is seen as deductive reasoning, in which the operational status of the step is important in the steps of reasoning, rather than the content. In this distinction, argumentation is considered non-deductive (Reid and Knipping 2010). Douek (1999), in response to Duval (1991), presents a further position on the relationship between argumentation and proof. She describes that 'mathematical proof can be seen as a special case of argumentation' (Douek, 1999, p. 129). In this context, her understanding of argumentation, in line with Webster's dictionary, includes both the process of arguing in the form of a logically coherent but not necessarily deductive discourse, and the argumentative text produced by the process of arguing (Douek, 1999).

Beliefs about proof have already been investigated by Furinghetti and Morselli (2011), who conducted an interview study with ten Italian teachers about their beliefs about proof in mathematics education. In a detailed analysis of four teachers of upper secondary school with different specializations, three different main poles could be identified in the teachers' teaching practice regarding proof: the view of mathematics, the perception of the context and the type of attention paid to the students' needs and expectations (Furinghetti & Morselli, 2011).

Methodology of subjective theories: the framework of individual curricula

The idea of the project was to learn from experts in the field of teaching how they would introduce argumentation and evidence into their teaching. The subjective theories research paradigm helps to structure the analysis of the expert interviews. Groeben & Scheele's (2000) subjective theories research programme is a qualitative social psychology research programme concerned with the study of subjective theories and the methodology of collecting subjective theories. The construct of subjective theories arises from the idea of theorizing everyday actions and thus representing the causes and effects of human actions (Groeben & Scheele 2000).

In mathematics education, this has been successfully done in the context of individual teacher curricula, initially developed by Andreas Eichler for the field of stochastics and applied to other areas such as geometry, see (Eichler & Girnat 2011).

Methods

After graduating with a Master of Education degree, every teacher in Germany must attend a teacher training programme for about 18 months, culminating in a final examination to complete their professional qualification. The teacher trainers in these programmes regularly observe lessons in this induction programme and prepare the future teachers for their classroom management. The sample for this study consists of experienced teacher trainers in mathematics in Germany. They come from the same federal state, which ensures that they refer to the same core curriculum.

The study was conducted in three steps:

1. In the first part of the interviews, the interviewees´ beliefs on mathematics as well as on proofs (Styliandes & Styliandes 2007) were investigated.
2. A structured interview on the subjective theories of proving proceeded in four steps:
   2a) proving processes in classrooms,
   2b) proving processes in classrooms on topics on the theory of numbers,
   2c) proving processes in classrooms on angles in triangles,
   2d) proving processes in classroom on the Pythagorean Theorem.
3. After the analysis of subjective theories, a second interview was conducted with each of the respondent to validate the qualitative analysis on the subjective theories based on the first interview.

Study design

A case study is presented here with two participants (teacher trainers A and B) whose attitudes towards mathematical beliefs and proofs (steps 1 and 2a in the steps described in the Methodology section) are comparable. This allows us to focus on their work on geometry in steps 2c) and 2d).

According to the anthropological theory of didactics (Bosch et al. 2005), a mathematical organisation emerges as a response to some kind of question or problematic task and consists of technical, technological and theoretical elements. The idea of steps 2c) and 2d) is to somewhat fix the theoretical block (technologies (θ_c) and theories (Θ_d)) as well as the tasks (T_a) in the practical block somewhat fixed by giving typical schoolbook material for proofs on the sum of the interior angles of triangles and on the Pythagorean theorem. In particular, the theoretical block was well known. The respondents were then asked to describe the techniques (τb) that they would use when carrying out the tasks described in the book material.

Inductive category development (Mayring 2015) was used to work out the teacher trainers' means-end arguments which were subsequently structured in form of a means-end-argumentation (Scheele & Groeben 2000). These are presented for 2c) and 2d) in the form in which they were presented in the validation interviews (step 3).

Analysis of the geometric learning environments on proving

Teacher trainers A and B have similar beliefs about mathematics and proof. They both see geometry as a suitable branch of mathematics because of the structure and clarity of the arguments, of which proofs are an essential part. For the theorem of the sum of interior angles, both teachers illustrate their views by using angle theorems and angle detective tasks to find the necessary arguments.

According to teacher trainer A in 2c), a proof text already requires a higher level of argumentation from the students. In his approach, teacher trainer A provides for graded differentiation measures (see Figure 1), as it may be difficult for some students in a learning group to construct and understand the argument without further help. For strong students it is also possible to give them only the sketch from material I3 and ask them to draw possible conclusions from it.

				Argument chain
			If the students can build arguments for a proof	→ then they can build a chain of arguments
			Building arguments for a proof	
		If the students can retrieve information from sketches on angles in triangles	→ then they can build arguments to be used in a proof	
		Retrieving information on angles in triangles		
	If the students can work with sketches as informative figures	→ then the students can retrieve information from a sketch on angles in triangles		
	Sketches as informative figures			
If the students work at preparing tasks on angle2	→ then the students work with sketches as informative figures			
Preparing tasks for angles				

Figure 1: The means-end-argumentation of teacher trainer A for angles in a triangle

For teacher B, it is important to create a need in the students to prove the theorem of the sum of the interior angles of a triangle by creating a contradiction or a hypothesis in class. Methodically, the teacher has the pupils measure the sum of the interior angles of their own triangle, which they have brought as homework. Teacher B describes how different results are obtained again and again, even though the students are already familiar with the concept of measurement inaccuracy. However, the students always have different 'reasons' why they now get a different sum of internal angles with their triangle.

			Need for proof
		If a hypothesis is generated	→ then a need for proving emerges
		Generating a hypothesis	
	If there are different measuring results	→ then a hypothesis on the sum of inner angles of a triangle occurs	
	Different measuring results		
If the students measure the sum of inner angles	→ then they obtain different results		
Measuring the sum of inner angles in a triangle			

Figure 2: The means-end-argumentation of teacher trainer B for angles in a triangle

These 'reasons' might be that they have drawn a triangle with different proportions or that one triangle is larger than the other. This raises the question of how large the sum of the interior angles really is.

For the Pythagorean Theorem, both teachers prefer decomposition proofs as lines of argument because they make the process clear and understandable. With respect to 2d), according to teacher A, the choice of this proof depends very much on the group of learners and their level of argumentation and ability to deal with symbolic mathematics. Teacher A describes that the independent presentation of a decomposition proof, e.g. with sponge rubber triangles and squares, is very convincing for the students. Furthermore, heuristic strategies such as drawing auxiliary lines, cutting and reassembling are necessary for a decomposition proof. For teacher trainer A, the main aim of the decomposition proof is for the students to understand the principle of the proof and to connect the steps of the argument.

According to teacher trainer B, teachers often choose station learning for the Pythagorean Theorem to do justice to the historical ideas and connections to students' lives on the one hand, and to offer students different approaches to proving the Pythagorean Theorem on the other. Overall, however, the teacher will always emphasize the idea of breaking down the Pythagorean Theorem, as she considers this to be very accessible to the students, in line with the general ideas of simplicity and self-discovery. For example, B claims that students can first discover the statement of the theorem through the tile game.

		If the students perform a dissection proof on their own	→ then the dissection proof plays a persuasive role in the course
		dissection proof for the Pythagorean Theorem	
If the students learn about dissection arguments before	+ when the students can perform a disassembly with foam rubber independently and actively	→ then they can work out independently a dissection proof for the Pythagorean Theorem	
Dissection arguments	**Hands-on work with foam rubber**		

Figure 3: The means-end-argumentation of teacher trainer A for Pythagorean theorem

		Lower obstacle for a symbolic proof	**Understanding the idea of the proof is independent of the symbols**
	If the students work visually and haptically for the proof of the Pythagorean theorem	→ Then the gap to the symbolic level of the proof is not so big.	+ Then even the students understand the idea of the proof who fail at the symbolic level
	Visualising and haptic work	**dissection proof for the Pythagorean Theorem**	
If the students puzzle according to the proof steps on their own	→ then this is a visualising and haptic experience for the Pythagorean Theorem	→ then they can work out independently a dissection Pythagorean Theorem proof	
Material for a dissection proof of the Pythagorean Theorem			

Figure 4: The means-end-argumentation of teacher trainer B for Pythagorean theorem

However, the exploration through the tile game is not sufficient for the learning objectives as it is not a generalizable proof. Furthermore, B describes how the material is also very suitable for teaching because of the internal differentiation it contains.

Discussion

Teacher trainers A and B have similar beliefs about mathematics and proof. But they both share important concerns about the techniques used, which are not at the heart of the discussion about argumentation and proof activities. Although only A explicitly mentions the need for proof, B also pays a lot of attention to it. Similarly, both give a lot of thought to methods of dealing with heterogeneous classrooms in this setting. However, the teachers also set different priorities in the interviews. During the interview, Teacher A repeatedly refers to the meta-level of teaching and the meta-communication with the pupils about the process. At this meta level, Teacher A justifies her planning decisions and involves the pupils in the implementation at the meta level. Teacher B, on the other hand, focused more on the content of the respective sentences in the interview and talked mainly about how to raise the need for evidence, the methodological implementation of the approach and the role of visualization in this. This does not mean, however, that the teachers did not also agree with the other teacher's focus. Some of the validation interviews suggest this. In the original interviews, both teachers addressed the evidence puzzle as a method, but evaluated it differently.

From a methodological point of view, the restriction to the techniques used has not made the discussion very narrow. In previous research on individual curricula, curricular arguments were discussed on a longer scale than a teaching unit. On the contrary, the interviews are more related to classroom situations and the repertoire that teachers have. It will be difficult to conduct many of these interviews, given the particular expertise of teacher trainers, but since evidence is seen as so difficult to bring into the classroom, it might be fruitful to look at variations of evidence and argumentation tasks through the eyes of experts.

Fostering students' geometric and spatial reasoning in geometry using duo of digital and tangible artefacts

Liying Huang and Taro Fujita

University of Exeter, Graduate School of Education, the United Kingdom; lh870@exeter.ac.uk

This study aims to describe and analyse the development of learner's geometric reasoning and spatial skills in geometry teaching and learning with the multi duo of artefact framework in this paper. To achieve this goal, we used duo of digital and tangible tools (Virtual Reality, GeoGebra and traditional tangible artefacts) for design-based research based on our previous study's findings about the instructional design. The data was analysed from our pilot study of spatial geometry experimental learning activities undertaken by grade 7-10 Chinese students. We identified moments of shifts in their geometric reasoning and spatial skills when the students undertook 3D geometry problems with VR, GeoGebra and tangible artefacts. The analysis also showed that students' geometric reasoning levels are effectively improved by using multi duo artefacts.

Keywords: Multi duo of artefacts, Virtual Reality, GeoGebra, spatial skills, geometric reasoning

Introduction

The importance of students' geometric reasoning and spatial skills has been recognized in the teaching of geometry (Fujita et al., 2017), and these can be fostered using a dynamic geometry environment (Sinclair et al., 2016). According to Bímová, et al., (2023), they explored how the students work with the tangible and virtual 3D geometric models. In this context, we will introduce new tools to broaden how students' geometric reasoning and spatial skills can be developed and then help teachers with experienced support and guidance to help students deepen their geometric concepts and properties. The overall goal of this study is using both tangible objects and digital technologies artefact as tools of framework to analysis students' geometric reasoning and spatial skills through their actions and talk related to the task. In this paper, the main research questions we explore are: 'How do students use Virtual Reality, GeoGebra and tangible objects to solve spatial geometry problems?', and 'What geometric reasoning and spatial skills are developed?'

Theoretical Framework

Our theoretical framework focuses on how and what supports a relationship consisting of three major parts: geometric reasoning, spatial skills and the multi duo of digital and tangible artefacts, theorising how the duo of artefacts and geometric reasoning support each other, and how the duo of artefact and spatial skills support each other, and how geometric thinking and spatial skills help students to solve geometric problems. We'll go into more detail about this framework in the coming sub-sections.

The learning of geometric reasoning

Van Hiele's (1986) model proposes that geometric thinking postulates five levels of geometric thinking which are labelled recognition, analysis, logical ordering, formal deduction, and rigor. These different levels of geometric reasoning can be observed. How well shapes are learned and reasoned about depends on the degree of connectedness between the representations used to express the

concept and the individual's ability to visualize and communicate the relationships. For example, Seah and Horne (2019) adapted the development of geometric reasoning moves through levels: (1) visual reasoning, (2) descriptive reasoning, (3) analytic reasoning, (4) relational-inferential property-based reasoning, leading to (Table 1). We identified moments of shifts in their geometric reasoning through qualitative data analysis when they used multi duo of artefacts.

Table 1 Geometric learning progression

Level 1: Visual reasoning 1.1 Pre-recognition. 1.2 Recognition.
Level 2: Descriptive reasoning 2.1 Visual informal reasoning. 2.2 Informal and insufficient formal reasoning
Level 3: Analytic reasoning 3.1 Reasoning about shapes based on properties. However, their definitions are not minimal.
Level 4: Relational-inferential property-based reasoning 4.1 Empirical relations. 4.2 Analysis. 4.3 Logical inference. 4.4 Hierarchical shape classification based on logical inference.

The learning of spatial skills

Lohman (1988) supported the existence of three major spatial skill factors: spatial visualization (Vz), spatial orientation (SO, e.g. remaining unconfused by changing orientations) and spatial relations (SR, e.g. mentally rotating objects). Lohman emphasized that Vz is defined by difficult spatial tasks that require a sequence of transformations of a spatial representation and more complex stimuli. In addition to these general spatial skills, domain-specific knowledge in geometry also plays a kind of coordinating role between spatial visualization and property-based spatial analytic reasoning (Fujita et al., 2020). In this study, we adopted the model of Fujita's which enables us to identify what makes problem-solving successful/unsuccessful in their use of spatial reasoning skills. For example, suppose a student is asked to determine a quadrilateral in a virtual 3D space in VR. To complete this task, the student might use spatial visualization skills to determine its shape and size before s/he started construction, and in the problem-solving process, the learner needs spatial orientation that is not confused by changing perspectives and spatial relation for the length of each side or face to be successful. This illustrates the role of spatial skills in problem-solving.

Duo of artefacts in math education

In this paper, we use both tangible objects and digital technologies to support students' development of geometric reasoning and spatial skills described above. While relationships between tangible and digital artefacts are not straightforward, Soury-Lavergne (2021) extended the instrumentation theory and proposed a duo of artefacts framework. In our study, one of digital artefacts, VR is used to break down the barriers of two-dimensional screen vision and allows students to enter the three-dimensional world of geometry more visually and intimately, while GeoGebra, the other digital tool, allows students to construct and drag the geometric shapes with the changing immediately. So that, a

complementarity between two artefacts may be required to make necessary the system of teaching and learning. However, the example of VR meso-operation and micro-operation in a tangible artefact shows that there must be antagonisms between the two artefacts. Tangible artefacts, our third tool, play an irreplaceable role in this because students and teachers are familied to it and understand it, and results show that students acquire specific ways of reasoning through it. As tangible artefacts, we prepared geometric models of shapes providing opportunities for students to manipulate physically which might be difficult to do with digital tools.

Three artefacts in the learning environment, chosen by the students themselves, our studies in this paper show that two of them are enough to solve the mathematical problems in the study. So, here we will use duo1: Virtual Reality and tangible artefact, duo2: Virtual Reality and GeoGebra, duo3: tangible artefact and GeoGebra, to help address the limitations in cognitive resources that may be imposed by only one artefact.

Models of the spatial skills and geometric reasoning development in multi duo of artefact instructional design

In this paper we use VR and GeoGebra as the digital tools, and a combination of traditional geometry tangible tools to support students' geometrical reasoning and spatial skills. Fig.1 is the framework that we used to summarize the relationships between the use of technological tools, geometric reasoning and spatial skills. In this figure, learners will activate any of the duo artefacts when solving problems, indicated by the support arrows: geometric reasoning and spatial skills are supported through their functional integration into the learners' use of the duo artefacts, and the actions feedback to the duo artefacts serve as functional extensions of the operations to assist in the completion of further tasks. Spatial skills and geometric reasoning in mathematical activities steadily support each other to operationalize the understanding of geometric concepts and properties. Based on this theoretical framework, we have examined each of the geometric reasoning and spatial skills processes of change and artefact manipulation and functioning and found that these different artefacts are gradually integrated into students' use schemes and support their reasoning.

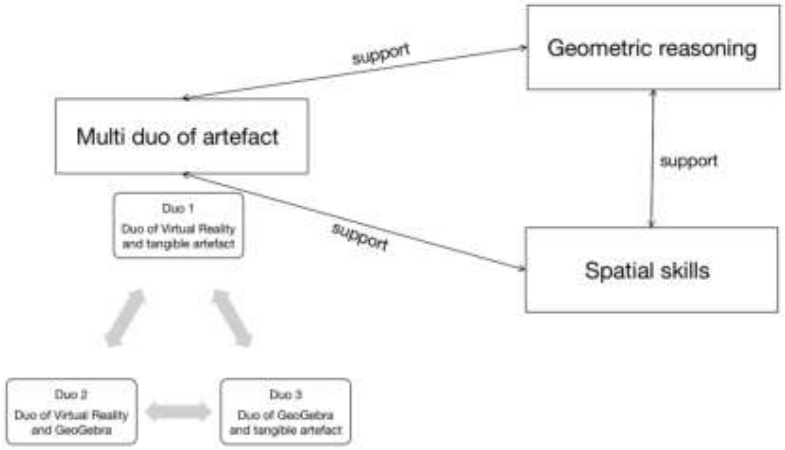

Figure 1 Framework for developing geometric reasoning and spatial skills through multi duo of artefact

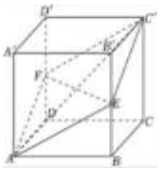
Methodology

Study design and data collection



In this paper, we use both tangible objects and digital technologies to support students' development of geometric reasoning and spatial skills. The main research questions we explore are: ‘How do students use these tools to solve spatial geometry problems?’ and ‘What geometric reasoning and spatial skills are developed?’ In March - May 2024, we piloted teaching sessions in Shenzhen, China with groups of grade 7-10 learners (both groups of 4 and groups of 2). These learners had prior knowledge of 3D geometric shapes but lacked experience in undertaking geometric problems based on the properties of parallel, perpendicular, and curved faces and edges, as well as combined or planar cut sections.

The table 2 summarises the task used. We specifically designed warm-up problems as our participants had limited experience of using VR and GeoGebra, for example, please create a cube through Virtual Reality. They can get familiarise themselves with artefacts through warm-up problems in 15 minutes. Then they were asked to solve the task in table 2 through the tools just introduced to them.

Table 2: Summary of the main task of episode

The length of a cube is 2, E and F are the midpoints of the edge, the area of a quadrilateral AEC'F is ( ) .

A. $2\sqrt{6}$ B. $2\sqrt{5}$ C.5 D.$4\sqrt{2}$

Data were collected through face-to-face geometry class activities with students' work and their communication and encompassed two types of evaluations: class observation data, pre-test/post-test data (10 questions) and delayed test 4 weeks after the post-test in this paper.

Data – observation data and participants

To examine the development of the student’s reasoning with the use of VR, GeoGebra and tangible objects (plastic cube models), we have analysed data collected total of 15 sessions with 18 participants, and in this paper, we selected the following two episodes based on students’ thinking-shifting reactions observed through qualitative analysis, as well as the development of geometrical and spatial reasoning during the processes, and their experience with correct/incorrect answers. Table 3 summarises the tool chosen by the two episodes and the participants.

Table 3 Analysed participants' duo of artefacts in this study

Episode	Duo of artefact	Participants
1	Duo3: duo of GeoGebra and Tangible Artefact	Group 1: Sara, Joyce
2	Duo1: duo of Virtual Reality and Tangible Artefact	Group 2: Benjamin, William, Mia, Isabella

Data analysis procedure

After conducting initial examinations of the video data, we selected specific episodes, resulting in a total of 15 sessions with 18 participants. We selected these two episodes because they were closely linked to the use of multi duo of artefacts for understanding, analysing, and solving spatial geometry problems, as well as for interacting with new tools, shifting in their reasoning, and overcoming difficulties in the spatial geometry problem-solving processes. Two of the episodes are presented here as examples of the research.

To begin, we identified the developmental moments of the learners, as evidenced by Seah and Horne (2019). We identified segments of students' interactions geometric reasoning process with four levels: visual reasoning, descriptive reasoning, analytical reasoning, and relational-inferential property-based reasoning. For the spatial skills, we examined the types of spatial ability: spatial visualization (Vz), spatial orientation (SO) and spatial relations (SR), used in their processes of forming their task solutions. To identify such shifting in their reasoning, we conducted a detailed qualitative analysis to determine patterns in problem-solving processes. This analysis serves as evidence to answer both research questions.

Results

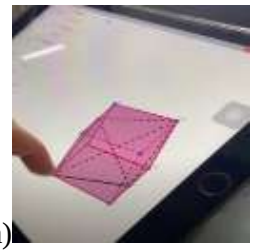
Pre and post-test results

The overall observation of 18 students the average pre-test score is 4.18 out of a total score of 10. The scope of the pre- and post-test tasks is the same type as the classroom tasks, and students are scored for each step during the writing process. Some of the students have demonstrated relatively a low level of understanding of 3D geometry. Upon reviewing the pretest data presented in this research, it is evident that students have had varying learning experiences regarding basic knowledge of 3D shapes. This includes understanding cubes, combination or planar cut sections, three views, and how to represent 3D shapes in 2D and 3D. After experiencing the designed sessions, the students' post-test scores reached 8.71, which is a significant improvement. The students then took the delayed test after 4 weeks, and their mean score was 8.00, suggesting that the students' performance remained relatively stable.

Development of geometric reasoning and spatial skills with multi-duo artefacts

For the chosen episode, we did qualitative analysis by using the transcript examined, the task required three main spatial skills and level 2-3 (Seah and Horne 2019) geometric reasoning, finding the area of the quadrilateral. To calculate the area of a quadrilateral, the key lies in identifying the type of quadrilateral. Therefore, after giving the students the question, the teacher asked the students to answer the name of the quadrilateral first. Most students answered as a square, but the quadrilateral is a rhombus.

During the session, for example, in episode one, in Figure 2 a), Sara (S1) and Joyce (S2) activated duo of GeoGebra and cube models in Figure 2b). The analysis suggests that they started from level 1 Visual reasoning in geometric reasoning, but GeoGebra supported spatial visualization and spatial relation skills, and finally reached level 4 Relational-inferential property-based reasoning in geometric reasoning through tangible artefacts.



a)  b)  c)  d) 

Figure 2 Artefacts - GeoGebra: a), Tangible Artefact: b), VR: c) and d)

At first, they chose to observe through GeoGebra (digital artefact). They both started by using visual control in decision-making. Sara used visual reasoning stating “kind of like” to indicate that it was a rhombus. Joyce eliminated the cube's appearance and only observed the quadrilateral in the middle, which she thought was a square. In the task, this implies that their geometric reasoning only stayed at the level of pre/recognition of shapes based on physical attributes.

Then, by dragging and converting the size and angle, spatial visualization skill seemed to be supported, combining concept and vision, and even if there was insufficient formal reasoning, they decided that it could be square based on some properties, e.g. four equal sides. It is this that they pointed their fingers at the screen and started to acquire formal language to describe properties, suggesting that this might have allowed them to reach Level 2: descriptive reasoning. At this point they discovered the key point that “The two diagonals are not equal!” with GeoGebra. And then Joyce explained that one of the diagonals was not equal to the other one with GeoGebra, meaning that the shape could be a rhombus. As they were using the fact ‘four equal sides’ and ‘different diagonals’, their reasoning was developing towards analytic reasoning (Level 3). Finally, to explain their thinking process more clearly, they chose the second artefact, i.e. tangible objects. They used diagrams as well e.g. Figure 2 b) and logic to confirm the quadrilateral was a rhombus by explicitly referring to critical attributes of the shape (two diagonals and four equal sides) and expressed their reasoning sufficiency. Because of this use of critical attributes of the rhombus, their reasoning might be seen as relational-inferential property-based reasoning, supported by their spatial orientation skill using tangible objects.

In the second episode, Benjamin (S9), William (S10), Mia (S11) and Isabella (S12) worked with the duo of tangible artefact and Virtual Reality. They started from level 1 in geometric reasoning, started using spatial visualisation and spatial orientation skills with the help of Virtual Reality, and finally reached level 3 in geometric reasoning with tangible objects, using spatial relations skills in the process.

At first, only Isabella said that the quadrilateral was a rhombus, but the other pupils thought it was a square. Because of this disagreement, they used VR, but their reasoning was still visually based, even though they were demonstrating their spatial visualisation skills. Then, by discussing the difference between a rhombus and a square, they proposed that "a square must have four equal angles", but not in this quadrilateral through the perspective-altered VR with the spatial orientation skill. This reasoning based on shape attributes might have supported them to move on to the second level: descriptive reasoning with visual informal reasoning, as they focused on the angels of the

quadrilateral. The other students in the group looked through the pad screen of the VR, taking turns to enter the VR world and observed. Then, "It doesn't have any right angles," William said, looking at the 3D VR shapes. "There are acute and obtuse angles," Benjamin noted. Their observation was further examined as they continued to investigate the diagonals of the quadrilateral using tangible artifacts. They examined the differences in the sizes of the four angles, stating in a quadrilateral where two angles are obtuse and two are acute. They concluded that a quadrilateral with four equal sides, two obtuse angles, and two acute angles is a rhombus. The use of digital and tangible objects creates a new way of thinking about abstract geometric concepts with properties, bringing them not only into the theoretical but also into the reasoning process, indicating that they started demonstrating the third level of analytical reasoning.

Discussion and conclusion

In this paper, we use both tangible objects and digital technologies to investigate the development of students' geometric reasoning and spatial skills. The central questions addressed in this paper are what geometric reasoning and spatial skills are being developed, and how students are using these tools to solve spatial geometry problems. In answering these questions, we identified three activated duos of artefacts. They are duo1: Virtual Reality and tangible artefact, duo2: Virtual Reality and GeoGebra, duo3: Tangible artefact and GeoGebra. When faced with a problem, learners activate different pairs of artefacts and use a new tool to generate a new way of thinking about abstract geometric concepts and properties. The complementarity between the pairs of artefacts may be necessary for the use of each, e.g. a rhombus suggested by GeoGebra, but the tangible objects were needed to confirm that the shape was a rhombus. Thus, by visualising and simulating geometric figures to understand them concretely, the presence of redundancy can contribute to the establishment of continuity. This theoretical framework was tested in data analysis. By improving the level of geometric reasoning (Seah and Horne, 2019), it supports the use of spatial skills (Lohman, 1988) and helps control the perception and recognition of geometric figures. For example, by training their spatial skills in VR, students were able to find the angles of four and form a new spatial understanding of 3D graphics. It allows students to move from informal to formal geometric reasoning through the second object, e.g. tangible objects (Fujita et al., 2020). The study illustrates the potential of the duo of artefacts for learners to improve their geometric reasoning and train their spatial skills. Through our tested theoretical framework, geometric reasoning, spatial skills and three tools' applications interact to help learners improve their understanding of geometry while supporting learners' geometric cognitive construction, improvement and training.

The multi duo of artefact theoretical framework can help mathematics teachers to better understand the role of students' reasoning and actions in grasping important geometric concepts and properties. Because of our findings: judging from the pre- and post-tests, the students' test scores improved significantly. Through our qualitative analysis research, this is because students' geometric and spatial reasoning are effectively improved by 2-3 levels (Seah and Horne, 2019) while active duo of tangible and digital tools. As a recommendation for practice, our findings may encourage curriculum designers to design activities that activate duo of artefact experiences in mathematics spatial problem.

Working with student solutions to understand geometry knowledge of preservice teachers

Daniela Kovalčíková[1] and Ingrid Semanišinová[1]

[1]Pavol Jozef Šafárik University, Faculty of Science, Institute of Mathematics, Košice, Slovakia;
daniela.kovalcikova@student.upjs.sk

The aim of this paper is to analyse and understand the geometry knowledge of preservice secondary school teachers (PSTs). Fifteen PSTs who had completed a university geometry course focusing on synthetic geometry participated in the research. PSTs were asked to solve a multiple strategies geometry problem and then to examine and report on the students' thinking based on seven samples of student work provided. The results showed that a number of teachers valued the solution using measurement, which was somewhat imprecise, more than the deductive solution, which contained a numerical error. They had difficulty working with the diagram in the solution, which is not an accurate visual representation of the situation; and they did not consider it important to argue and justify the solution, especially if the student had followed the expected solution strategy.

Keywords: Geometry knowledge, preservice teacher, problem solving, students' solutions.

Introduction

Geometry is a very important area of school mathematics that is essential for students' success not only in geometry but also in other areas of mathematics, because many of the ideas of geometry and properties of geometric objects are used throughout mathematics (e.g. transformations of functions, vector space, etc.). Unfortunately, the results of Slovak students in national tests and the results of various competitions for gifted students show that the situation in this area is getting worse. In the research literature we can find several reasons why students struggle with geometry, e.g. Steele (2013, p. 245-246) mentions that an important reason is the limited knowledge of teachers in geometry. Aware of this reason, we have changed the geometry training of preservice teachers (PSTs) at our university over the past three years by adding more geometry courses.

Based on our experience and recent literature, we know that a major challenge in university teacher education is the appropriate design of basic mathematics courses, including geometry, for PSTs. We believe that the link between the content of mathematics courses and future mathematics teaching needs to be clearer and more explicit. This problem has been mentioned by several researchers (e.g. Winsløw & Grønbæk, 2014; Eichler & Isaev, 2023). It is known as the double discontinuity. We focus on the second discontinuity – the transition from academic study (as a PST) to working as a mathematics teacher (Klein, 2016).

To analyse the current mathematics teacher specialised knowledge of geometry, we propose the activity for PSTs with the multiple strategies problem with selected students' solutions to this problem. The aim of the activity was to identify possible discontinuities in the current geometry knowledge of PSTs. The research question formulated within this aim is: How do preservice teachers approach students' solutions that vary in level of argumentation, use different solution methods, and include both correct and incorrect results?

Theoretical Background

There is a consensus among researchers that problem solving should be a key activity in mathematics education. These ideas were among the first to be emphasised almost 80 years ago by George Pólya in his famous book How to Solve It (1945). On the other hand, problem-oriented learning requires the teachers to have a deep understanding of the foundations of mathematics and to be adept at solving mathematical problems (Ronau et al., 2015) in order to deal with both predictable and unpredictable situations, as their students may generate and explore unexpected conjectures about familiar objects.

Several researchers also suggest using problem solving to investigate and better understand teachers' professional competencies (Felmer et al., 2019). The use of open-ended mathematical tasks, as characterised by Klein & Leikin (2020), should enable PSTs to bridge the gap between the mathematics they have learned and the mathematics they will teach (Zaslavsky & Leikin, 2004). In addition, the use of students' solutions provides PSTs with opportunities to experience alternative ways of learning (challenging) mathematics and possibly foster their sensitivity to students and their ability to assess students' mathematical understanding (van Dooren et al., 2002). Research, such as that by Gal (2011), suggests that although PSTs' mathematical knowledge is usually adequate, they often struggle with analysing and understanding students' solutions and identifying their difficulties.

We decided to use the Mathematics teacher's specialised knowledge model (MTSK, Carrillo et al., 2018) to analyse the mobilised specialised knowledge of PSTs. We chose this knowledge model because it focuses on understanding teachers' knowledge rather than assessing it (Carrillo et al., 2018). The MTSK model includes the domain of Mathematical Knowledge and the domain of Pedagogical Content Knowledge. These two domains are composed of subdomains and categories, which allow a detailed distinction of aspects of mathematics teachers' knowledge. This paper focuses on one subdomain of Mathematical Knowledge – Knowledge of Topics (KoT) applied to pre-service teachers' approach to students' solutions that vary in solution strategies and level of reasoning.

Method

Participants and context

The research was conducted with 15 PSTs studying at the Pavol Jozef Šafárik University in Košice, Slovakia, as part of the course Seminar for Mathematics Club. The course is designed for PSTs who will be teachers in lower and upper secondary schools (usually students from 10 to 18 years old). It is recommended for PSTs in the 3rd year of the bachelor's programme. The class consisted of six 2nd year bachelor PSTs (3 male and 3 female) and nine 3rd year bachelor PSTs (1 male and 8 female). The PSTs had completed all the basic mathematics courses from the first year (Mathematical Analysis and Algebra). As for geometry, which is the subject of our research, all PSTs had completed Geometry I (knowledge of classical Euclidean geometry including the axiomatic system) and Geometry II (knowledge of synthetic stereometry – positional and metric properties). Geometry III (dealing with analytic geometry in n-dimensional space) and Geometry IV (dealing with quadratic surfaces and congruent and similar representations) had only been taken by 3rd year bachelor PSTs.

Research instrument

The research instrument consisted of two parts. The first part was a geometry problem from the Slovak Mathematical Olympiad competition for 14-year-old students, presented in Figure 1.

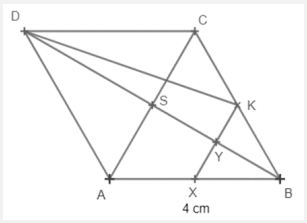
> *In a rhombus ABCD with a side length of 4 cm and a diagonal AC of length 4 cm, the point K is the centre of the side BC. Next, points L and M are constructed, which together with points D and K form the square KLMD. Calculate the area of the square KLMD.*

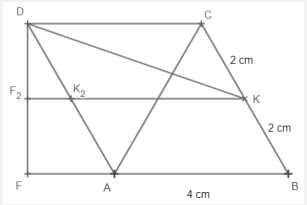
Figure 1: Geometry problem

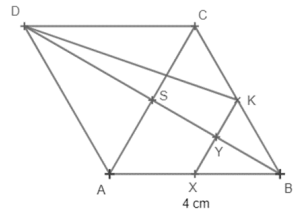
The second part consisted of 7 student solutions to the same problem. In order to select different student solutions for the research instrument, we analysed the solutions of 70 students who participated in the competition. 22 students used a correct solution strategy, 19 students used an incorrect solution strategy, 20 students used the strategy "draw and measure" and 9 students had no solution. We assigned each student's solution to a group with the same solution strategy according to the identified auxiliary elements they chose to solve the problem (see Table 1, 2nd column). Then we selected one or two solutions from each group based on the level of reasoning (Jones, 1998) and the correctness or incorrectness of the problem-solving outcomes. This is in line with the methodology used by Palatnik & Dreyfus (2019). The more detailed description of the chosen solutions is in Table 1. Moreover, each of the 7 selected students identified the sub-goal of the problem, find the length of the line segment DK. All correct strategies used the Pythagorean Theorem at least once.

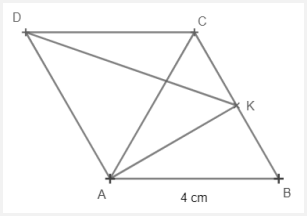
Data collection

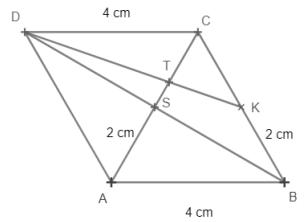
Firstly, the PSTs were asked to solve the problem (see Figure 1) themselves during the seminar. They were given 20 minutes to do so. Those who found a solution were asked to look for other solution strategies. We collected written solutions to the problem for further analysis.











Secondly, the PSTs were given a homework assignment with 7 student solutions to the problem. They were asked with analysing and providing a written report on the students' reasoning based on selected examples of their work. In addition, they were asked to rank the solutions from the best to the worst.

Results

PSTs' solution to the problem

For the qualitative analysis of the PSTs' solutions to the geometry problem we used the same method as for the students' solutions. 4 PSTs used the same solution strategy as Emma (marked as S_E in the 2nd column of Table 1), 2 of them used the same solution strategy as Christian (S_C) and 1 PST used the strategy that is only appropriate for high school students (S_H). For more details, look at the last row of Table 2. The rest of the PSTs did not solve the problem during the seminar. Regarding the PSTs' solution process, we observed that at the beginning of the problem solving, each PST sketched a prototypical image (see Tall & Vinner, 1981) of the rhombus in which the diagonal AC is longer than BD. In comparison with the solutions of the 7 selected students, the PSTs had difficulties in identifying the sub-goal of the problem (only to determine the length of the line segment DK). This was confirmed by the PSTs' questions about the position of the square KLDM ("it is not clear in which half-plane it lies").

Table 1: Description of selected students' solutions

Student	Strategy explanation	Visualisation of identified auxiliary elements	Authors' comment to student's solution
Adam	**Strategy S_{AD}** - Properties of the midsegment of a triangle - Properties of the diagonals of a rhombus - 2x use the Pythagorean Theorem		The solution is without drawing a picture. It is well justified, except for the explanation of the labelling of the two points used. The result is correct.
Boris	**Strategy S_{BG}** - The result is obtained by measuring the length of the segment KD.	No auxiliary elements	This solution begins by observing some invariant properties. The result is obtained by drawing and measuring. The incorrect result is obtained when Boris squares the measured number.
Christian	**Strategy S_C** - Draw the height of the rhombus - Identify similar triangles - Use the Pythagorean Theorem		The solution contains the statement that the height of the equilateral triangle is 7/8 of the triangle's side, which is probably approximation of the true value ($\sqrt{3}/2$). Some of the statements used were not clearly explained. The incorrect result is due to rounding during calculations.
Daniel	**Strategy S_{AD}** - Same strategy as Adam		Some of the used statements are not clearly explained in the solution. The result is correct numerical expression with irrational numbers, which is not calculated.
Emma	**Strategy S_E** - Calculate angles in triangles AKC and AKD - 2x use the Pythagorean Theorem		The most effective solution. It is almost without any argumentation, explanation of why the properties and relations used are valid. The result is correct.
Franklin	Strategy S_F - Properties of the diagonals of a parallelogram. - Properties of the median of an equilateral triangle - 2x use the Pythagorean Theorem		The picture in the solution is not an accurate visual representation of the situation. For the student, it is a diagram that has the desired properties, although it looks different. Used statements are well explained. A numerical expression containing an irrational number is calculated incorrectly in the last step.
George	**Strategy S_{BG}** Same strategy as Boris	No auxiliary elements	The problem is solved as a construction problem with the construction procedure written down exactly. The result is obtained by precise measurement the segment KD and squaring it.

PSTs' evaluation of students' solutions

As explained above, the PSTs were asked to rank the students' solutions from best to worst and to write at least two sentences to evaluate them. Table 2 gives an overview of how the PSTs ranked the students' solutions.

Table 2: Preservice teachers ranking of the students' solutions

Pre-service teacher (year of study) Ranking of students	1 (3)	2 (3)	3 (2)	4 (2)	5 (3)	6 (3)	7 (2)	8 (3)	9 (2)	10 (3)	11 (2)	12 (2)	13 (3)	14 (3)	15 (3)
1.	E	D	E	D	D	E	E	D	A	E	A	D	E	E	E
2.	D	F	D	F	F	G	A	E	D	D	D	A	D	A	A
3.	A	G	B	A	B	A	D	F	E	F	E	E	G	D	D
4.	F	B	A	E	G	B	C	A	B	A	B	G	F	G	C
5.	C	A	G	C	A	D	F	C	G	G	G	B	C	C	F
6.	G	C	C	B	E	C	B	B	C	B	C	C	A	F	B
7.	B	E	F	G	C	F	G	G	F	C	F	F	B	B	G
PST's solution strategy	0	0	0	S_C	0	S_E	0	0	S_E	S_H	S_E	S_C	0	0	S_E

In the qualitative analysis of the PSTs' comments, we observed whether they distinguished between students' intuitive and deductive reasoning, similar to the methodology used by Jones (1998). Examples from the PSTs' reports on students' thinking, which help us to analyse and understand the thinking of the PSTs in our sample, are presented in Table 3. According to the analysis, we could observe the following:

- Only the solutions of Emma, Daniel and Adam occur in the first place. Emma's solution was effective, written clearly and transparently with a large, colorful picture. The PSTs in her case mostly tolerated the lack of argumentation, perhaps because most of them used the same solution strategy or started solving the problem in a similar way. As for Daniel and Adam, they had the same solution strategy. The solutions given were easy for the PSTs to follow, even though none of the PSTs used it in solving the problem. Both solutions were written in such a way that the steps followed each other logically. We believe that the primary criterion for ranking the solutions was the PST's understanding of the solution itself, or the clarity and structure of the notation.
- For the same reason, in this case misunderstanding, the solutions of Christian and Franklin appeared in the last place next to the measurement solutions. We believe that in the case of Christian's solution, understanding the solution was complicated by the non-standard approximation of the irrational number, which most PSTs identified as incorrect, as well as the lack of clarity in the notation and insufficient justification of the procedure. In Franklin's case, following the solution was complicated by a picture that incorrectly captured the metric relationships between points, but was schematically correct. In addition, Franklin made a numerical error in the last step of the solution, and his result was the furthest from the correct result, which may have influenced the PSTs.
- Two thirds of the students ranked the solutions by measurement (marked in red in Table 2) before at least one of the deductive solutions. They were surprised by this constructive approach to the problem. They often described it as nice and considered it one of the

appropriate strategies for solving such a problem. PSTs tended to tolerate imprecision in measurement. The tolerance for numerical errors in calculations was lower.

Table 3: Preservice teachers report on the solution

Student	PSTs report on the solution
Adam	PST 1 – *I'm missing a picture in the solution. Even if the picture wasn't already there, it would need more comment, e.g. where did we get point S from, etc.*
	PST 8 – *The solution is cluttered and difficult to read.*
Boris	PST 4 – *However, the graphical method above is also a possible way of solving the problem, but it is not completely accurate and using this method would not satisfy the conditions formulated in the text of the problem.*
	PST 6 – *The only error is in the result, because he wrongly squared 5.2, just a numerical error.*
Daniel	PST 6 – *Nice and clear notation. The result is in a confusing expression, it needs to be calculated.*
Emma	PST 2 – *You didn't include an explanation of why the triangles are right-angled and a description of your sketch. How did you determine the angles?*
	PST 6 – *Very nice and clear sketch. Emma has probably come up with the quickest and most elegant solution.*
	PST 10 – *Very nice idea and simple solution to the task. However, there is no comment on the solution of the problem.*
Franklin	PST 8 – *The information used in the solution is nicely outlined in the diagram. What we are starting from is well named and sequentially written down and explained.*
	PST 12 – *There was a fundamental error in this solution, because the rhombus is not drawn correctly. Everything else is based on this error, so the result is also far from reality.*
George	PST 2 – *I like the style/approach of the problem and the mention of the second way of drawing the KLMD square. There is an error in the labelling of the circle k_1 in the construction procedure.*

Discussion and Conclusion

In this study, we were especially interested in how PSTs addressed students' solutions with both correct and incorrect results and with used different solution methods. According to Table 2 and Table 3 we can observe the following:

More than half of the PSTs chose Emma's solution as the best. Her solution has a clear and large colour picture, and important points, segments and angles used are labelled. On the other hand, there is almost no reasoning, no explanation of why the properties and relations used are valid. In the case of other solutions using a less common strategy, teachers sometimes criticised the lack of justification, but in Emma's case most of them did not mind (see PST 6 report in Table 3). This raises the question. Are PSTs aware of the need for justification and reasoning, or do they consider it necessary only to facilitate their understanding of the solution?

As mentioned above, 5 PSTs rated Franklin's solution as the worst. We think there are 3 possible reasons for such a bad evaluation of Franklin's solution: (1) His picture is not an accurate visual representation of the situation but the diagram that has the desired properties, although it looks different. (2) The used method of solution was rare (only 2 students out of 70 used it and no PST). (3) Compared to other solutions, the result is the most different from the correct result. On the other hand, some PSTs appreciated Franklin's solution (see Table 2 and Table 3, PST 8 report).

Our findings on the ranking of Boris and George's solutions also indicated that many PSTs in this study did not see the difference between solutions using measurement and those using deductive reasoning (see PST 2 report in Table 3). Although none of the PSTs attempted to solve the problem using measurement, many of them ranked the solution with a result close to the expected result, albeit obtained by measurement, higher than the correct deductive reasoning. This begs the question. Do the PSTs understand that measurement is an estimation process and that only calculation based on correct deductive reasoning leads to an accurate result?

When working with the selected student solutions, most PSTs showed an ability to understand different student solution strategies. Although no one used a solution strategy like Adam and Daniel in the first part of the activity, the PSTs understood this solution strategy and evaluated the students positively despite the missing picture (Adam's solution) and despite the inappropriate expression with irrational numbers and small deficits in reasoning (Daniel's solution). These results suggest that the proposed activity with students' solutions can help mobilise KoT (Knowledge of Topics) in PSTs, especially in the case of our activity: finding the subgoal of the problem, the different ways of representing the problem, the connections between the different elements of the triangle (midpoint, midline, etc.).

The results of our research showed the challenges we must face in the professional development of PSTs during the last two years of their university studies. They show that PSTs did not apply in practice some of the mathematical knowledge they had to demonstrate during their geometry training, indicating a second discontinuity in the transition from training to practice. We believe that one way to overcome this is to include teacher-oriented tasks, as suggested by several studies (e.g., Eichler & Isaev, 2023). We also believe that the inclusion of open-ended mathematical tasks, such as multiple strategy tasks, multiple outcome tasks and investigative tasks, as suggested by Klein & Leikin (2020) in geometry preparation, could help to overcome some of the identified problems. Of course, more research is needed in this area.

Geometry to be taught in Taiwanese and Japanese junior high schools

Takeshi Miyakawa[1] and Yi-Wen Su[2]

[1]Waseda University, Tokyo, Japan; tmiyakawa@waseda.jp

[2]University of Taipei, Taiwan

The aim of this paper is to advance understanding of the geometry curriculum and the arguments that support such a curriculum through an international comparative study of geometry to be taught in Taiwan and Japan. While these countries share a similar educational culture, the geometry curriculum in junior high school is organised in a very different way. Adopting the perspectives proposed by the Anthropological Theory of the Didactic, we analyse curricular documents to shed light on the differences in the mathematical organisation of geometry to be taught and try to identify the arguments (conditions and constraints) that shape such organisation.

Keywords: international comparative study, geometry curriculum, textbook analysis.

Introduction

Geometry is a domain that traditionally occupies an important place in secondary mathematics in any country. Looking at the history of geometry education, the geometry knowledge supposed to be taught at schools, especially secondary schools, is not stable because of some educational reforms or events: for example, in East Asian countries, such as Japan, the reception of Western mathematics, including Euclidean geometry in the 19th century revolutionised geometry teaching, pushing aside traditional mathematics (*wasan*) (Ueno, 2012); New Math movement has led to the downfall of Euclidean geometry; the dynamic geometry software (DGS) changed classroom activities.

Today, geometry curriculum seems to be diversified according to country or region throughout the world. In Japanese junior high school, students learn traditional quasi-axiomatic Euclidean geometry where the proof and congruent triangles play an important role, while this is not the case in some other countries (Miyakawa, 2017). The different arguments could be advanced to justify such a curriculum. For example, some tensions can be identified in such arguments: teaching between mathematical proof (or reasoning) and problem solving (or tools for human activities) (Jones & Fujita, 2013); between intuitive geometry and deductive geometry (Jones, 1998).

In this context, we started working on an international comparative study of the geometry curriculum in Taiwan and Japan. While these two countries have traditionally had a close relationship in terms of culture and distance, junior high school geometry curriculum is organised in a very different way today. It will be interesting to see what geometry is being taught and what kinds of arguments are being developed to teach such geometry. It is expected that this study will provide insights into the discussion of geometry curriculum reform in the future.

The aim of this paper is therefore to present preliminary findings from our comparative study of Taiwan and Japan, focusing on the organisation of the geometry curriculum and the arguments underpinning its structure.

Theoretical perspectives

This study adopts perspectives proposed by *the Anthropological Theory of the Didactic* (ATD; Chevallard, 2019), especially to formulate our research questions. Within this framework, we first consider that the nature of mathematical knowledge differs according to the *institution*. The notion of institution here should be understood in a broader sense, including 'any created reality of which people can be members' (Chevallard & Bosch, 2019, p. xxxi). Second, we consider that what is taught at school originates in other institutions, and the following process of didactic transposition is often considered: scholarly knowledge ↔ knowledge to be taught ↔ taught knowledge ↔ learnt knowledge (Chevallard & Bosch, 2020). In our case, the institutions considered are Taiwanese junior high schools and Japanese ones, in which geometry, a body of mathematical knowledge to be taught, is organised in a different way. Third, we consider that the mechanism of producing such differences is governed by the system of *conditions* and *constraints* prevailing in the institution: conditions supporting the life of a piece of mathematical knowledge and constraints hindering it. These conditions and constraints, called *ecology*, shape the mathematical organisation. Different arguments advanced for geometry teaching imply part of the ecology of school geometry. From these perspectives, the research questions can be formulated as follows:

- What are the mathematical organisations of geometry to be taught in Taiwanese and Japanese junior high schools? How are they organised, and how do they differ from each other?
- Why such mathematical organisations? What conditions and constraints shape them?

Contexts and data

Taiwan and Japan share a similar educational system. In both countries, prior to university, the school system consists of six years of elementary school, three years of junior high school, and three years of senior high school. The ministry of education publishes national curricula which are revised almost every ten years. Mathematics textbooks are published by private publishers and should be approved by the ministry. Their influence in the classroom teaching is significant, because the use of textbooks is required by law (e.g., Article 51 of the Ordinance for Enforcement of *the School Education Act* for Japan) to assure the quality education in any part of the country.

In this study, we analyse curricular documents that determines the geometry to be taught in Taiwanese and Japanese junior high schools: the mathematics textbooks for three years of middle school and the official documents published by the ministry. The textbook series we chose are the one published by Keirinkan publisher for Japan (2021) and the one published by Kang-Hsuan publisher for Taiwan (2023), both of which are the major textbooks series in each country. The official documents we used are *The Guides of the Course of Study for Mathematics* (MEXT, 2017) for Japan and *The Curriculum Guidelines of the 12-Year Basic Education in the Domain of Mathematics* (TME, 2018) for Taiwan.

Method of analysis

While ATD provides some analytical tools such as *the praxeology* and *the scale of levels of didactic codeterminacy* (Chevallard, 2019), we explore, as a preliminary analysis, the curricular documents without explicit tools but broadly aligning with the three types of analysis—horizontal, vertical, and contextual—proposed by Charalambous et al. (2010). The analysis comprises three steps.

The first step involves identifying horizontally the overall organisation of the geometric content as presented in the textbooks. We examined the chapters and sections dedicated to geometry across the three years of junior high school, as well as the proportion of pages devoted to geometry.

The second step investigates vertically how specific concepts are addressed in the textbooks—namely, proof and the Pythagorean theorem. These concepts were chosen because proof plays a pivotal role in geometry learning, while the Pythagorean theorem has been an iconic theorem in geometry since the time of Euclid. This step allows us to elucidate the *habitat* (place or address) and *niche* (role or function) of each concept to be taught in each country, as defined by Chevallard (1994). Together, these two steps address the first research question concerning the organisation of geometry content.

The third step explores the arguments (conditions and constraints) underpinning the organisation of geometry in each country. Specifically, we examine curricular documents to identify key aspects of geometry teaching that are frequently emphasised as supporting arguments without relying on a specific analytical tool. The results of this step, which are discussed in the final section, help to clarify the contextual or cultural factors that contribute to answering the second research question.

Results

Organisations of the geometry in junior high schools

The overall organisation of the geometry to be taught in Taiwan and Japan is presented in Tables 1 and 2. The number of pages in a chapter or section is given in brackets. Each grade in Taiwan has two volumes (two numbers are given under the grade). One may find from these numbers that geometry in Taiwan is mostly concentrated in the second semester of Grades 8 and 9, that is, later in the middle school, while it is distributed almost equally throughout three years in Japan.

Table 1: Geometry content in Taiwanese textbooks

Grade	Chapter	Section
7 (215) (215)	2-6 Geometry in life (30)	1. Perpendicular, line symmetry, and three-view drawings
8 (219) (223)	1-2 Square root and Pythagorean theorem	3. Pythagorean theorem (18)
	2-3 Basic properties of triangles (90)	1. Interior and exterior angles of triangle and polygon 2. Construction by straightedge and compass 3. Congruence of triangles 4. Properties of perpendicular bisector and angle bisector 5. Relationship between sides and angles of triangle
	2-4 Parallel lines and quadrilateral (54)	1. Parallel lines 2. Parallelogram 3. Properties of special quadrilaterals
9 (179) (123)	1-1 Similar figures	2. Proportional line segments (18) 3. Expanding, contracting, and similarity (24) 4. The application of similar triangles (18)
	1-2 Circle (48)	1. Relationships among points, straight lines, and circles 2. Relationships among angles at the centre, angles at the circumference, and the arc
	1-3 Geometry and proof (48)	1. Proof and reasoning 2. The circumcentre, incentre, and centroid of a triangle
	2-3 3-dimensional graphics in life (30)	1. Lines, planes, and shapes in 3D space

Table 2: Geometry contents in Japanese textbooks

Grade	Chapter	Section
7 (263)	5 Plane figures (32)	1. Straight lines and figures 2. Movement and geometric construction 3. Circles and sectors
	6 Spatial figures (36)	1. Solids and spatial figures 2. Volume and surface area of solid figures
8 (205)	4 Investigating figures (30)	1. Parallelism and congruence 2. Proof
	5 Properties of figures and proofs (34)	1. Triangles 2. Quadrilaterals
9 (237)	5 Figures and similarity (40)	1. Figures and similarity 2. Parallel lines and ratios 3. Measurement of similar figures 4. Application of similarity
	6 Properties of circles (20)	1. Inscribed angle theorem and central angles 2. Application of the circle properties
	7 Pythagorean theorem (22)	1. Relationship between sides in right triangle 2. Application of Pythagorean theorem

The geometry content of textbooks from the two countries appears to be very similar: triangles, parallel lines, parallelograms, congruence, similar figures, circles, proofs, the Pythagorean theorem, and so on. In principle, the content of Japanese textbooks is fully covered by Taiwanese textbooks. There are a few topics taught in Taiwan that are not included in Japan (e.g., trigonometric ratios). One notable difference lies in the positions of some mathematical topics, particularly the Pythagorean theorem and proofs. In Taiwan, the Pythagorean theorem is introduced in the first semester of Grade 8 at an earlier stage of geometry learning, whereas in Japan, it is taught as the final chapter of Grade 9. Furthermore, proofs are introduced earlier in Japan than in Taiwan. We explore these topics in detail, focusing on how they are presented and treated in the textbooks of both countries.

Pythagorean theorem

As mentioned above, the Pythagorean theorem is introduced at different stages within the geometry curricula of Japan and Taiwan. This difference implies a difference of the geometry system to be taught in each country.

The position in Japanese curriculum aligns with the axiomatic system of geometry presented in Euclid's *Elements Vol. 1*, where the Pythagorean theorem and its converse are addressed towards the end (Propositions 47 and 48). In the Japanese textbook, the *quasi-axiomatic* system is supposed in geometry (Miyakawa, 2017): beginning from Grade 8, fundamental properties such as parallelism and triangle congruence are introduced; following the introduction of proof, the geometric properties are proved one by one, constructing an edifice of geometry. The Pythagorean theorem and its converse are introduced and proven in the final section of the geometry content (Ch. 7 of Grade 9).

In contrast, the Pythagorean theorem is introduced in Taiwan in the first volume of Grade 8 textbooks, which are arranged in the same chapter as square roots, at the earlier stage of geometry learning. One reason for this organisation can be found in the teachers' guide of textbooks called *Lesson Preparation Book* (Hung, 2022): 'since Pythagorean theorem is often used in future geometry topics, teachers must confirm students' understanding of Pythagorean theorem and should require students

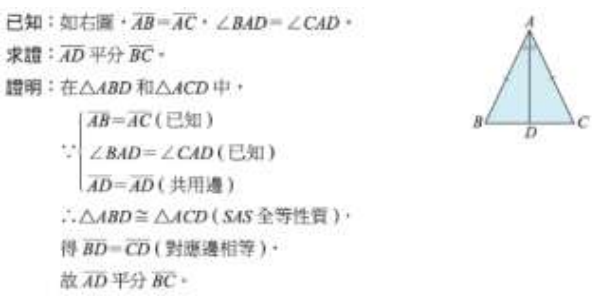
to memorise this theorem' (p. 94). The importance of this theorem for solving mathematical problems lets students to learn earlier. In fact, students are asked to apply this theorem to solve mathematical problems in subsequent chapters, including the areas of geometry and algebra. In addition, the introductory activity in the Taiwanese textbook is to find the relationship between the areas of the squares on each side of a right triangle. The theorem is then derived from an algebraic calculation of the area by placing four identical right triangles. The converse of the theorem is introduced later in the second volume of Grade 8 (Ch. 3, Sec. 5) after learning triangle congruency, and justified by the congruence of two triangles. At this stage, the proof has not yet been introduced in the textbook.

Proof and proving

In Japan, the notion of proof (証明 in Japanese) is officially introduced in Grade 8 as 'a means to show that a proposition is always true' (MEXT, 2017, p. 113). This is the main function of the proof explicitly claimed in an official document. As mentioned above, after introducing some fundamental properties in Grade 8, new statements are proven one by one, even those which have already been introduced in elementary school (e.g., the properties of triangles, parallelograms). Proof plays a role in reconstructing a geometry system axiomatically (while the term *axiom* is not introduced). In the textbook, proof is introduced in Grade 8 as 'Deriving a conclusion from hypotheses, based on something that is already accepted as true, is called proof' (Okamoto et al., 2021, Vol. 2, p. 115). An example of a proof from a textbook is presented in Figure 1. This is a proof for the base angle theorem, which is formulated in the textbook as 'The two base angles of an isosceles triangle are equal' (p. 127).

Proof: By drawing a bisector of ∠A, let D an intersection with BC. In △ABD and △ACD,
because AD is a bisector of ∠A,
∠BAD = ∠CAD ····· (1)
By the hypothesis,
AB = AC ····· (2)
And, because AD is common,
AD = AD ····· (3)
From (1), (2), and (3), because two pairs of sides and the angle in-between are equal,
△ABD ≅ △ACD
Because in the congruent figures the corresponding angles are equal,
∠B = ∠C

Figure 1: Proof in Japanese Gr. 8 textbook (Okamoto et al., 2021, Vol. 2, p. 126) and its translation



In Taiwan, the notion of proof (證明 in Chinese) is officially introduced in Grade 9 at a point when the junior high school geometry has been almost taught (see Table 1). Unlike the Japanese case, the proof is *not* for constructing a geometry system. However, the lack of proof does not mean that there is no justification for the introduction of theorems. For example, the property of a perpendicular bisector is justified, as shown in Figure 2 in the Grade 8 textbook. At this point, the term 'explanation' is used instead of proof; that is, explanation (not necessarily proof) plays the role of justifying that a proposition is true. The reasons are given in parentheses.

Like the diagram on the right, when line L is a perpendicular bisector of $\overline{AB}$, if C is an arbitrary point on line L, then is $\overline{CA}$ equal to $\overline{CB}$, or not?
Explanation: In △CAD and △CBD,
$\overline{AD}$ = $\overline{BD}$ (L is a perpendicular bisector of $\overline{AB}$)
∵ ∠CDA = ∠CDB = 90° (L is a perpendicular bisector of $\overline{AB}$)
$\overline{CD}$ = $\overline{CD}$ (common side)
∴ △CAD ≅ △CBD (SAS congruency property),
Hence, $\overline{CA}$ = $\overline{CB}$ (corresponding sides are equal).

Figure 2: Explanation in Taiwanese Grade 8 textbook (Hung, 2023, Vol. 4, p. 141) and translation

Proof is introduced in the chapter of "Geometry and Proof" in Grade 9, as "The process of deriving a 'conclusion to prove' from 'known conditions' or 'confirmed properties' is called proof" (Hung, 2023, Vol. 5, p. 135). In this textbook, the term 'proof process' is used for the process from 'known conditions' to 'conclusion to prove' in contrast to the term 'analysis process' for the inverse process of analysing how to prove from 'conclusion to prove' to 'known conditions'. These terms correspond to Pappus' terms 'analysis' and 'synthesis'. An example of the proof process is presented in Figure 3. This proof is very similar to the explanation given in Grade 8 (see Figure 2). The part 'proof' is written almost in the same form as the explanation. The 'known' and properties are given in parentheses. However, a difference is that the proof in Grade 9 consists of three parts, 'known', 'prove', and 'proof'. The students' activity with respect to the proof also differs. In Grade 9, students need to be able to fully express the proof process, while in Grade 8, students are required to be able to write down the reasons for some steps of the geometric reasoning (NAER, 2024). The proof is considered not only a product written in a specific form but also an activity comprising analysis and synthesis.

Known: As in the diagram on the right, $\overline{AB}$ = $\overline{AC}$, ∠BAD = ∠CAD.
Prove: $\overline{AD}$ bisects $\overline{BC}$.
Proof: In △ABD and △ACD,
$\overline{AB}$ = $\overline{AC}$ (known)
∵ ∠BAD = ∠CAD (known)
$\overline{AD}$ = $\overline{AD}$ (common side)
∴ △ABD ≅ △ACD (SAS congruency property)
We get $\overline{BD}$ = $\overline{CD}$ (corresponding sides are equal)
Hence, $\overline{AD}$ bisects $\overline{BC}$.

Figure 3: Proof in Taiwanese Grade 9 textbook (Hung, 2023, Vol. 5, p. 135) and its translation

A comparison of the Japanese and Taiwanese proofs shows that both use a specific geometrical object (e.g., triangle ABC) and step by step derives a new statement on this object from known statements using known properties. In both cases, the deductive structure of propositional logic is shown. However, a specific structure of proof process (known-prove-proof) is required in the Taiwanese textbook. According to this textbook, this is 'a commonly used writing methods of geometric proofs' (p. 134). Both proofs use many symbols. The Taiwanese proof adopts a more formalised language without ordinary sentences. Although the Japanese proof is less formalised, the sentences used in it are far from the ordinary texts that one may read aloud.

Discussion and conclusions

The mathematical organisation of geometry to be taught was different between Taiwan and Japan. The Pythagorean theorem and proof are positioned in different places within the geometry curriculum and play distinct roles. Examining the curricular documents from the two countries implies some arguments or conditions underpinning the organisation of geometry to be taught in each context. We identified five aspects that may be considered as arguments in the geometry curricula of different countries. Those are one of the key results highlighted by our comparative study, the significance of which should be further explored in future research.

The five aspects include *theory/system*, *reasoning/proving*, *problem solving*, *modelling/application*, and *culture/history*, some of which have been mentioned in different ways in previous studies (González & Herbst, 2006; Fujita & Jones, 2014; Herbst et al., 2017). We consider that the organisation of geometry to be taught is shaped according to the importance placed on each aspect in the curriculum, as illustrated in Figure 4, which provides a preliminary overview of to what extent each aspect is addressed. First, *the theoretical aspects* were considered differently between Taiwan and Japan. *The quasi-axiomatic system* of geometry is an object of teaching in the Japanese curriculum. Second, *reasoning and proving* were also considered in a different manner. Although the term 'proof' is not used, most of the new properties or theorems introduced are accompanied by justification in Taiwan, without requiring students to write down formally. Third, *solving mathematical problems* is an aspect highlighted in the Taiwanese curricular document. The Pythagorean theorem plays an important role in later problem-solving activities. This was a reason for introducing it earlier. The fourth and fifth aspects, *the modelling or the application of mathematics in everyday life* and *the culture or history of mathematics*, are not as explicit in the results of the previous section but are often found in the textbooks and curricular documents. Regarding the Pythagorean theorem, the textbooks of both countries similarly refer to the history of mathematics in its introduction and emphasise the application of the theorem for everyday life and for mathematics (e.g., finding the hight, area, distance, etc.). Furthermore, the Taiwanese official document explicitly mentions the fifth aspect as follows: 'The history of mathematics can help us understand the differences regarding how different cultures during different eras have influenced different developments in mathematics' (TME, 2018, p. 1).

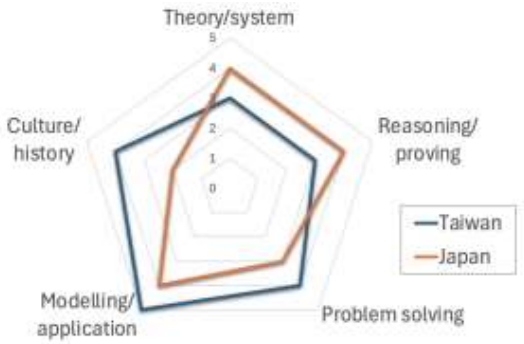


Figure 4: Five aspects dealt with in Taiwanese and Japanese geometry curricula

Developing geometrical reasoning skills in primary school

Shogo Obayashi [1] and Taro Fujita[2]

[1]Saga University, Faculty of Education, Japan; obayashi@cc.saga-u.ac.jp

[2]University of Exeter, School of Education, UK

The present study conducted and analysed lessons aimed at improving geometrical reasoning skills among primary schools students. Students could engage with the figure in a generative mode of interaction through the activity of cutting a symmetrical figure in half. Analysis of the group's dialogue revealed that after grasping the figure through Duval's perceptual, operative and sequential apprehensions, they were able to grasp the figure through discursive apprehension and make inferences on the basis of the shape's properties. Additionally, the effect of the teacher's questioning of the rationale in this dialogue enabled students to shift to discursive apprehension. Consequently, students were able to provide a logical explanation using the properties of shapes that the straight line they drew was the axis of symmetry. These results highlighted three critical elements essential for fostering geometric reasoning skills in primary school lessons.

Keywords: geometric reasoning skills, generative mode of interaction, cognitive apprehension

Introduction

The existing literature suggests that students' difficulties in geometry in secondary school mathematics are largely due to the *empirical-deductive* gap between *intuitive and operative activity* oriented teaching in primary schools and *argumentation* oriented teaching in secondary schools (e.g. Knox & Kontorovich, 2022). Particularly, deductive proofs are often employed in geometry, which are difficult to understand (e.g. Fujita & Jones, 2014; Herbst, 2004). To cope with this difficulty, it would be effective not only to improve classes in junior high schools, but also to conduct classes in elementary schools to foster argumentation understanding (Stylianides & Stylianides, 2017).

Thus, in the study of geometry, it makes sense 'to develop the ability to reason in primary school as a basis for teaching argumentation in secondary school'. And such lessons should be conducted. However, the necessary elements for such lessons need to be determined. First, we established a theoretical framework for the development of geometric reasoning based on the previous literature. Then, the research questions and methodology were described. Thereafter, data from students' geometrical reasoning were analysed to examine the contribution of the lessons in developing students' geometric reasoning and obtaining suggestions for improving their geometric reasoning.

The findings of this study can contribute to the CERME discussion paper on students' competence (visual, reasoning, operational, and figural) and issues in geometry classrooms and curricula (e.g. Palatnik et al., 2023).

A theoretical framework for designing lessons that foster geometric reasoning

A useful idea concerning geometrical reasoning is to examine students' skills in dealing with geometrical figures. French psychologist Duval approached geometry from both the cognitive and perceptual perspectives. For example, Duval (1995, pp. 145–147) has provided a detailed framework

for analysing the semiotics of geometric figures. In this framework, he has identified four types of *'cognitive apprehension*' (Duval, 1995; the following descriptions have been taken from Jones, 1998, p. 31).

1. *Perceptual apprehension*: this is what is recognised at first glance; perhaps, for instance, sub-figures which are not necessarily relevant to the construction of the geometrical figure.
2. *Sequential apprehension*: this is used when constructing a figure or when describing its construction. In this case, the figural units depend not on perception but on mathematical and technical constraints (in the latter case this could be ruler and compasses, or perhaps the primitives in computer software).
3. *Discursive apprehension*: perceptual recognition depends on discursive statements because mathematical properties represented in a drawing cannot be determined solely through perceptual apprehension, some must first be given through speech.
4. *Operative apprehension*: this involves operating on the figure, either mentally or physically, which can give insight into the solution of a problem.

He indicated that for a picture or diagram to function as a geometric figure, it must be understood perceptually and by at least one other type of apprehension (sequential, discursive or operative). We observed how these *apprehensions* were manifested in practice. For example, in argumentation lessons, students need to problem solve by using discursive understanding to capture the picture.

When considering the developmental process, it is necessary to consider how students perceive geometric figures. Fischbein (1993) proposed the 'figural concepts' in which, geometric reasoning is driven by the interaction of two aspects: the figure and the concept (Fischbein, 1993; Jones, 1998). Fischbein (1993) describes that the difficulty in understanding geometrical figures is rooted in these two aspects, stating that "the integration of conceptual and figural properties in unitary mental structures, with the predominance of the conceptual constraints over the figural ones, is not a natural process" (p.156). Moreover, it is suggested that to cope with difficulties, it is necessary for teachers to provide learning opportunities to integrate and harmonise the visual and theoretical aspects of geometrical figures.

Next, we considered the learning environment that should encourage the development of geometric reasoning. When designing geometry lessons, the manner in which students engage with diagrams is central to the study of teaching materials. Herbst (2004) considered the interaction between students and diagrams in geometry and proposed four modes of interaction between the actors (A), diagram (D) and geometric object (O). He advocates the *generative mode of interaction* as one of them and describes *generative* as follows (p.134):

> ——— a mode of interaction between actor, object, and diagram whereby an initial, hypothetical identification between object and diagram affords conditions and constraints for the actor to anticipate operations on the diagram and their results, and whereby the actualization of those operations on the diagram constrains the interpretation of the results of those operations in ascribing properties to the object, further differentiating the object from the diagram

Additionally, Herbst (2004) states that 'The work of "deductive guessing" — building reasoned conjectures or using deductive reasoning to find out what could or should be true — can be aided by tasks that engage students in generative interactions with diagrams', stating that 'Therefore, engaging students in "generative interaction" with the diagram could help them to reason' (p. 138). Furthermore, he states that 'engaging students in generative interactions with diagrams requires a teacher to do more than design tasks and manage students' (p. 138). This also emphasises the need for designing lessons through deliberate teacher interventions.

Based on the above theoretical ideas, the following research question was explored in the present study:

What elements are necessary to improve geometrical-reasoning skills as a basis for enhancing argumentation understanding in primary school lessons?

Methods

Using the framework described above, the lessons on symmetry were implemented in a primary school in Japan. Students' use of *apprehension*, interaction between students and diagrams, and the reasoning utilised during actual lessons were analysed. Regarding students' use of *apprehension* for reasoning, their statements were analysed considering Duval's four types of apprehension. Then, students' manner of engaging with the diagrams in class were analysed using Herbst's (2004) mode of interaction.

The study task required students to cut a line-symmetrical garment in half (Figure 1). A useful approach to draw a line to cut the garment presented in Figure 1 in half is to regard Figure 1 as a symmetrical figure and draw an axis of symmetry. The following prerequisites should be identified:

- Figure 1 should be line symmetrical.
- The point at the neck is the middle (point on the axis of symmetry), and the axis of symmetry can be drawn by defining another point.

Figure 1: Shapes presented to students

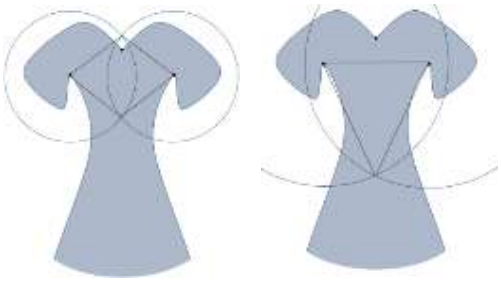

Figure 2: Anticipated drafting

Participants attempted to draw an axis of symmetry using a ruler and compass which are commonly used in Japanese mathematics lessons. They drew curves around various points and shapes by connecting the resulting intersections to the points displayed in Figure 1. Figure 2 presents the drawings expected from the participants. Participants could draw lines that appear as axes of symmetry while drawing various shapes. They discussed why the axis of symmetry could be subtracted and were able to relate the operations performed on the diagram to the properties of the shape.

The above geometry lesson was conducted in a Grade 6 classroom with 30 students in 2022 in a Japanese primary school. By then, students had already learnt about the properties of the axes of symmetry. In the pre-survey, most children were able to draw the axis of symmetry on the figure. However, few students were able to answer in writing about the nature of the axis of symmetry. The study included students from a public school in Japan with an average academic performance. Thus, some children were good at mathematics, whereas others were not. Ethical approval was obtained from an author's affiliated school. All names mentioned in this paper have been pseudonymised. The 45-minute lesson was recorded using three cameras and subsequently analysed.

Results

Students' cognitive apprehensions

In the actual lesson, the activities were conducted individually, followed by discussions in groups of four. First, we examined the *cognitive apprehensions* observed among the students. An example of the group interaction is provided below.

Table 1: Group interactions and participants' views

students	proposal	perceptual	sequential	discursive	operative
Sara	With a compass, I drew around here (flank) and then around here (opposite flank) and then I could draw the line.	○			○
Risa	Is that at 90° ?				
Tomo	Isn't it supposed to be 90° because it overlaps the folded line?	○			○
Teacher	Why is it at 90° ?				
Tomo	90° is 90° because it is vertical. I didn't figure it out, but I feel it would be 90° .	○			○
Risa	Ah! Wait, I get it!(draw a rhombus) Rhombus... look.	○	○		○
Tomo	What, what do you mean?				
Risa	This is a circle. This radius is the same. So, this one has the same length.It's an equilateral triangle over here and an equilateral triangle over there, so they're all the same length and form a rhombus.And because they are diagonals, they are perpendicular.	○	○	○	○

Figure3: Figure drawn by a student

As we can see, students initially attempted to draw different lines using a compass and ruler. Then, as demonstrated in Sara's statement, 'With a compass, I drew around here (flank) and then around here (opposite flank) and then I could draw the line'. She attempted to draw the axis of symmetry by using her *operative apprehension*. Through trial-and-error, students eventually realised that an axis of symmetry could be drawn by connecting the intersections of circles drawn around the corresponding vertices. However, they captured the figure through *perceptual apprehension*, as demonstrated in the statement by Tomo, 'I did not figure it out, but I feel it would be 90°'. Therefore,

they could not determine whether the line was an axis of symmetry and could not reason. Thereafter, the teacher asked, 'Why is it at 90°?'. Students then began to use *sequential apprehension* to recapture the diagram, such as by tracing curves and drawing rhombuses. This can be observed in Risa's statement: 'This is a circle. This radius is the same. Therefore, they have the same length. It is an equilateral triangle here and there; therefore, they are of the same length and form a rhombus. As they are diagonals, they are perpendicular'. Therefore, she was able to use her *discursive apprehension* and the properties of shapes to logically explain the axis of symmetry.

Students' interactions with diagrams

Next, we analysed how the students handled the diagrams. First, the students hypothesised that they should be able to draw an axis of symmetry to achieve the objective of *cutting the clothes in half*. They used a compass and ruler to add various lines to the diagram of the clothes, which added a new meaning of *rhombus* in the figure redrawn by the line. Subsequently, they used the properties of the rhombus to solve the problem through reasoning. Thus, the students engaged with the diagram through a *generative mode of interaction*.

Therefore, students were able to engage in the task using *operative apprehension* as they engaged with the diagram through a *generative mode of interaction*. The teacher's questions triggered *sequential* and *discursive apprehensions* to advance geometric reasoning. These were also for example observed in the following exchanges:

Kazu: The axis of symmetry is at right angles to the line drawn by connecting the corresponding points. I contemplated that the feature of equal distance from the corresponding point to the axis of symmetry was similar in character to the line drawn between the top vertex and the base of an isosceles triangle. Therefore, I drew it using isosceles triangles. (Figure 4)

Teacher: Very interesting. Did you understand that?

Students: I know.

Teacher: What shapes do you see in his head?

Students: Triangles with two equal sides.

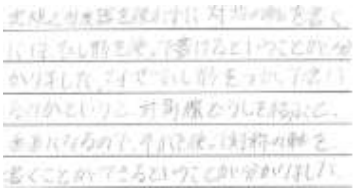
Jin: Can we have equilateral triangles?

Figure 4: Kazu's figure

Figure 5: Jin's figure

Teacher: Oh, that is an interesting word. Someone was thinking in terms of equilateral triangles. Please explain the significance of this point.

Jin: Collar point is definite and in the centre. The triangles are of the same length (Fig. 5). If you connect here (collar points) to here (the apex of the equilateral triangle), you can draw an axis of symmetry.



Kazu discovered an isosceles triangle and used it to draw an axis of symmetry. Jin stated that the same could be performed using equilateral triangles. Thereafter, the teacher prompted him to explain, and Jin provided a logical explanation using the properties of the equilateral triangles that he had drawn himself. This interaction was analysed. First, Kazu drew a line using a compass through

operative apprehension. Kazu looked at the line and thought that 'the feature that the axis of symmetry has an equal distance from the corresponding point to the axis of symmetry is similar in character to the line drawn between the topmost vertex and the base of an isosceles triangle'. Then, a new property was added to Fig. 4 as 'a diagram with several isosceles triangles'. This allowed them to explain how an axis of symmetry could be drawn. While listening to the explanation, Jin also thought that it could be done using equilateral triangles, and drew an equilateral triangle (as shown in Fig. 5). Jin used *sequential apprehension* as he deliberately limited the length of the sides using a compass. Here, the teacher asked, 'What is the name of this triangle?'. Then, Jin was able to draw an axis of symmetry using the property that the vertex of an equilateral triangle is *in the middle* and provided a verbal explanation. Thus, the *generative interaction* between the student and diagram could be observed, as the diagram produced by the new manipulation added the new figure properties of isosceles and equilateral triangles. Even in this context, students could use *perceptual, operative, sequential and discursive apprehensions* to explain how the axis of symmetry could be drawn.

Discussion

The results revealed that through children's engagement with the diagrams by means of the *generative mode of interaction*, they were able to use various *cognitive apprehension* to capture geometric objects. This was because the activity of *cutting the clothes in half* allowed them to engage with the diagram through a *generative mode of interaction*. They replaced 'cutting the clothes in half' with the act of *drawing the axis of symmetry* and worked with the diagram using *operative apprehension*. In doing so, students could deepen their understanding of shapes by thinking about questions such as, 'What do the lines drawn with the compass mean?', 'What kind of shapes were drawn?' and 'What are the properties of the shapes they drew?'. During the discussion, they deliberately drew shapes and axes of symmetry using *sequential apprehension*, thinking that they could also use the properties of other shapes to draw the axes of symmetry. This process may have enabled students to provide a logical explanation about drawing the axis of symmetry using the properties of the shape by engaging in *discursive apprehension*.

The worksheet below shows that students in the class began to recognise the axis of symmetry.

I have found that a rhombus is a good way to draw the axis of symmetry without using a measuring tape and protractor. A rhombus can be used because when the diagonals are connected to each other, they become perpendicular.

Figure 6: A student's description

As can be seen from the exchanges in Table 1, in the early stages of their learning, students were able to use their *perceptual apprehension* and judged that the lines were 90° to each other by appearance. In addition, students were able to use *sequential apprehension* to relate the properties of the rhombus to the compass marks through drawing with the compass. This enabled them to write an explanation of how to draw the axis of symmetry (Figure 6). This is the result of concepts controlling images, leading to a state where conceptual and figurative properties are integrated (Fischbein, 1993). A similar students' development can be found in Herbst (2004). This suggests that activities that engage with diagrams through *the generative mode of interaction* are suitable as what Fischbein calls the

'learning opportunities to integrate and harmonise the visual and theoretical aspects of geometrical figures'.

On the other hand, how could they verbalise information that they understood unconsciously? The students perceived the diagram through *perceptual apprehension*, observed through their statements such as, 'It will be 90° when folded' or 'I haven't measured it, but it's probably 90°'. However, the teacher's question, 'Why is it 90°?' prompted them to engage in *discursive apprehension.* Students who had been influenced by the images were able to explain the rhombus by referring to its properties because the teacher's questions created a need to provide a logical explanation. Therefore, an appropriate method of teacher involvement suggested by Herbst (2004) is for the teacher to question the rationale when he or she wants to encourage *discursive apprehension*.

The following three elements were identified as requirements for designing lessons to improve geometric reasoning in primary schools.

(i) Create situations in which students engage with the diagram using the *generative mode of interaction*, activating their *perceptual*, *operative* and *sequential apprehensions*; (ii) provide opportunities for determining logical explanations of the basis of events in the dialogue; (iii) question the rationale and encourage a shift in *apprehension* to *discursive understanding*.

Regarding (iii), the importance of appropriate teacher involvement in improving reasoning skills has been previously noted. (e.g. Stylianides et al., 2019). This study demonstrated the role of linking *operative apprehension* to *discursive apprehension*. This can be considered as a valid perspective for teaching to bridge the *empirical-deductive* gap between primary and secondary schools.

Conclusion

In this study, we analysed a lesson conducted in the area of primary school geometry aimed at developing reasoning skills and discussed the factors that contribute to the development of geometrical reasoning skills. Consequently, the following three elements were derived.

(i) Create situations in which students engage with the diagram using the *generative mode of interaction*, activating their *perceptual*, *operative* and *sequential apprehensions*; (ii) provide opportunities for determining logical explanations of the basis of events in the dialogue; (iii) question the rationale and encourage a shift in *apprehension* to *discursive understanding*.

Lessons that incorporate these elements can provide a foundation for understanding argumentation in secondary school. This allows us to situate lessons in primary schools that bridge the 'experiential-deductive' gap.

The following research possibilities emerged from the conclusions drawn in this study.

- How do students who have experienced the practices described in this study react to proof problems in secondary schools? It is possible to examine the elementary role of argumentation guidance and the need for practices described in this study.
- Applying these three elements to enhance geometric reasoning skills in other areas of geometric learning allows for the verification of the generality of the conditions and demonstrates their practicality in the classroom.

We aim to develop curriculum and learning environment designs that bridge the empirical-deductive gap between primary and secondary education through the advancement of these research.

High School Mathematics Teachers' Support for Students' Focus on the Properties of Geometric Solids Using Dynamic Geometry Software

[1]Samet Okumus, [2]Karen Hollebrands

In this study, we examined two high school mathematics teachers' uses of dynamic geometry software (DGS) while solving three-dimensional geometry tasks, and investigated the ways in which they supported students' attention to the properties of geometric solids through the use of a drawing or construction. The data were collected from two geometry classes. In the first geometry class, students used DGS drawings in which they were not able to drag objects. In the second geometry class, students used DGS constructions where they could actively drag and interact with geometric objects. We found that the mathematics teacher who used DGS drawings cited the lack of precision in DGS as a means to resolve contradictions, whereas the teacher who employed DGS constructions relied on task instructions to navigate variables and complete the tasks.

Keywords: Drawing, Construction, Figure, Diagram, Dynamic geometry software.

Introduction

Students often struggle to interpret three-dimensional objects when they are represented in two dimensions. Such representations can be misleading, as crucial information, particularly depth, is lost (Parzysz, 1988). However, with the advent of dynamic geometry software (DGS), students can drag properly constructed objects to explore geometric relationships (Laborde, 2008). Students may also use a DGS drawing without using any function tools (e.g., the Perpendicular Line tool), which messes up when a primitive element (e.g., points) of the geometric object is dragged (Healy et al., 1994). Hollebrands and Smith (2009) describe the drawing and construction in DGS as follows.

> We refer to *drawing* as a process that involves the use of "freehand" tools to create a geometric object…. When a geometric object is created using specific tools, such as perpendicular line command to ensure all angles are right angles, then this process is referred to as *constructing* and the final object is called a *construction.* (pp. 221-222)

In the current study, we focused on high school mathematics teachers' use of DGS drawings and constructions to characterize their teaching activity in which the properties of geometric solids represented within a Euclidean Geometry landscape. Different from prior research on examining students' understanding of Euclidean concepts in DGS where loss of information is minimal, our investigation enabled us to characterize how high school mathematics teachers supported students' attention to the properties of geometric solids represented within plane geometry. The research

question that guides this study is: "How do high school mathematics teachers support students' attention to the properties of geometric solids in DGS, through the use of a drawing or construction?"

Theoretical Background

In a teaching activity, students might be given a DGS construction, a construction with limitations (e.g., soft constructions), or a drawing. Also, students might create their own constructions or draw shapes in DGS. A properly constructed shape preserves its properties upon dragging, while a construction with limitations may not. If a student uses a drawing, then geometrical objects not constructed using DGS tools (such as a midpoint that does not preserve its properties upon dragging) or objects drawn with traditional tools cannot be dragged. Regardless of the tool a student uses, if the student focuses on the properties of the geometric object by viewing its representation, then the student is focusing on the *figure*. However, if the student does not attend to the properties or perceptual characteristics of the visual representation, then the student is working with the *diagram* (Hollebrands & Smith, 2009). Hollebrands and Smith (2009) make a distinction between a figure and diagram as follows.

> When a student views visual representation of a geometric object and attend to its properties, then we state that the student is reasoning about a *figure*. In contrast, we use the term *diagram* when it is not evident whether the student is attending to the properties or the perceptual characteristics of the visual representation of a geometrical object. (p. 222)

Dick and Hollebrands (2011) emphasized the importance of maintaining mathematical fidelity (adhering to accurate mathematical principles) and cognitive fidelity (aligning students' perceptions with the intended mathematical meaning) in dynamic sketches. Prior research investigated students' uses of DGS drawings or constructions and characterized their learning. For instance, Healy (2000) investigated the different types of task constructions employed by students (aged 14-15 years) when working on geometric proofs. One dyad created a robust construction that preserved its critical attributes upon dragging. Another dyad created a soft construction that did not stay true in mathematics, leading to situations where the construction did not preserve properties when its primitive elements were dragged. Healy reports that this second dyad encountered counterexamples due to the limitations of their sketch, which at times resulted in decreased motivation. However, Laborde (2008) appreciates the use of soft constructions, as they allow students to adjust their solutions or reasoning when they gain new insights into the problems.

González and Herbst (2009) describe how DGS enables a functional mode of interaction, where students can explore mathematical relationships dynamically by dragging and measuring elements within a diagram. This dynamic mode contrasts sharply with static, unmodifiable diagrams, allowing students to focus on the properties of figures rather than merely their visual attributes. This flexibility facilitates what they call a "measure-preserving conception" of congruency, where students test congruency by checking for consistency in measures during dragging (González & Herbst 2009). In static diagrams, visual perception often leads students to treat figures based on surface-level visual characteristics, which can obscure deeper geometric relationships. This perceptual approach, typical of static interactions, differs from the measure-based approach fostered by DGS, which allows

students to maintain congruent relationships as they adjust parameters. Herbst et al. (2017) elaborate on these differences, noting that DGS enables students to explore collections of diagrams continuously, rather than isolated, static instances. This approach emphasizes geometry as a dynamic process, where conjectures are grounded in observed invariants across multiple instances. The DGS environment thus provides a foundation for moving from empirical observations to theoretical generalizations, an essential skill for deep geometric understanding (Herbst et al., 2017).

Herbst and colleagues (González & Herbst 2009; Herbst et al., 2017) approach provides a broader classification that includes multiple modes of interaction, accounting for the evolving ways students can engage conceptually with diagrams. Yet, Hollebrands and Smith (2009) emphasize the distinction between students focusing on the properties of a geometric object (figures) and their attention to its visual representation without regard to properties (diagrams) in DGS.

Methods

Mrs. Dabney, and Mr. Taylor (pseudonyms) were two of the participants in a three-year professional development project focused on teaching and learning geometry and algebra with technology. They participated in two weeklong summer institutes and engaged in two years of online professional development, with additional support provided at the classroom level in the southeastern United States. Although the professional development was primarily focused on Euclidean geometry with the use of the Geometer's Sketchpad (GSP), a few teachers used the GSP for teaching three-dimensional geometry. The teachers utilized GSP drawings or constructions in which the geometric solids were not allowed to rotate and examine from different perspectives.

Mrs. Dabney and Mr. Taylor first introduced the tasks to the whole class. Students worked on the GSP tasks individually or in pairs, while the teachers moved around the room, providing feedback as students engaged with the tasks. Finally, they concluded the lesson with a whole-class discussion. Mrs. Dabney implemented tasks accompanied by sketches that were not constructed in the GSP, referred to as drawings. As a result, when students attempted to drag objects within these sketches, the objects did not retain their original properties. Video recordings from a lesson in which students used the GSP to find the surface area and volume of rectangular pyramids were analyzed. Students primarily focused on using the GSP to compute surface areas and volumes in various ways. In contrast, Mr. Taylor had his students study three-dimensional objects using the GSP constructions, which allowed them to drag the objects and change the radius and height of the right circular cylinder. His students engaged in solving optimization problems, such as minimizing the volumes and surface areas of geometric objects. Yet, the cylinder was not allowed to be rotated and examined from different perspectives since the construction was made in a Euclidean Geometry landscape.

During each 90-minute class session, a video camera recorded students' work, including whole-class discussions, individual tasks, and pair activities, as well as teachers' use the GSP. The analysis framework, based on the theoretical distinction between reasoning about a figure and a diagram, guided the examination of students' interactions with DGS drawings and constructions. The researchers focused on the challenges students encountered in preserving mathematical properties, particularly how these challenges varied between static drawings and dynamic constructions. A

comparative analysis of the instructional strategies used by two mathematics teachers highlighted how different approaches to DGS integration influenced students' geometric reasoning.

Results

Focusing students' attention on the properties of geometric solids through a DGS drawing

In Mrs. Dabney's class, students studied geometric relationships using DGS drawings which were not constructed with DGS tools. In other words, students were not able to drag objects, points, etc. and observe the relationships dynamically. Before Mrs. Dabney had her students use the GSP, in a whole-class presentation, she had given directions about finding the areas (the faces and the base of the pyramid), and the volume of the rectangular pyramid as shown in Figure 1, exemplifying on a static pyramid on the board. Mrs. Dabney mislabeled the height and the slant heights. Yet, this did not cause any difficulties since she directed students' attention to calculate the surface area. Students mostly had difficulty understanding the relationships of the pyramid when it was drawn on the board. For instance, in the following dialogue, the student (line 2) could not make the distinction between the slant height and the height of the rectangular pyramid.

1	Teacher:	Mmhmm. 10 is my base. So, 10 would be my base. What would be the height of that triangle?
2	Student:	9.
3	Teacher:	Uh-huh. The 9 goes in the very center. So, the 9 is actually how tall the whole pyramid is. So, look just on the face over here. What is the other number that you see? 8. That's the height of that triangle. Ok, so put an 8. OK, now, if it is a rectangle, what do we know about rectangles?
4	Student:	Opposite sides are the same, aren't they?
5	Teacher:	This side is equal to this side. So, the triangle that makes up this side is the same as the triangle that makes up that side. So, there is how many of them?
6	Student:	2.
7	Teacher:	2, OK, get that area. And, do for like the front triangle, OK. And then, there're two of those. Then, you'll find the area of the rectangle. And, add them all up.

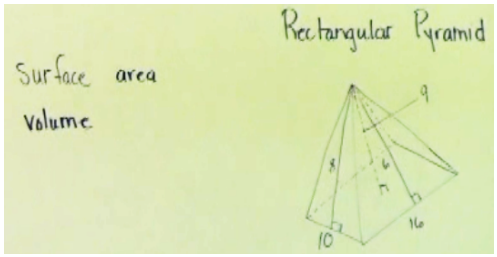

Figure 1: A rectangular pyramid drawn by Mrs. Dabney on the board

The difficulty of using the correct attribute for calculating the surface area was also evident in the GSP drawing Mrs. Dabney implemented. For example, as indicated in the excerpt below in Mrs. Dabney's class, some students used the height of the pyramid instead of slant heights, when they tried to find the surface areas of the triangles on the faces. The exchanges between Mrs. Dabney and a student who worked individually took as follows.

1	Teacher:	OK. For the front one, you did ½ the base. So, *GE*, right?
2	Student:	Mmhmm.

3	Teacher:	Times the height, which is *AC*.
4	Student:	Yeah.
5	Teacher:	Correct?
6	Student:	What? I think, I did the wrong thing.
7	Teacher:	OK. Let's do this. Let's see if I can get the height so we don't get confused.
8	Student:	Well, I made the one of them showing on. I mean, I need…
9	Teacher:	OK. The height of the pyramid, that's the pyramid. I really do not need it right now, that's just for volume. The height of the triangles (pointing at slant heights), I definitely need those.

Mrs. Dabney had her students find the surface area of the pyramid with two methods both of which lacked in mathematical fidelity. The first method that students used was to find the areas of the pink and orange triangles using ½ times base times height and double them, and find the area of the base multiplying two adjacent sides of the rectangle (Figure 2). However, the isosceles triangles representing the lateral surfaces were not created with the DGS function tools. Therefore, they were scalene triangles representing the lateral surfaces. Afterwards, they found the surface area of the pyramid by summing the surface areas and the base. In the second method, students found the areas by choosing the polygon tool of the GSP and placing triangles to the vertices of the pyramid and a quadrilateral for the base. Then, they highlighted the triangles and the rectangle, and found the areas using the area tool of the GSP automatically. These two methods resulted in two different surface areas (77.63 cm^3 vs. 75.18 cm^3 in Figure 2) because in the first method, students used medians of the scalene triangles representing the lateral surfaces, and the base was not a properly constructed rectangle. Students were confused with this mathematical contradiction. Mrs. Dabney provided the following explanation:

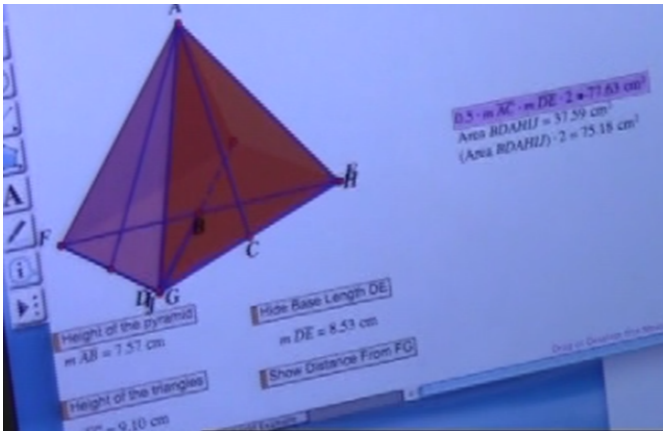

Figure 2: A student's individual work in the GSP in Mrs. Dabney's class

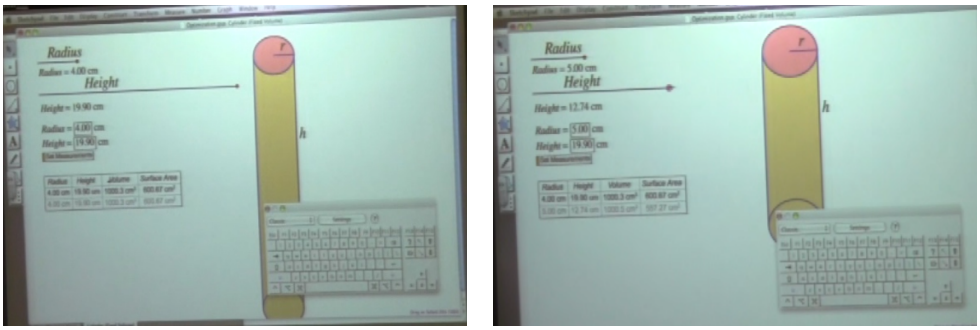
10	Teacher:	They are not exactly the same, but that is ok what we're doing because when we constructed, we're not making it exactly.
11	Student:	So totally different.
12	Teacher:	Oh no, because I want to see that. Because that's how, that's how you found the area only directions. By here it says find the surface area of the pyramid by using the polygons and by using the surface area formula.



Later, during the whole-class discussion, Mrs. Dabney described this situation to a different student by saying "so, this is one way of finding the area using the polygon tool. This is another way of calculating the area yourself. They should be very close. OK, they're not gonna be identical because

you know when we draw this polygon it is not exact." In both of her explanations, Mrs. Dabney did not refer to the use of the incorrect height leading to the different results. Mrs. Dabney constructed slant heights of the pyramid which were constructed as medians with actions buttons in the GSP. Therefore, students obtained different surface areas. Also, the base was not a properly constructed rectangle, so students calculated different area results with the two different methods.

Focusing students' attention on the properties of geometric solids through a DGS construction

In Mr. Taylor's class, students studied geometric relationships using DGS sketches constructed with DGS function tools. He posed an optimization problem that asked students to find the minimal surface area of a cylinder whose volume was 1000 cm^3. During the task description, he referred to the cylinder with a 1000 cm^3 volume as a liter of shampoo bottle. Students had to maintain a volume of 1000 cm^3 while changing the length of the radius of the base and the height of the cylinder. However, some students dragged either height or radius for observing the change of surface area without keeping the solid at the same volume. In the following example that took during the whole-class discussion, Mr. Taylor asked students to come up with a systematic process by recording some possible radii and volumes.

1	Teacher:	I'm feeling good about 4. Start with 4. So, I wanna make my radius 4.
2	Student 1:	Height?
3	Teacher:	Umm, see radius of 4. Do the math, carry the 1. You have to divide. Yeah, the height is gonna be 19.9. See how I am doing math, I like that.
4	Student 1:	Yeah, you got 19.9 (inaudible).
5	Teacher:	Mmhmm, 19.9. So, I am putting that in as my height (Figure 4a).
6	Student 1:	Why do you say 19.9?

(a) (b)

Figure 4: (a) Mr. Taylor adjust the height at 19.9 cm, (b) He obtains a volume of 1000 cm^3

7	Student 2:	Equals 600 (the surface area).
8	Teacher:	Cause I'm looking for a volume of a 1000. That's why.
…		
13	Teacher:	So, the question is can I do better, or can I do worse? The surface area, I wanna minimize. The volume, I wanna keep constant. Alright? So, I'm gonna show something you can do here. Double click on your table. Again, set it 4, 19.9, and then double click. They'll keep track the volume for you. Alright?
14	Student 2:	So, that will leave you the radius the same?
15	Teacher:	Well, no. We should probably chance the radius to what?
16	Student 2:	5.
17	Teacher:	5. So, what I want you to do is to change the radius 5.

18	Student 2:	It worked!
19	Teacher:	Now, when I go to 5, my volume is too big. What I need to do?
20	Student 1:	Lessen the height.
…		
26	Teacher:	Alright, so let's lessen the height, so we find the volume of a 1000. Ugh, so close. Got it., right? There we go (Figure 4b). The, my surface is going down?
27	Student 1:	(Nods)
28	Teacher:	Good. So, I want you to keep following that procedure, right? And, go ahead and tell me where you think the minimum surface area is going to occur.

In this example, the student could not understand why he should change the height of the cylinder (line 6) because Mr. Taylor computed the height of the cylinder with a radius 4 cm mentally to keep its volume constant. However, when the teacher dragged the height to 19.9 cm, it became clear why the height had to be 19.9 cm. On the other hand, another student (line 14) asked if he had to keep the height the same. However, once Mr. Taylor dragged the radius to 5 cm, the student observed that the volume was larger than 1000cm^3. Later on, a student (line 25) proposed reducing the height of the cylinder to keep the volume constant, which indicated that he was reasoning about properties of the object. Despite his directions, some students had difficulty keeping the volume 1000cm^3 in their individual work with the task. For instance, Mr. Taylor noticed a student's difficulty while he was observing the working students and monitoring the progress. He addressed the student's difficulty as the following:

> That's wrong. Is that gonna hold a liter of shampoo? No!... So, I want you to mess with both (radius and height), right? I want you find the optimal radius for my surface area, alright, and I also want you to umm chance the height so that what do I always need, what's the centiliter becomes for the volume. You have to change the height make sure you always continue with 1000 cm^3 for your volume.

By prompting the student to "mess with" both the radius and height, Mr. Taylor encouraged an experimental approach to refining the shape's dimensions while meeting the volume constraint, aiming to deepen the student's understanding of how changes in dimensions affect both surface area and volume.

Concluding remarks

In this study, we exemplified cases in which students did not focus on the properties of three-dimensional objects using the GSP drawings or constructions. From there, we characterized how the teachers addressed students' difficulty. Mrs. Dabney, who used a DGS drawing, pointed out the inherent limitations of DGS in achieving exactness. Her comments to students, emphasizing that the measurements were "not exact" and that results could differ slightly, reveal her attempt to resolve potential misunderstandings caused by the imprecision of digital tools. This approach suggests that Mrs. Dabney was aware of students' potential confusion and used discussions to clarify the expected level of precision in DGS environments. On the other hand, Mr. Taylor aimed to help students focus on properties by encouraging them to dragg the sliders and observe the dynamically changing volume and surface area outputs.

The differences in instructional strategies between Mrs. Dabney and Mr. Taylor highlight the importance of using dynamic geometry tools to facilitate students' reasoning about geometric objects. Mrs. Dabney's reliance on static drawings and procedural instructions limited students' engagement with the geometric properties, resulting in contradictory calculations and persistent errors. In contrast, Mr. Taylor's dynamic approach allowed students to explore and manipulate geometric objects actively, fostering a deeper understanding of the relationships between different geometric attributes.

The findings of this study further support Herbst et al.'s (2017) emphasis that dynamic geometry environments not only increase student engagement but also promote a shift in how students understand geometric properties. The students in Mr. Taylor's class demonstrated an understanding of the relationships within geometric objects through active manipulation, allowing them to transition from treating diagrams as static forms to viewing them as flexible representations. This dynamic engagement was less apparent in Mrs. Dabney's class, where students were limited to static diagrams. Integrating dynamic diagrams more consistently into classroom practice may thus support students' cognitive development and reasoning skills more effectively than static approaches alone.

A group of 5 pre-service teachers engaged in constructing and exploring a body-scale icosahedron model. Triangulating audio–video and mobile eye-tracking data, we analyzed the roles of motor actions and sensory perceptions in the emergence and propagation of geometrical insight. We present an exemplary episode where Gail multimodally expresses a valid argument for finding the icosahedron's half-height. Another participant's eye-tracking data revealed that his perception of Gail's manual actions helped him interpret and then replicate non-verbal features of her argument. The study contributes to our understanding of embodied cognitive processes in authentic educational contexts, particularly the role of perception–action engagement with concrete media in collaborative mathematics tasks. Teacher awareness of these perceptuomotor micro-processes might enhance the pedagogical efficacy of integrating embodied activities into classroom geometry instruction.

Keywords: Embodied argumentation, collaborative learning, preservice teachers, spatial geometry

Introduction

There has been growing interest in 4E (embodied, enactive, embedded, and extended) approaches to mathematical learning, particularly in geometry (e.g., Abrahamson et al., 2020). These approaches, unlike traditional ones, emphasize physical interaction and sensory experiences in developing mathematical understanding. Geometry—a study of shape and space, where spatial visualization and reasoning are vital components of learning—is particularly amenable to the pedagogical implementation of these approaches. Through manipulating physical models, moving around and through the models, measuring them, and using various gestures, learners engage in embodied argumentation, a collaborative process where action-based experiences are integral for reasoning and proving (e.g., Palatnik & Abrahamson, 2022; Walkington et al., 2019).

Mathematical argumentation is "a line of reasoning that intends to show or explain why a mathematical result is true" (Sriraman & Umland, 2020, p. 65), produced by students and teachers in mathematics classrooms. This paper introduces the concept of *embodied argumentation*—a form of math argumentation, in which learners use physical actions, such as interactions with objects, as well as gestures, to construct, support, and communicate mathematical proofs and explanations. The empirical context of the investigation is a geometric task involving the collaborative construction of a human-sized Platonic solid followed by exploring its global features, such as determining its total number of vertices. Drawing on insights from gestural reasoning, collaborative problem-solving, and Proofs Without Words (PWW, Marco et al., 2022), this study examines how pre-service teachers use their bodies, physical interactions with the model, and gestures to develop and communicate geometric arguments. The goal of this research is to contribute to the field's understanding of how embodied cognition manifests in collaborative mathematical argumentation and to investigate the educational potential of integrating embodied activities into geometry instruction.

Theoretical Background

The late David Tall suggested that mathematical reasoning evolves through three worlds: the embodied, the symbolic, and the formal–axiomatic world. The embodied world, where learners use physical interactions and sensory experiences to grasp mathematical concepts, provides the foundation for math before transitioning to symbolic and formal reasoning (Tall, 2003). He presented a PWW on the sum of the *n* first integers as the manipulation of pebbles (embodied), then proof by arranging a sum of two lines of numbers, one of them in reverse order (symbolic), and finally proof by induction (axiomatic). Tall noted that the first two proofs have "clear human meaning, the first translating naturally into the second. The induction proof, on the other hand, often proves opaque to students, underlining the gap that occurs between the first two worlds and the formal world" (p. 8).

Embodied cognition posits that human thinking is deeply rooted in physical interactions with the environment (e.g., Barsalou, 2008). In mathematics education, this framework has supported claims that learners engage with concepts through gestures, movement, and manipulating physical objects: moving in a new way by perceiving in a new way and then naming in a new way (Palatnik et al., 2023). This embodied view is especially valid in geometry, where physical interaction with geometric figures, such as objects and diagrams, is inseparable from understanding (Herbst et al., 2017).

An embodied approach to geometry instruction aligns with research suggesting that embodied reasoning can support the development of geometric understanding. Nathan et al. (2021) emphasize that intuition and insight in geometry often arise through embodied experiences, such as gestures, that allow learners to transition from informal exploration to more formal proof. Their study provides evidence that dynamic depictive gestures, which involve motion-based transformations of mathematical objects (e.g., dilation or rotation), significantly support the production of valid proofs, whereas static gestures are less effective in fostering mathematical generalizations necessary for proofs. Other studies investigating learners interacting with physical models—such as 3D geometric shapes—show they gain insights through bodily movements (Benally et al., 2022). These actions form the basis of geometric argumentation and reasoning, as learners use their bodies to represent, explore, and communicate geometric properties (Palatnik & Abrahamson, 2024).

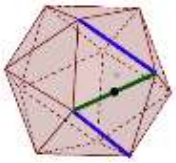
Embodiment and dynamism are constitutive to geometric reasoning, whether observable by others or only covertly experienced by individuals through multimodal processes, like mental transformations, or in the form of imaginary auxiliary constructions. We speculate an experiential spectrum between covert and overt multimodal mental activity. We further assume that covert and overt aspects of mathematical reasoning afford complementary contributions: at times, it is helpful to imaginatively manipulate a geometric structure, unbound by available media, whereas, at other times, it could be vital to materially realize these mental figments in the form of publicly inspectable models. A case in point is PWW-based activities, where learners engage in *gap-filling*, which is the process of identifying missing components in visual representation and constructing formal proof (Marco et al., 2022). In the absence of formal symbolic displays, PWW artifacts provoke mathematical thinking and support diverse legitimate forms of argumentation (Nelsen, 1993); they help learners bridge embodied experiences and formal argumentation. Engaging students in interpreting PWW diagrams

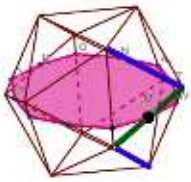
fosters opportunities to experience authentic mathematical reasoning, which, as Lakatos (1976) insisted, is the actual lived phenomenological underbelly of the eventual written proofs.

Still, nurturing students' capacity to understand proofs—what they are as epistemic forms—may take holistic entrainment. From a didactical perspective, one might wish to scaffold mathematics students' epistemic practices, cognitive routines, and interpersonal argumentation by way of occasioning for them opportunities first to engage in the *overtly* manifest enactment of geometric reasoning prior to introducing problems more so conducive to *covert* reasoning. One powerful cultural tradition incorporating overt geometric actions is construction activities, for example, the historical pedagogical methodology established by Friedrich Fröbel (Brosterman, 1997). Whereas Fröbel designed his geometry construction tasks for kindergarten students, our philosophical and theoretical commitment to embodiment perspectives, as well as our empirical research, have led us to believe that high-school students, too, should build knowledge through building objects (Palatnik & Abrahamson, 2022). Namely, implicit to the hands-on pedagogical regimens characteristic of our studies into geometry education is an enactivist argument that humans are life-long sensorimotor learners—we never actually graduate the sensorimotor stage Piaget theorized as ending in early childhood (Abrahamson, 2022). Yet these polemic epistemological debates would avail from empirical data. As such, as we now argue, introducing material stuff into geometry pedagogy may shift the focus of *research* on geometry pedagogy, drawing attention to students' authentic praxis and multimodal phenomenology of manipulating concrete objects, possibly revealing the critical cognitive roles of perception and action that embodied mathematics-education researchers allege.

Recent research on embodied learning in proving and argumentation has largely focused on gestures' role in mathematical reasoning. Walkington et al. (2019) show how collaborative gestures support group reasoning, while Nathan et al. (2021) highlight that dynamic gestures may enhance proof production by simulating geometric transformations. While these studies provide valuable insights into the body's role in mathematical reasoning, they focus almost exclusively on gestures as the manifestation of embodied learning. A notable gap remains in understanding other forms of embodied cognition, such as physical interaction with manipulatives, sensorimotor experiences, or spatial reasoning through body movement, and how these contribute to mathematical proving and argumentation. Furthermore, research in authentic classroom settings, where students and teachers collaboratively develop embodied argumentation, is still missing. Further research is needed to investigate these broader manifestations of embodied learning in various educational contexts.

The research questions guiding our study were: What are the roles of motor action and sensory perception in mathematical argumentation? What is the educational potential of fostering opportunities for embodied argumentation in geometry instruction?





Illustrative case study of embodied argumentation

Our empirical context is a spatial geometry activity in which five pre-service mathematics teachers participated voluntarily: Aya, Gail, Ruth, Tim, and Yoni (pseudonyms). They were tasked to construct and analyze a body-scale Platonic solid (Figure 1). Whereas we had used this activity extensively in researching geometry education (Benally et al., 2022; Palatnik & Abrahamson, 2022, 2025), we had yet to examine experiences related to argumentation. The session was audio-video

recorded. During the activity, three participants wore mobile eye-tracking (MET) devices (Pupil Lab Neon), generating Multimodal Learning Analytics (MMLA) data.

Our data further comprised a stimulated-recall group interview, in which participants discussed their experience of collaboratively constructing the model. We prepared the activity transcript, juxtaposing the three MET sources and adding photos to capture movements, actions, and gestures. We transcribed the SRI interview. We coded data by marking key moments in the construction and exploration processes to capture elements of cooperative action and argumentation. Utterances were transcribed and coded, marking aspects of perception and action. We later juxtaposed key video moments in the construction process with relevant testimonials from the stimulated-recall interview.

We focus our analysis on the episode that begins at the 16th minute of the activity when the participants had already successfully constructed the icosahedron model and answered questions about its number of edges, vertices, and faces. The next question, however, presented a different challenge: "Assume the polyhedron was placed on one of its faces and filled with water. What would the shape of the water's surface be?"

 a	 b	 c	 d	  e
Because *this* is here, [slides her right hand down along the edge, starting from the top base (top blue segment on 1e)]	*that* is there. Symmetry. [slides her left hand up along the edge from the bottom base (bottom blue segment on 1e), establishing symmetry]	And then we have… [puts both hands on the ends of the center edge, where her previous movements had ended; slides her hands simultaneously to the middle of the edge]	*this* [The meeting point (M on 1e) is the middle of the edge and precisely at half the model's height when it stands on the face.	

Note: (a)-(d) blue arrows indicate the movement of Gail's hands; a red circle is an eye-tracking marker of Tim's gaze; (e) a scheme of Gail's argumentation and the form of the cross-section—dodecagon

Figure 1: Gail's embodied argumentation

The participants perceived this problem as non-trivial. Aya remarked, "Oh, interesting, because it's not... no, it's not symmetric. Part of (the edges) will be cut in the middle, and part will be cut…" Realizing they needed to establish the height of the cross-section, the participants quickly began approximating the position of the model's half-height above the ground. Yoni intuitively placed his hand on an edge close to the correct height but expressed uncertainty. Other participants offered suggestions on where the half-height might be located and, based on their approximations, attempted to count the vertices of the imagined cross-section. They debated between a pentagon and a hexagon (both suggestions are incorrect) but were unsure of the correctness of the answer.

The group then split into two sub-groups, which, due to the large physical size of the model, became separated: Aya, Yoni and Ruth on one side, Gail and Tim on the other. While partially aware of each other's actions, they worked somewhat independently. Aya first suggested that the cross-section at half-height would include one of the vertices. Aya and Yoni then agreed that two vertices on the same edge were not the same height from the ground. Their argumentation was supported by the observation of the model while touching the vertices, sliding the hands along the edges, simulating and comparing each other actions

Meanwhile, Gail engaged in searching for the half-height in a different way. First, she approximated the half-height of the icosahedron by comparing it to the distance between the palms of her hands put vertically. She took several such measurements with her hands. Then, she stepped back to change her perspective to be able to capture the whole model from a distance. She observed the model from different angles. At 16:08, when the instructor asked, "Where is it, exactly, half of a height?" Tim initially supported the idea that it was located at one of the vertices. However, Gail confidently stepped toward the model and indicated (correctly) horizontally with the palm of her hand: "No. This is half of a height." When the instructor asked, "Why is this half of a height?" Gail produced a concise argument through a series of three coordinated actions (Figure 1).

Tim's eye-tracking data revealed that he followed Gail's gestures closely. His gaze tracked each movement (marked by a red circle in Figure 1). Tim fixed his gaze and pointed at the midpoint of the edge before Gail completed her third movement. Based on this MMLA data, we conclude that he understood the argument before she finished her demonstration. He exclaimed, "Wow, cool!" recognizing the solution.

 a	 b	 c	 d
"Yes. Because this [slides a right hand down]	and this are the same height.[slides a right hand up]	And here, [slides both hands simultaneously toward the edge's middle]	this is its middle.
Note:(a)-(d) blue arrows indicate the movement of Tim's hands; a red circle is an eye-tracking marker of Aya's gaze; Gail continues to hold her hands, indicating the half-height point			

Figure 2: Tim's embodied argumentation

Note that the eye-tracking and audio data of Aya and Yoni revealed that they were not yet aware of Gail's embodied proof. Having endorsed Gail's argument, the instructor directed the other subgroup's attention: "Guys, did you hear what Gail said?" This prompted Aya, Yoni, and Ruth to look toward the first group, and Tim quickly took over the explanation (see Figure 2). While Tim's actions enact

the same chain of reasoning as Gail's, his actions are not precisely the same—he captured the essence of argumentation while varying the movements' motorics.

Further, the participants established that the cross-section had 12 vertices: six midpoints of the edges, as Gail demonstrated, and six additional points (see Figure 1e), which they found using a spare wooden edge as a line of intersection of the cross-section plane with the icosahedron's edges.

Discussion

The illustrative case study shows that embodied argumentation is not merely an aid but an integral part of how pre-service teachers construct and communicate geometric proofs. The analysis of the icosahedron task reveals how physical actions and perceptual processes constitute the mathematical argumentation of pre-service teachers.

Firstly, Gail's embodied argumentation exemplifies how a sequence of physical actions can serve as a form of mathematical proof. By sliding her hands along the edges and establishing symmetry, she transformed an abstract geometric property into a concrete perceptual experience for her and the group. The activity in which a group of peers first constructed and then explored the model prepared Gail and other participants to establish a more intimate connection to the mathematical object to externalize their reasoning, supporting both her insight and other arguments of the group (see Nathan et al., 2021 on insight and proof). When she prepared her argumentation, Gail used her hands to approximate distances and moved toward and from the model, thus changing perspective and angles of view (literally zooming in and out of the model). Gail's embodied argumentation emerged gradually through simulation, changes of gaze, and repositioning of the body in relation to the model.

Secondly, Tim's eye-tracking data (following Gail's gestures and anticipating the midpoint identification) reveals how perception is tightly coupled with physical action in embodied argumentation. As Walkington et al. (2019) suggest, gestures can act as collaborative tools, allowing learners to share their reasoning. In this case, Tim's tracking of Gail's physical movements enabled him to quickly understand and replicate her argument for the rest of the group.

Moreover, the internalization, reproduction, and endorsement of Gail's embodied proof by her peer—a future teacher, suggests he finds it valid. Given that the participants are prospective teachers, this acceptance provides a valuable opportunity to influence classroom culture by broadening the scope of argumentation to include movement, manipulation, and gestures involving physical models. In the milieu of the embodied collaborative construction activity, the group accepted the argument as valid.

In contemporary classroom culture, mathematical proof is typically limited to formal, symbolic logic (Herbst et al., 2017). However, embodied argumentation—which includes physical actions, manipulation of artifacts, and gestures—offers a compelling expansion of what constitutes valid reasoning. Rooted in embodied cognition, which posits that human thought is deeply interconnected with physical interactions (Barsalou, 2008), this form of reasoning is particularly relevant in classroom discourse, where participants can perceive each other actions on shared artifacts. Manipulating objects or engaging in physical interactions, such as rotating models, constructing auxiliary elements, or positioning geometric shapes, often reveals mathematical relationships that might be difficult to express verbally (Palatnik et al., 2023). These actions, along with gestures such

as pointing to a diagram or highlighting spatial connections, are not supplementary but integral to mathematical argumentation. Expanding the definition of proof to include embodied argumentation aligns with the interactive nature of classroom learning, where norms are shaped by teachers and students collaboratively constructing knowledge (Stylianides et al., 2022).

Expanding the definition of proof to include embodied argumentation reflects the multimodal ways students interact with mathematical notions, promoting a more inclusive understanding of proof. By fostering a classroom culture that embraces embodied argumentation, educators can better support students' reasoning processes, particularly in spatial and geometric contexts, where physical interaction with objects significantly enhances comprehension. This shift also echoes practices in professional communities, such as in research settings, where manipulating physical models and performing gestures play a role in the collaborative negotiation of meaning and problem-solving (e.g., Roth, 2001). Embodied argumentation may be integrated into sedentary classroom practices in ways similar to PWW-based activities (Marco et al., 2022), where reasoning based on visual information is a stepping stone for the gap-filling process, leading to more formal proving methods.

In conclusion, recognizing embodied argumentation as a legitimate form of proof in classroom discourse expands the cultural norms of mathematics education, making it more reflective and inclusive of how humans do mathematics by naturally integrating its embodied and formal aspects. Future research should explore tasks that best elicit embodied argumentation, methods for training teachers to facilitate it, and strategies for fostering effective group interactions.

Analysis and categorization of errors in the geometry of prospective primary teachers

Petra Pirklova[1], Jiri Brehovsky[2] and Daniela Bimova[3]

[1,2,3]Technical University of Liberec, Faculty of Science-Humanities and Education, Liberec, Czech Republic; petra.pirklova@tul.cz

In this paper, we present the results of a quantitative and qualitative analysis of geometry tests taken by prospective primary teachers. The main objective was to develop a classification of the errors made by students and to assess them qualitatively in terms of their nature, severity and potential danger to the understanding of geometry at an appropriate level. The results of this analysis were compared with the results of similar studies in an attempt to reveal which deficiencies in knowledge and skills in geometry future first-grade primary school teachers exhibit and how serious they are. The findings allow us to better focus on important areas and innovate geometry teaching so that it has a high potential to increase the level of geometric thinking of the students.

Keywords: Geometry, errors, prospective primary teachers, geometric thinking.

Introduction

It is obvious that already in the first grade of elementary school it is necessary to pay increased attention to the teaching of geometry. It is during this period that pupils form basic geometric ideas, the first definitions of geometric concepts are introduced, and the relationships between geometric objects are explored. This leads to an important development of geometric thinking (Douglas & Clements, 2011; Robichaux-Davis & Guarino, 2016). Increasing the level of geometric thinking contributes to enhancing students´ proficiency in other mathematical skills that are important, for example, for problem-solving (Clements & Sarama, 2007). Geometric thinking has a significant impact on the correct representation of numerical magnitude and the understanding of numerical relationships (Geary, 2007) and supports arithmetic transformations (Hubbard et al., 2005).

However, many studies have shown that prospective primary teachers do not achieve the level of geometric thinking necessary for their future profession (e.g. Milsaps, 2013). Unal et al (2009) state that one of the reasons for pupils´ low knowledge in geometry is the fact that many primary school teachers lack sufficient geometric knowledge and are unable to provide their pupils with appropriate educational opportunities to facilitate their geometric understanding. Thus, the depth of the teacher's understanding of the taught topic is what most influences the type of mathematics instruction (van der Sandt & Nieuwoudt, 2003). It is obvious that in order to achieve better pupils´ results in geometry, it is necessary to consider the level of knowledge of their future teachers.

Students' mathematical errors

The level of understanding of geometric tasks and the ability to solve geometric problems varies among students. The errors that students make when solving problems also vary. Newman (1977) presented a basic classification of the types of errors that students make during their written solutions. She divided errors into five categories:

- **Reading errors** are caused by the solver's inability to read keywords, variables, or symbols written in the mathematical problem task;
- **Comprehension errors** arise from the inability to understand the meaning of the words in the assignment of a mathematical problem, the solver then uses an inappropriate approach to the solution;
- **Transformation errors** are caused by the solver´s inability to convert the given problem into a mathematically accepted form or to schematically represent the given information;
- **Process skills errors** occur when the solver does not know the steps needed to complete solution algorithm;
- **Encoding errors** occur when the solver incorrectly interprets his results (the solution or answer is correct, but the solver is unable to explain it).

Morales (2014) states that solving mathematical problems requires both conceptual and procedural knowledge. A student´s **conceptual knowledge** refers to knowledge of mathematical facts and properties that are related to each other, whereas **procedural knowledge** consists of a set of rules and algorithms that the student uses to solve mathematical problems. Brown and Skow (2016) also address pupils' errors in mathematics. They divide these errors into three categories.

1. **Factual errors** are caused by a lack of factual knowledge (the student does not understand the meaning of concepts such as line segment, angle, triangle or perimeter);
2. **Procedural errors** are caused by the incorrect use of a rule or solution algorithm (e.g., missing sketch or discussion for a geometric construction);
3. **Conceptual errors** are caused by misconceptions or a misunderstanding of the basic principles and ideas associated with a mathematical concept (e.g., failure to recognize a geometric figure when its position changes).

In his publication, dedicated to the correction of mathematics tests and intended for future teachers, Trávníček (2006) introduces six categories of errors. The first four categories **A-D** are devoted to the types of errors made by students, the fifth category includes grammatical errors, and the sixth category refers to an error made by the teacher during correction.

Aim of the Study and Research Questions

The aim of this study is to find out which errors are made by prospective primary teachers when solving geometry problems in written work and how serious they are, and then to create a classification of these errors. This study seeks to find answers to the following questions: What types of errors do students training to become first-grade primary school teachers make when they solve geometry problems? Based on this, what impact might these errors have on the future practice of prospective primary teachers?

Research method

In order to answer the research questions, a detailed analysis of the writings of students training to become first-grade primary school teachers was conducted, providing sufficient quantitative and qualitative data. The analysis focused on written final exam paper that students take in the 4th year after the completing the two-semester Elementary Geometry course. The analyses were carried out

annually from 2021 to 2024. A total of 161 final tests were assessed over four years. For each test, the authors of the paper carefully reviewed them to determine the number and types of errors in each problem. The types of errors were registered according to the chosen categorization. The identified errors were classified using the categorization according to Brown and Skow (2016) (**BS**) and a modified categorization based on Trávníček (2006) (**T**). The original error categories **A-D** from Trávníček (2006) were supplemented by an additional category **E** called Inattention errors. The modified categorization can be viewed in Table 1.

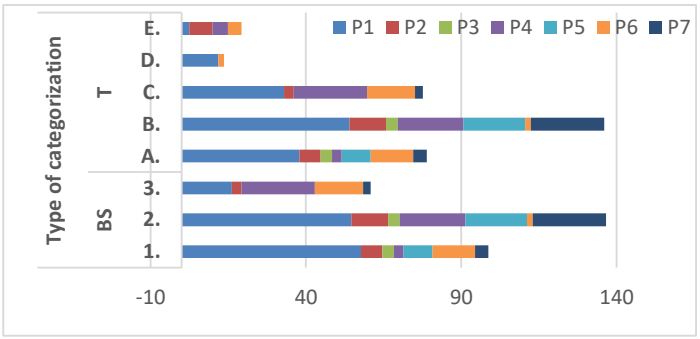
Table 1: Modified categorization of errors in tests by Trávníček (2006)

Category	Description
A. Clueless errors	The solution of the problem or its essential part is completely missing or is replaced by disjointed, confused notations or random constructions (e.g., confusion of geometric operations, construction of a different figure than requested in the assignment, confusion between formulas for volume and surface area, choosing a formula for a different solid than requested in the assignment).
B. Factual logical errors (semantic)	These errors invalidate the factual and logical part of the solution (a part of the construction is neglected, or an inaccurate analysis of the construction task initiates an incorrect construction, e.g. marking faulty properties of the figure, using incorrect analogies).
C. Factual numerical / graphical errors	Partially incorrect or incomplete knowledge of principles, formulas, and algorithms, or their incorrect use (e.g., misleading sketch, translation by an incorrect vector, incorrect visibility of the solid, faulty conversion of units).
D. Formal errors	These errors may seem minor, but they can sometimes become factual, i.e. serious, errors during the construction (e.g. careless symbolic of the construction, a missing part of the solution in the construction task, inaccurate drawing, or unprofessional expression).
E. Inattention errors	These are errors caused by careless reading of the assignment. The solver overlooks a condition in the assignment and does not apply it during the solution process, but otherwise has the solution completely correct (e.g., incorrect size of the segment, rotation in the plane made around a different point, or by a different angle than given in the assignment).

The combination of these two categorizations was selected because **BS** provides a basic overview of student errors; however, it does not divide them in as much detail as is necessary for the selected analysis. Therefore, the categorization was refined according to **T**. The second reason for using the **T** categorization is its application in detecting errors in student tests in Czech schools. Both of these categorizations then provide a comprehensive overview of errors in student tests. While the error groups in **T** classification are not necessarily disjunctive (Trávníček, 2006), several types of errors may occur in each problem. The decisive factor for assigning an error to a category was its nature and cause. Each error was assigned to one category in the appropriate categorization, **BS** or **T**. The test each year contained the same seven types of problems: **P1**. A constructive positional non-parametric problem solved using locus with given properties; **P2**. the representation of a planar figure in a plane-congruent geometric mapping; **P3**. identifying the intersection or union of two planar figures;

P4. the representation of a solid in free parallel projection; **P5**. the representation of a solid in a spatial-congruent geometric mapping (in free parallel projection); **P6**. the calculation of a solid's measure (volume or surface area); **P7**. determining the set of all points in the plane according to the given properties.

These problems were selected to cover the content of the mentioned course Elementary Geometry, while also theoretically and practically addressing the topics taught in Czech elementary schools. These problems also aim to verify whether prospective primary teachers have the appropriate overview and a sufficient understanding of the theoretical foundations of these topics. More specifically, problem P1 assesses the ability to master and apply the properties of basic geometric shapes when constructing them using loci defined by specific properties. It also evaluates knowledge of all parts of the construction problem, the use of symbolic notation, and correct geometric expression. Problem P2 tests whether the student is able to display planar figures using planar geometric mappings. In problem P3, the test checkes whether the students understand, recognize, and can use operations on point sets, and also whether they have knowledge of the properties of basic geometric shapes and the relevant scholarly terminology. In solving problem P4, students demonstrate their knowledge of terminology, the properties of solids, and ability to project solids onto the plane using free parallel projection. Problem P5 focuses on spatial geometric mappings, understanding the difference between planar and spatial mappings, and also tests knowledge of the use and properties of free parallel projection. Solving the numerical problem P6 requires the solver to recognize the difference between the area of a planar figure and the volume of a solid, to know the properties of solids and planar figures needed for calculating measurements, to be familiar with the appropriate scholarly terminology, units of measurement, and their conversions. The understanding of the metric and spatial relationships of point sets in the plane and the use of geometric operations on point sets are demonstrated when students solve the problem P7. The test as a whole assesses whether the student has sufficient knowledge, understanding, and skills to develop geometric reasoning and spatial visualization skills in their future pupils.



Results and discussion

For each problem described above, the frequency of individual errors within the given categories was determined. The relative frequencies of errors in each problem for the appropriate category are given in Table 2 and Diagram 1.

Table 2: Relative frequencies of errors in problems by categories

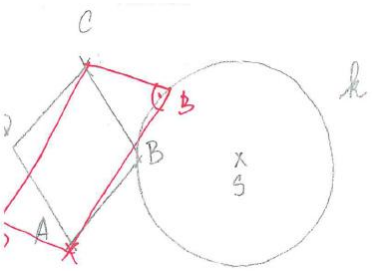
problem	Type of categorization							
	BS [%]			T [%]				
	1.	2.	3.	A.	B.	C.	D.	E.
P1	58	55	16	38	54	33	12	2
P2	7	12	3	7	12	3	0	7
P3	4	4	0	4	4	0	0	0
P4	3	21	24	3	21	24	0	5
P5	9	20	0	9	20	0	0	0
P6	14	2	16	14	2	16	2	4
P7	4	24	2	4	24	2	0	0

Diagram 1: Relative frequencies of errors in problems by categories

We will now describe the above-mentioned results for each type of problem, which are sorted in descending order according to the number of errors that students made during the solution process.

P1. The constructive positional non-parametric problem solved using a set of all points of loci

The results of the analysis show that tasks of this type pose the greatest difficulties for students. Factual and procedural errors were made by more than 50% of students. Factual logical errors were the most common, occurring in 54% of cases (e.g. missing part of the geometrical construction, lack of knowledge of important properties of the constructed figures – an example is shown in Figure 1, resulting in a different figure being constructed, or one of the solutions being omitted because, for example, not all necessary intersections were marked), clueless errors appeared in 38% of cases (the problem was not solved at all, or the solver did not know the rules for symbolic notations of the construction, which did not match the construction), and factual graphical errors occurred in 33% of cases (the solution included an inadequate and imprecise sketch, which contained misleading information). These results highlight significant deficiencies in students´ cognitive domain.

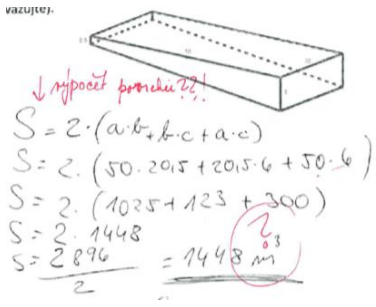


Task: Circle k and two points A, C are given in the plane. Construct a rectangle $ABCD$ with point B on the circle k.		Error: In the sketch, a parallelogram was marked instead of a rectangle. Red note by the teacher.

Figure 1: Example of a logical error in P1.

P4. The representation of the solid in free parallel projection;

This is the second most challenging type of problems, in which more than 20% of students made procedural and conceptual errors. Similarly, there were factual logical errors (students did not follow basic rules for representation in free parallel projection) and graphical errors (incorrectly indicated the visibility of the represented solid). This indicates insufficient understanding of the issue among more than one-fifth of the students.



Task: Calculate the volume of the represented solid.		Error: Instead the volume area is calculated. Furthermore, the formula for calculating the area is also chosen incorrectly – for a different solid. At the end of the calculation, an incorrect unit is written. Red note by teacher.

Figure 2: Example of a clueless error in P6.

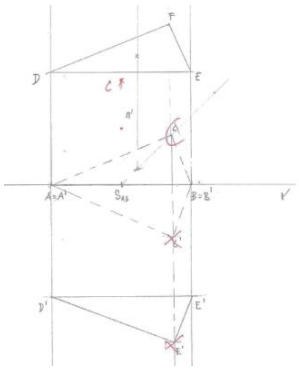
P6. The calculation of a solid's measure (volume or surface area of a solid)

In this type of problem, both factual and clueless errors occur (e.g., confusion of formulas for calculating volume and surface area, using a formula for a different solid than specified in the assignment

– an example is shown in Figure 2, or not solving the problem at all) (both occurring in 14% of cases), as well as conceptual errors and factual computational errors (incorrect unit conversion) (both 16%). In these cases, students lack the necessary factual knowledge as well as algorithmic and numerical skills. The other categories are minimally represented.

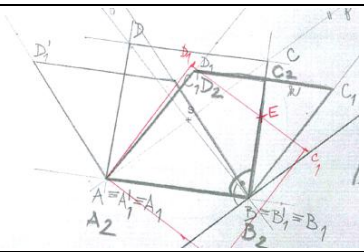
P7. Determining the set of all points in the plane according to the given properties.
This type of problem is close to P6 in terms of the number of errors but differs in the types of errors. Procedural errors and factual logical errors both have the same representation (24%) (students have a poor understanding of the given figures and the relationships between them, leading to failure in identifying the essence of the problem, or students create a correct sketch of the situation but is unable to correctly name the set represented). Other categories are represented in less than 4%. Therefore, students have the greatest difficulties with the process of solving the problem.

P5. Determining the image of a solid in a spatial geometric mapping (in free parallel projection)
The last task type in which any of the categories reaches 20%. These are procedural errors and factual logical errors (e.g., confusion between axial symmetry in the plane and in space – an example is shown in Figure 3, negligence or lack of knowledge, such as representation in homothety with an opposite sign). Again, the biggest complications are in the geometric construction process itself. Factual errors and clueless errors reached 9% (i.e., the problem was either not solved at all or was solved chaotically without knowledge of the properties of the mapping). Other categories are not represented.



Task: Represent a regular triangular prism $ABCDEF$ in free parallel projection with axial symmetry in space with respect to the axis AB.		Error: The solid is not displayed in spatial axial symmetry (in free parallel projection), but instead with axial symmetry in the plane. Red note by the teacher.

Figure 3: Example of a logical error in P5.



Task: Rotate the square $ABCD$ by an angle of $-30°$ about centre of rotation A.		Error: The result is not a square but a parallelogram $A_1B_1C_1D_1$. Red note by the teacher.

Figure 4: Example of a logical error in P2.

P2. Representation of a planar figure in a planar congruent geometric mapping
The most common errors in the solution were procedural and factual logical errors (both 12%) (due to a lack of knowledge of the principles of mapping and its properties, e.g., the type of figure was not

preserved – an example is shown in Figure 4), followed by factual errors and clueless errors (the problem was not solved) (both 7%). We also observed inattention errors, particularly in reading, where, for example, a different center of rotation was chosen than the one specified in the assignment. Students made such errors in 7% of cases.

P3. Identifying the intersection or union of two plane figures

In this type of problem, students made the fewest errors. None of the categories exceeded 4%. The most common issue was the incorrect naming of the resulting figure from a given operation due to a lack of knowledge of the properties of the figure, or confusion regarding the set operations mentioned.

Conclusion

Procedural and factual errors (**BS**), factual logical errors (semantic), and clueless errors (**T**) were the most commonly observed in the tests. The most significant difficulty students struggled with was their demonstrated lack of knowledge of the basic properties of geometric shapes and their components. These difficulties were evident in the majority of tasks. For example, they led students to construct different figures than required in construction problems solved using sets of points with given properties or in free parallel projection, or to calculate the measurement of a different shape than described in the task. They also incorrectly determined the resulting figure from set operations such as intersection and union. A major issue is the lack of understanding of the properties of geometric transformations, whether planar or spatial. A sign of helplessness in solving problems is, of course, the complete absence of a solution. Student solutions show that, in many cases, prospective primary teachers understand the properties of geometric figures in isolation, lacking a conceptual understanding based on the synthesis of their properties. These findings are consistent with Cunningham and Roberts (2010). The observed difficulties and types of errors made by prospective primary teachers are very similar to those made by students in the Unified Secondary School Entrance Examination (CERMAT, 2023). Primary school teachers build the foundations of geometry and geometric skills in their pupils. If these teachers do not have a solid understanding of these concepts, they cannot effectively pass them on. This is especially true when the teacher does not understand the reasons and significance of the errors described above. In such cases, they will not recognize these errors in their students and will be unable to address them methodologically and didactically. The results of this study will help us to focus on the areas where prospective primary teachers struggle the most during instruction.

On the mutual relationship of different construction tools and mathematical concepts

Marc Sauerwein[1]

[1]Technische Universität Berlin, Germany; sauerwein@math.tu-berlin.de

For many reasons, straightedge and compass have been regarded as the classic construction tools of geometry since Euclid's Elements. With increasing experience, their use becomes decoupled from the direct construction activities with straightedge and compass. If this decoupling process is not given space in geometry lessons, there is a risk that pupils will not recognise the underlying structures and will not be able to use individual standard constructions in a meaningful and relevant way to solve geometric questions. The article would therefore like to start before this abstraction process and focus on different construction methods in order to show how the respective construction could shape the view on the geometric object. The interplay of different construction methods in geometry lessons can create opportunities that can be beneficial for both conceptual and language development in geometry lessons.

Keywords: Subject-matter didactics, planar geometry, mathematical notions/concept, development of mathematical language

Introduction

Since Euclid's Elements, geometric constructions have had a firm place both in mathematical culture and in mathematical school curricula worldwide. In the case of Euclid's Elements, geometric constructions always refer to the special tool set consisting of (unscaled) straightedge and (collapsing) compass. 38 such (consecutive) construction problems are presented in the first four books, based on the three postulates:

> "I.) Let it be granted that a straight line may be drawn from any point to any other point. II.) Let it be granted that a finite straight line may be produced to any length in a straight line. III.) Let it be granted that a circle may be described with any centre at any distance from that centre." (Byrne, 1847, p. xxii)

Basic constructions include perpendiculars, bisectors and perpendiculars/parallels to a straight line through a given point. In addition to the aspect of mathematical tradition, numerous other central objectives of maths lessons are associated with geometric constructions with straightedge and compass, such as discovery learning, proving, concept learning and problem solving (Kuzle, 2013). In the game Euclidea, a further aspect (intellectual challenge) is added, as the fastest possible constructions are sought there. For example, constructing the perpendicular to a straight line g through a point A (Book 1, Prop. 11) is possible with only 1 circle and 2 straight lines and thus faster than Euclid, who needed 3 circles and 1 straight line (Berendonk, 2021). A further strength of these construction tools is, on the one hand, their simple describability in terms of the above three postulates, which nevertheless induces an enormously rich mathematical structure, as can be seen in the concept of constructible numbers and their connection to the three classical problems of antiquity (cube doubling, angle division, squaring of the circle).

Different ways of construction

With increasing experience, the use of these tools is decoupled from the direct construction activities with straightedge and compass after the first standard constructions have been recognised as feasible.

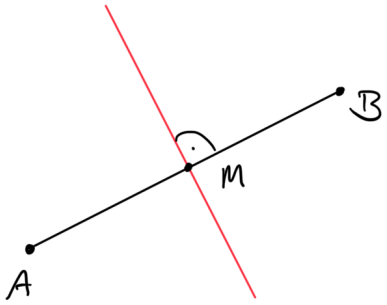

Figure 1: The perpendicular bisector of the line segment *AB*

When you look at a drawing like the one in Figure 1, it is not immediately clear what exactly this red line represents. The view of this red line depends on the context in which it was drawn and the underlying construction:

- 'Centre-perpendicular[1]': A straight line could have been drawn with a geometry set square that runs through the midpoint of the line segment AB and is perpendicular to it.
- 'Iso-distance line': Using a straightedge and compass, two points could have been constructed using circles that are the same distance from A and B respectively. It can then be quickly shown that the straight line g defined by these two points has the following property: $g = \{P | d(P, A) = d(P, B)\}$.
- 'Axis of symmetry': Folding the paper by folding point B onto point A creates this straight fold or mirror axis.

The previous example illustrates that even the concept illustrated in Figure 1 can give rise to different points of view. These perspectives and their interconnection become necessary in a school context, for example, when it is proven that the perpendicular bisectors of a triangle intersect at a point and that this point is the centre of the circumcircle of the triangle. In this article we propose to vary construction tools, thereby varying the focus on the constructed object. With our theoretical considerations we follow the idea of Pandiscio:

> […] a single task completed with a variety of construction tools fosters a greater sense of mathematical contemplation than multiple tasks done with the same tool. The premises are simple: each tool fosters different mathematical ideas, and using multiple tools not only requires understanding of a greater breadth and depth of geometric concepts but also highlights the connections that exist among different ideas. (Pandiscio, 1995, p. 32)

[1] In order to emphasise the perspectives of the construction tool on the constructed objects, we do not use the canonical identifier (perpendicular bisector) at this point, but ad-hoc formulations appropriate to the respective context.

The interaction of different construction methods in geometry lessons can create opportunities that can be beneficial for both concept development and language development in geometry lessons. For the following explanations, we assume that the learners are familiar with straightedge and compass constructions. The change of construction tool should therefore serve to reflect on (and possibly expand) the familiar concepts.

Theoretical background

The van Hiele levels are a classic theory of concept development which is an "important but less frequently used reference" within the CERME geometry group (Palatnik et al., 2023, p. 686). It assumes that a learner starts at the zeroth van Hiele level for each geometric object (independent of the concrete course of instruction). The activity of local ordering of object properties is primarily associated with the second level:

> At the Second Level properties are ordered. They are deduced one from another: one property precedes or follows another property. At this level the intrinsic meaning of deduction is not understood by the students. The square is recognised as being a rectangle because at this level definitions of figure come into play. (van Hiele, 1985, p. 245)

We will see that the constructions and their associated activities presented here create appropriate occasions for questioning the standard constructions with straightedge and compass and the associated terminology with the intermediate level learners. The learning of (mathematical) concepts is strongly interwoven with the development of an appropriate language as van Hiele points out:

> Each level has its own linguistic symbols and its own system of relations connecting these signs. A relation which is "correct" at one level can reveal itself to be incorrect at another. Think, for example, of the relation between a rectangle and a square. Numerous linguistic symbols appear at two successive levels; moreover they establish a liaison between the various levels and assume continuity of thought in this discontinuous domain. But their meaning is different: it becomes manifest by other relations among these symbols. (van Hiele, 1985, p. 246)

Instead of using the generally adopted mathematical terms directly, we will follow Winter's (1978) *workshop language* approach, in which we use appropriate terms for the geometric objects in order to better distinguish between the different nuances of meaning. These different terms should reflect the construction of the named object. Although this intermediate language is strongly context-bound, Winter emphasises that this is an important step in the development of technical terms that should not be taken too quickly (Winter, 1978). The transition from the informal to the formal language register and the space in-between are still being researched (Ingram et al., 2023) and Prediger & Zindel (2017) used the term "school academic register". However, this notion does not reflect the roughcast character of Winter's naming.

The cardboard wedge as alternative method of construction

In the following, we will use a cardboard wedge (as shown in Figure 2) for our geometric constructions. It can be used to mark off a given angle and to draw straight lines. If students made their own cardboard wedge after seeing my cardboard wedge, this would result in different acute angles. In addition to the construction of the straight line in Figure 1, we want to construct the

perpendicular to a straight line g through a point P, the parallel to a straight line g through a point P and the bisector of two legs and illustrate potentials with regard to the development of language and concepts.

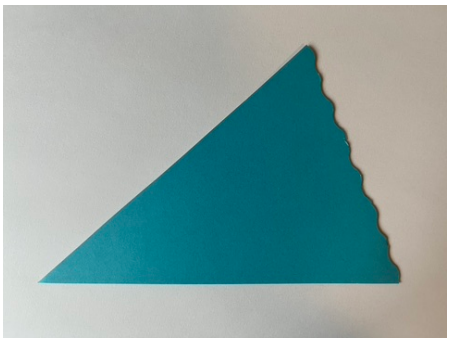

Figure 2: A cardboard wedge without length unit (due to Karl-Heinz Hürten[2])

If we now consider a given line segment AB, we can use the cardboard wedge to take a bearing of a direction. This results in a ray with initial point A consisting of all points P such the angle BAP is the same for all P. If we repeat this angle bearing three more times, we obtain two points P_1 and P_2 such that ABP_1 and AP_2B form isosceles triangle (Figure 3). In the spirit of workshop language, we could name these triangles *isobaseangular* triangles, as they were created by only marking off the given angle. It must now be discussed with learners that the straight line through P_1 and P_2 is independent of the specific angle in the cardboard wedge and that this straight line is an *iso-angle straight line*, that it contains all points P for which A, B and P form an *isobaseangular* triangle.

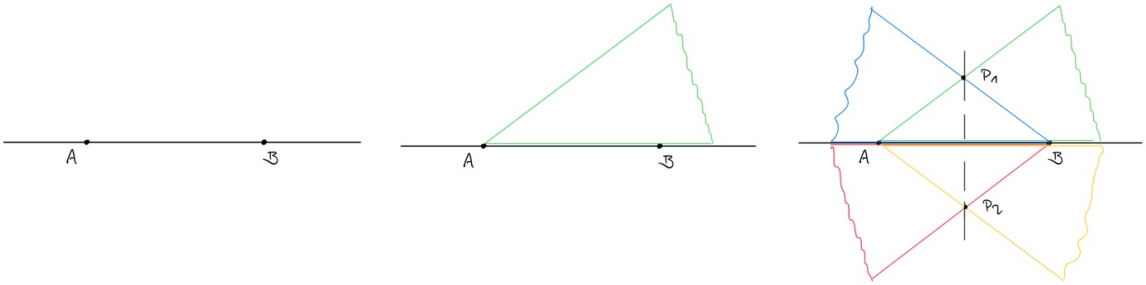

Figure 3: Construction of the *iso-angle line* via a cardboard wedge

The construction of the line in Figure 3 exclusively uses the angular ablation and should therefore also be distinguished from the perpendicular bisector from a linguistic and conceptual point of view. If we now organise the properties ‘iso-angle line’ and ‘iso-distance line’ by considering symmetry, we obtain the base angle theorem in a natural way.

If we want to construct the parallel to a given straight line g through a point A, the corresponding task for the construction with the cardboard wedge requires a different formulation: first we look for the point on the straight line g so that we can aim at point A and the straight line g at the fixed angle.

[2] Karl-Heinz Hürten belonged among other teachers and didacticians to a group which was concerned with subject-matter didactics and was involved in the design and development of teaching materials (Behnke & Stowasser, 1979).

Finally, we aim at the angle from point A again (but rotated by 180°). This gives us the green straight line (in Figure 4), which we do not yet know whether it intersects the given straight line or not. Instead of the true parallel property (having no intersection points), this construction allows us to focus on the alternating angle theorem.

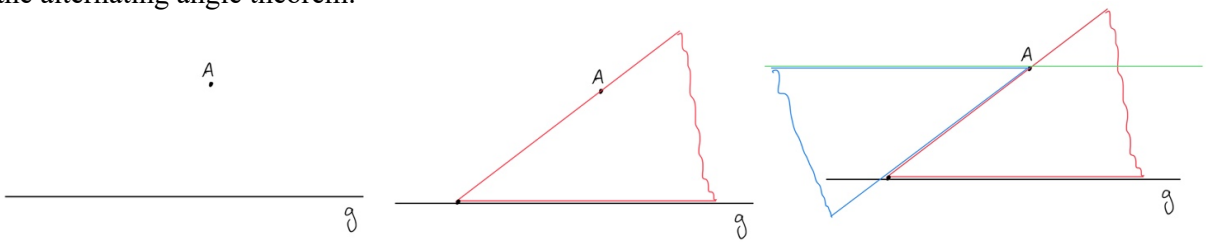

Figure 4: Construction of the parallel through a given point

If we want to construct the perpendicular to a straight line g through a point A, it becomes clear that the cases of whether point A lies on the straight line g or not must be solved differently. If A does not lie on the line, we can first construct an *isobaseangular* triangle ABC by taking a bearing (Figure 5). For the line BC, we can now apply the lower half of the perpendicular centre line construction and finally obtain the perpendicular through point A.

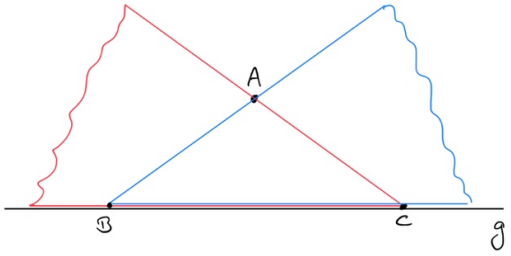

Figure 5: (Auxiliary) Construction of an isobaseangular triangle

Although the cardboard wedge can only be used to mark off angles of a fixed size (instead of distances), constructions were possible that were very similar to the classic straightedge and compass constructions. When trying to construct the perpendicular of a straight line g through a point A on the straight line, it is noticeable that we cannot easily imitate this: we cannot mark off a fixed length. However, it is possible to construct a perpendicular bisector to any two points on the line and then draw a suitable parallel through point A (Figure 6).

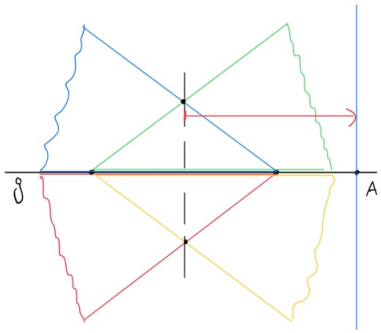

Figure 6: Translation of an arbitrary perpendicular (bisector)

The previous problem has shown that we have not yet been able to mark off any distances. We therefore extend the wedge by a fixed marked length, which is marked off on both sides of the cardboard wedge (Figure 7).

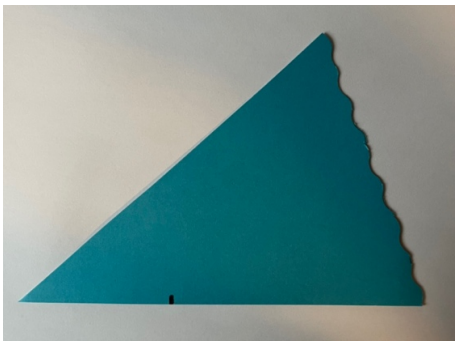

Figure 7: The marked length on the wedge

With this marked wedge, it is now possible to shorten the construction from Figure 6 by placing the wedge with the marked point at point A as shown in Figure 8. With the construction shown, we now obtain the perpendicular bisector to the points that lie at the tips of the blue and green wedge (B and C). The constructed line also passes through A due to its isodistance property.

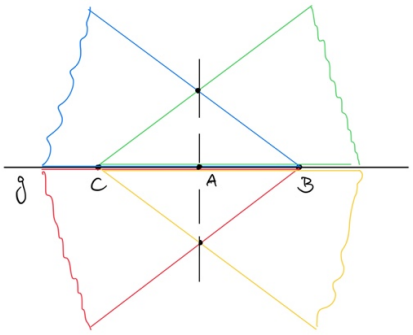

Figure 8: Shorter Construction of the perpendicular

The possibility of marking off a given fixed line segment opens up another previously impossible construction: the angle bisector. To do this, we mark off the fixed distance on both legs of the angle and obtain the points A and B. The perpendicular bisector of AB is then the angle bisector of the angle BSA (Figure 9).

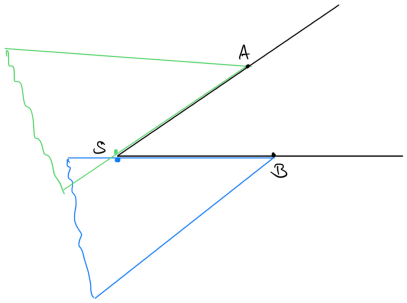

Figure 9: Preparation for the bisector of an angle

Discussion

The different constructions of the perpendicular bisector of a line segment AB and their different terms in the workshop language initially make it necessary to distinguish the constructed lines from each other. Only when learners argue on the second van Hiele level, it is possible to connect these *different* lines by relating their primary properties and agree on a single term (independent of its concrete genesis). The theoretical analysis indicates that the activity of local ordering is strongly connected to the use of appropriate lingual means taking up the genesis of the constructed objects. The presented constructions with a cardboard wedge give rise to tasks and problems which can initially question the canonical approach in German schools via the Euclidean straightedge and compass constructions (in the spirit of Pandiscio). Moreover, it is an easily accessible material and can be easily made from cardboard.

In the afore-mentioned analysis, it was assumed that the learners would be familiar with constructions by straightedge and compass. It should be noted that there is no indication that the presented approach via the cardboard wedge cannot be used as a first encounter with geometric constructions in school. Furthermore, this context offers opportunities to the learners for their own investigations: for example, what would happen if the cardboard wedge had an obtuse angle or a right angle? Hence, the presented construction holds different possible applications for teaching with different goals.

Conclusion

Although the constructions with the wedge are as powerful as the classical constructions with straightedge and compass[3], the focus here is on the contribution to the development of concepts (and language) and less on the discussion of the range (resp. limitations) of these constructions[4]. It has become clear that the use of different construction methods can offer opportunities for the activity of local ordering (second van Hiele level). Thus, by comparing at least two construction methods, a richer conceptualisation can be made possible, which would hardly unfold with an exclusive straightedge and compass construction. The subject-matter analysis in this article can be seen as a first step towards an implementation in a developmental research project (or the like).

Acknowledgment

I would like to thank Alois Görg and Peter Fitting for making me aware of the work of Karl-Heinz Hürten.

[3] Martin (1998, p. 102) calls these wedge constructions “acute-angle ruler constructions” and shows their equivalence to the straightedge and compass constructions.

[4] From such a point of view, the approach via origami would be better as it is more powerful than the Euclidean constructions in the sense that the Delian problem (doubling the cube) can be solved (Geretschläger, 1995).

3D printed manipulatives as an aid in constructing parallel and central projections of solids

Petra Surynková

Charles University, Faculty of Mathematics and Physics, Charles University, Prague, Czech Republic; surynkov@karlin.mff.cuni.cz

The main goal of this research was to explore the effect of using concrete 3D printed manipulatives on students' ability to construct projections of solid figures in both parallel and central projections. These projection techniques were introduced to university students in the course "Basics of Projections" at the Faculty of Mathematics and Physics, Charles University, Czech Republic. The use of 3D printed manipulatives in this course was implemented during the winter semesters, first in 2021/2022 with twenty-seven students, and again in 2023/2024 with twenty-four students. This study aimed to assess how manipulating physical 3D printed models could improve students' grasp of different projection methods and deepen their conceptual understanding. The research sought to evaluate and compare students' performance in solving geometric projection tasks, both with and without the use of 3D printed manipulatives. Students were more successful in constructing projections, when using 3D printed models.

Keywords: projections, 3D printed manipulatives, geometry of solid figures.

Introduction

Geometry is often challenging for students at all levels of education, as it requires strong spatial perception and abstract thinking. Instructional aids, particularly 3D models, can help by turning abstract concepts into tangible objects. The use of 3D printing technology has expanded into many fields, including construction, medicine, and cultural heritage (Tsoulfas et al., 2020) and has also opened new possibilities in education by providing innovative methods to support the teaching and learning of STEM subjects (Novak & Wisdom, 2018). Research suggests a positive impact of 3D printed tools on spatial reasoning and mathematical understanding (Herrera et al., 2019), while other studies highlight its role in concrete mathematical concepts like surface area (Corum & Garofalo, 2015). Although 3D printing and the 3D printed objects are becoming more common in education, further research is needed to better understand its impact on teaching.

Building on these findings, our research investigates the specific impact of ready-made 3D printed models on teaching projections in university education. Based on my long-term teaching experience and international studies (Garmendia et al., 2007), it is evident that even university students often struggle with spatial ability which is essential in all areas of geometry, including projections. They find it challenging to visualize spatial situations without physical or virtual models, which can assist them in solving geometric tasks. Although 3D models can be made from various materials, using 3D printing has clear advantages – source files for models can be shared with other students or schools, and models can be reproduced quickly and affordably. Many schools, at least in the Czech Republic, already have 3D printers, allowing them to produce their own models rather than purchasing them.

Our research, therefore, focuses on the following research questions:

Does the use of 3D printed models in constructing projections of basic solid figures help students understand spatial relationships?

Does the use of 3D printed models help determine the visibility of parts of geometric objects in the resulting images of projections?

In addition, we inquire about the specific types of geometric tasks in which 3D-printed models are most beneficial. We explore whether repeated use of 3D-printed models throughout the course enhances students' long-term retention of projection techniques and whether students can maintain their improved skills in projection techniques even after they stop using the models. Finally, we investigate students' perceptions and attitudes toward the use of 3D printed models in their learning process, focusing on how these models influence their understanding.

Theoretical Framework

Concrete and virtual manipulatives in mathematics education

Manipulatives are tools designed to support teaching and learning, engaging students in the learning process while helping them build conceptual understanding and solve mathematical problems. Concrete manipulatives are physical objects, while virtual manipulatives are dynamic, interactive visualizations on computers (Clements, 1999; 2009; Moyer et al., 2002). Pupils and students can interact with dynamic visual representations in ways similar to handling physical objects. 3D printed models, which we use in our teaching and examine for their impact on learning, are a prime example of concrete manipulatives. These models are tangible aids that help students comprehend abstract mathematical concepts.

The effectiveness of manipulatives in mathematics instruction has been widely studied. In a meta-analysis, Sowell (1989) found that the use of manipulatives led to higher achievement at all elementary school levels. However, the study did not clearly identify which specific situations are most suitable for the use of manipulatives. Students who use manipulatives often outperform those who do not (Clements, 1999), a finding that holds across different grade levels, ability levels, and mathematical topics, provided the manipulatives are appropriate for the mathematical topic. Manipulatives are particularly beneficial for helping students to grasp abstract mathematical ideas (Kontaş, 2016). Using models (e.g., 3D printed, wooden, or made of modeling clay) significantly contributes to improving students' understanding of geometry (Bímová et al., 2023).

Action-oriented teaching methods that involve the use of real physical models have consistently shown positive effects on the development of spatial ability. This is linked to the theory of embodied cognition, which emphasizes the role of motor behavior in cognitive processes (Schneegans & Schöner, 2008). Embodied mathematical thinking suggests that mathematical cognition is deeply rooted in physical interactions with the environment and materials (Palatnik & Abrahamson, 2022; Ng & Ye, 2022).

However, not all research supports the use of manipulatives. Some studies have found that manipulatives have no significant effect on students' mathematical achievements (Clements, 1999,

Uribe-Flórez & Wilkins, 2017). It is important to recognize that manipulatives alone do not guarantee success or meaningful learning. If we use it only for rote learning, they may fail to enhance students' understanding of mathematical concepts. Sometimes, teachers use manipulatives without fully considering how these tools support the understanding of the particular mathematical content. In such cases, manipulatives are used merely as a distraction or novelty in the classroom.

Students' Perception of Drawings

Visualizations play a critical role in understanding mathematics, especially in geometry. Mathematical objects, both two-dimensional and three-dimensional, are often represented on a two-dimensional plane. First geometry lessons usually focus on two-dimensional figures, which serve as the foundation for understanding three-dimensional objects. These drawings are crucial tools for comprehending complex mathematical ideas, bridging the gap between our experiences in three-dimensional space and abstract mathematical concepts.

To interpret a drawing that illustrates a mathematical or geometrical idea, it is necessary to establish the connection between the drawing and the concept it represents. Duval (1995) describes this process as involving four types of figure apprehension: perceptual, discursive, sequential, and operative. Each type provides a unique perspective on how a drawing corresponds to the underlying mathematical concept.

Duval (2005) also distinguishes between two forms of geometric visualization: iconic and non-iconic. Iconic visualization involves recognizing shapes that resemble familiar objects, while non-iconic visualization interprets drawings as representations of geometric entities, emphasizing the relationships between components rather than their appearance. Students often alternate between these two forms of visualization when developing geometric understanding. Iconic visualization allows students to identify a three-dimensional object based on its overall shape—especially when the object is presented in a typical, familiar view. Physical models provide tangible representations that support students in connecting their spatial perception with the interpretation of geometric drawings, facilitating the development of iconic visualization. However, non-iconic visualization is essential for a deeper understanding of spatial geometry. In this approach, students move beyond mere recognition of shapes and begin to perceive objects as a composition of interrelated elements and structures. Physical models play a crucial role in supporting students as they physically explore and analyze the relationships between different components of an object, such as edges, vertices, and faces. For example, manipulating a model can help students understand how edges are connected, how different parts of a solid are oriented relative to each other, or how visibility changes depending on the viewing angle. These relationships are often abstract or difficult to visualize from drawings alone. When students work with physical models to project three-dimensional objects, they shift from simply identifying shapes (iconic) to analyzing the relationships and components of the objects (non-iconic).

Parallel and Central Projections

Three-dimensional objects can be represented on a two-dimensional plane using the technique of projection. There are two primary methods of projections: parallel projection and central (or perspective) projection (Carlbom & Paciorek, 1978). In parallel projection, objects maintain their

relative proportions and shapes. A common example of parallel projection is orthographic projection, in which the viewpoint is placed at infinity, and the lines of sight are perpendicular to the projection plane. On the other hand, central or perspective projection reflects how objects naturally appear to the human eye, providing a sense of depth and perspective.

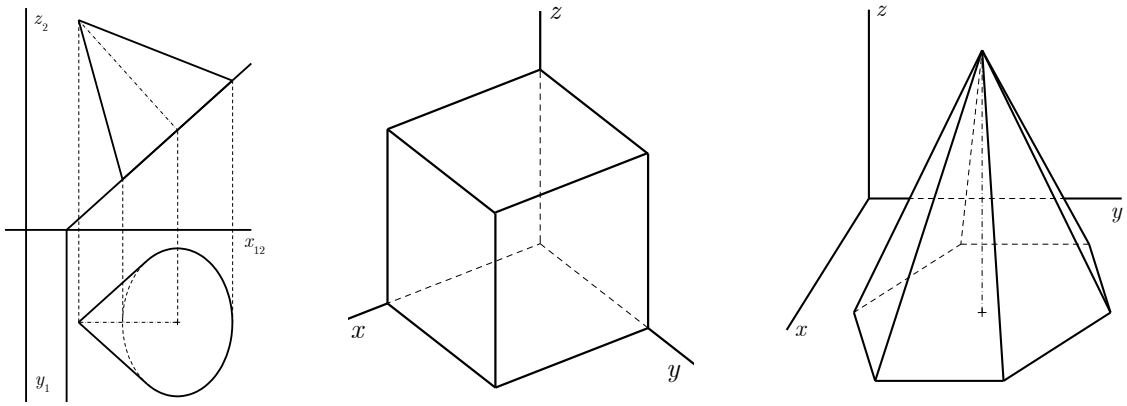

Figure 1: Examples of projections – top and front orthographic view of a cone (on the left), an axonometric orthographic projection of a cube (in the middle), and an oblique projection of a hexagonal pyramid (on the right)

In the university course where this research was conducted, various types of parallel and central projections were introduced. Specifically, we explored top and front orthographic views (see Figure 1, on the left), axonometric orthographic projections (see Figure 1, in the middle), oblique projections (see Figure 1, on the right), and linear perspectives as examples of central projections. In each case, students were tasked to manually construct the projection of a solid figure on paper.

The main problems students face in constructing the projections of solid figures are related to imagining how solid figures appear, determining the visibility of their parts, and understanding spatial relationships between components. Sorby & Baartmans (2000) specifically describe difficulties students experience in spatial visualization tasks using various standardized tests, such as determining cross-sections and cutting planes or performing mental rotations. We believe that the use of 3D physical models can help students overcome these challenges.

Materials and methods

3D Printed Set of Solid Figures

For our experiments, we designed and 3D-printed a new set of solid figures. The set contains right and oblique prisms with regular three- to six-sided bases, cubes, cuboids, right and oblique pyramids with regular three- to six-sided bases, right and oblique cylinders and cones, and spheres. Each set contains all of these types of solid figures and was created for each student to work independently. One such set of solid figures is shown in Figure 2 on the left.

Research context and data collections

The study aims to explore how activities with 3D printed manipulatives contribute to developing students' conceptual understanding of solid figure projections. It also investigates how these models help students understand geometric relationships between the components of objects and determine

the visibility of parts in the resulting projection. The use of 3D printed manipulatives was integrated into the "Basics of Projections" course during the winter semesters of 2021/2022, with twenty-seven students, and 2023/2024, with twenty-four students. Each session lasted 90 minutes and was held weekly throughout both semesters.

Each course was partially structured as a lecture with exercises, demonstrated alongside their solutions. During the lectures, 3D printed models and 3D modeling software were used (by the teacher) to illustrate the projections. This was followed by practical sessions where students constructed the projections of individual solid figures themselves. Students were assigned various tasks, including constructing projections of different solid figures such as polyhedrons, cylinders, cones, and spheres. Additionally, students engaged in geometric exercises involving these projections, such as determining the intersection between a polyhedron and a plane.

The tasks were completed both with and without the use of 3D printed manipulatives or, in some cases, first without and then with—this approach was specified for every exercise. This allowed us to compare students' success rates. For all tasks, students manually drew the projections on paper. The students' work throughout both semesters was continuously analyzed (with selected tasks being evaluated) to assess whether the use of 3D printed models led to increased success in solving geometric problems.

Let us focus on one representative exercise to discuss how students worked:

"Construct the top and front orthographic views (Monge projection) of an oblique prism *ABCDA'B'C'D'* with a square base *ABCD* in the (*x*, *y*)-plane, given the coordinates of *A*, *B* and *S'* (the center of the base *A'B'C'D'*). Determine the visibility of the solid figure." (Semester 2021/2022, submitted by 25 students, the solution can be seen in Figure 2 on the right).

Figure 2: A 3D printed set of solid figures and the right solution of the exercise

The exercise had three subtasks, each evaluated with one point for correct solution: constructing the top view, constructing the front view, and determining visibility. Students initially worked without any visual aids, and the exercise was evaluated by the teacher. Afterwards, the same students were provided with a 3D printed model of the solid and asked to solve the same exercise again. Other exercises were tested in a similar manner.

Students were asked to discuss the benefits of using the 3D printed models as visual aids after each intervention. The feedback from students regarding their experiences with the use of 3D printed models was analyzed (gathered only through oral interviews and discussions).

To pass the course and earn credits, students were required to complete a final test consisting of five exercises on various types of solid figure projections, this time without any visual aids. The final test was administered at the end of the semester. Students were not graded based on their performance during the semester.

Results

The comparative analysis of student success rates for the presented geometric task is summarized in Table 1. This table summarizes the performance of 25 students in three subtasks in the exercise without and with the use of 3D models. The "Score" column indicates whether students achieved 0 or 1 point for each subtask, and the corresponding columns show the number of students who achieved these scores in each category. The last row labeled "Total Success" highlights the overall percentage of correct solutions for each subtask. Additionally, a "Difference" row has been added to show the improvement in success rates between the two scenarios.

Table 1: Comparison of student success rates in geometric exercise with and without the use of 3D printed models

Score	Top view (without/with 3D model)	Front view (without/with 3D model)	Visibility (without/with 3D model)
0	6 / 1	5 / 1	7 / 1
1	19 / 24	20 / 24	18 / 24
Total Success	76.0% / 96.0%	80.0% / 96.0%	72.0% / 96.0%
Difference	20.0%	16.0%	24.0%

From the data in Table 1, it is apparent that when solving the same tasks for the second time with the model, students were more successful, particularly in the subtask related to visibility determination. This was somewhat anticipated, as the use of models can effectively demonstrate both visibility and the front and top views. Only one student remained unsuccessful even with the 3D model; however, with the teacher's guidance, they were able to identify the correct solution. The correct solution to the task was shown to the students only after they had completed the tasks.

Regarding other exercises, in some cases, the success rate did not improve (some students even solved the task incorrectly with the model), while in others, it did. Students' success rates in more complex exercises were lower (in several cases less than 50%). Overall, the results show that when students used 3D printed models, they were more successful in constructing projections of solid figures, particularly when determining the visibility of vertices, edges, or faces of the objects.

Student feedback regarding the use of 3D printed models was overwhelmingly positive. Their responses highlighted the educational advantages and increased engagement that these models provided. For example, one student noted: “The models really helped me understand the visibility of the solid figure. I finally grasped why some edges are hidden in certain projections.” Another student commented on the enjoyment: “The models made even the drawing part more enjoyable—it felt a bit like playing a game.” These responses suggest that 3D models not only deepened students' understanding of geometric concepts but also made the learning more engaging and enjoyable.

The findings of our study indicate that the use of 3D printed models significantly enhanced students' ability to construct projections of solid figures. By working with physical models during the projection process, students progressed from merely recognizing shapes (iconic visualization) to understanding the complex relationships and structures within the objects (non-iconic visualization). At the beginning, students identified only the shape of the solid (iconic visualization) and made errors in projections, particularly in determining visibility. However, through working with 3D models, they were able to distinguish hidden edges and spatial arrangements (non-iconic visualization), which is an example of the development in their visualization skills. Similarly, Mithalal and Balacheff (2019) demonstrated the effectiveness of 3D Dynamic Geometry Environments, which allowed students to explore and manipulate drawings representing three-dimensional geometric objects. This approach played a key role in bridging the gap between iconic and non-iconic visualization. Our findings also align with prior research (Kontaş, 2016), which highlights the value of manipulatives in making abstract mathematical concepts more concrete.

Conclusion and future plans

This study demonstrated the potential of 3D printed models in assisting students with constructing projections of solid figures. Their impact was particularly evident when students determined the visibility of vertices, edges, and faces in projections. Furthermore, the use of physical models significantly enhanced students' ability to solve geometric problems on paper by improving their spatial visualization. These results underscore the value of 3D printed models in helping students transition from iconic to non-iconic visualization, a critical step in geometric comprehension.

In our future work, we plan to expand the collection of 3D printed models and further involve students in the design and creation process. This approach could encourage students to develop a stronger understanding of geometric principles through hands-on 3D printing experience. We also plan to conduct further tests with larger student groups to collect more comprehensive data on the impact of 3D printed models in various geometrical contexts.

Teaching the concept of minimal definition with the CoD Method

Leonardo Tortorelli[1] and Francesco Saverio Tortoriello[1]

University of Salerno, Faculty of Mathematics, Salerno, Italy; ltortorelli@unisa.it

Solving the difficulties students face in gaining full understanding of definitions is a significant challenge faced by mathematics education: without this, it is difficult, for example, to acquire problem-solving or proof skills. This study, conducted in a 5th-grade class, is a first step towards modelling a teaching-learning experience regarding minimal definitions. The method used is new and innovative (Cost of Definition Method) and consists of a mathematical discussion, orchestrated by the teacher in which a method is taught to identify redundant definitions and, in such cases, to reduce them to minimal definitions. In this activity, the children must carefully analyse each critical attribute and evaluate whether it is necessary or redundant. This process forces them to delve deeply into the meaning of the definition and each of its parts, fostering a more profound understanding.

Keywords: Geometrical definitions, non-economical definitions, quadrilaterals, mathematical discussion, classificatory thinking.

Introduction

Several studies have proven that students and trainee teachers at all school levels encounter various difficulties related to geometric definitions: difficulties in identifying, classifying, and constructing examples and counterexamples of the concept (Haj-Yahya et al., 2022). Numerous studies highlight issues due to a less-than-optimal understanding of the structure and meaning of definitions. In this regard, chronologically, one could refer to the articles by Hershkowitz (1987), Vinner & Dreyfus (1989), Hershkowitz (1989), Hershkowitz et al. (1990), Fujita & Jones (2007), Pickreign (2007), Marchis (2012), Fujita (2012), Haj-Yahya & Hershkowitz (2013). The difficulties associated with defining activities increase significantly in primary school due to the tendency of teachers to provide definitions as a long list of properties of the object. Given these challenges in geometric definition, this study explores the potential of the *Cost of Definition* (*CoD*) *Method* to enhance primary school students' understanding. The research question guiding this study is: 'Can the application of the CoD Method improve the meta-concept of minimal definition in primary school?' The analysis of the results is qualitative, focusing on the examination of transcripts from mathematical discussions, and will be elaborated upon in the following sections.

Theoretical Framework

In this study, following Haj-Yahya et al. (2022), *minimal definitions* are defined as those that include the minimum number of critical attributes necessary and sufficient to define a concept. This criterion is referred to as the *Criterion of Minimisation of Definitions*. It implies that definitions should not include redundant or derivable information from other parts of the definition itself. The principle aims to promote clarity and essentiality, avoiding overwhelming students with unnecessary details. Definitions that do not adhere to the *Criterion of Minimisation of Definitions* are also referred to as non-economical or redundant definitions (Linchevsky et al., 1992; de Villiers, 1998) because minimal definitions generally lead to more economical proofs, resulting in shorter and sometimes less

repetitive demonstrations. These studies show that students and teachers use redundant definitions because they consist of more critical attributes than are strictly necessary. Similar findings are also noted in de Villiers et al. (2009) and Foster (2014), where it was observed that students propose correct but descriptive definitions. Specifically, they tend to list all the properties of the concept. Learning the concept of minimality in definitions and educating students to recognise or produce minimal definitions is considered crucial for developing and enhancing definitional thinking (Tortorelli & Tortoriello, 2024; Haj-Yahya et al., 2022). A clarifying example of a minimal definition can be found in Vinner (1991), where the following minimal definition of a rectangle is presented: 'A quadrilateral is defined as a rectangle if and only if it is a quadrilateral with at least three right angles.' This definition differs from the one typically found in textbooks: 'A quadrilateral is defined as a rectangle if and only if it is a quadrilateral with all right angles.' The latter definition is not minimal because, according to a theorem in Euclidean geometry, the measure of the fourth angle can be deduced by knowing the total measure of the other three. In this experiment, the *Cost of Definition Method* (Tortorelli, 2025), abbreviated as *CoD Method*, will be used. This method is designed to teach students how to recognise whether a definition is redundant. The method also suggests a model of mathematical discussion that could lead to the minimality of definitions. This is achieved through the estimation and comparison of their *costs*. It is now necessary to specify what is meant by the 'cost of a definition.' In this work, a function is proposed that assigns to each definition formulable in a given theory of quadrilaterals a positive integer, which will be called the *Cost of Definition*. The *Cost of the definition D* of a quadrilateral *q* is defined as the number of critical attributes it utilises. The properties considered as possible *critical attributes* are being a quadrilateral or having: 2 parallel sides, 2 perpendicular sides, 2 congruent consecutive sides, 2 congruent opposite sides, 2 congruent opposite angles, 2 congruent adjacent angles, 2 complementary angles, 2 opposite supplementary angles. Each of these properties is conventionally assigned a virtual value of 1 *ca* (initial letters of *critical attributes*). To indicate *Cost of Definition D of a quadrilateral q* we suggest using the notation: $c(D,q)$. For example, denoting by *D*, the Vinner definition of a rectangle (Vinner, 1991), i.e.: 'A quadrilateral is defined as a rectangle if and only if it has at least three right angles', we have that the cost of the definition is: $c(D,rectangle) = 3\ ca$. The concept of 'cost' in this context serves as a pedagogical tool to help students and teachers recognize the efficiency of definitions. By assigning a numerical value to each attribute, this method encourages a focus on the most essential attributes, avoiding the inclusion of redundant or derivable properties. This not only streamlines the learning process but also fosters a deeper understanding of the role of each attribute in defining geometric figures. The following theorem illustrates the equivalence of two definitions in terms of cost, further supporting the principle that minimal definitions can be derived from more complex ones without losing essential meaning. In this study, the term 'equivalent definitions' is used in the sense of Haj-Yahya et al.: 'Two definitions of the same concept are equivalent if one can deduce one formulation from the other and vice versa.' (Haj-Yahya et. al., 2022, p. 610) *Theorem of the cost of equivalent definitions*: *Given two minimal definitions* D_1 *and* D_2 *of the same quadrilateral q constructed in the Theory of Quadrilaterals, it results that:* $cod(D_1,q) = cod(D_2,q) \Leftrightarrow$ (D_1 and D_2 are equivalent definitions). For example, consider the following two right-angled trapezia definitions, D_1: 'A right-angled trapezia is defined as a quadrilateral having at least one pair of parallel sides and at least two perpendicular sides'; D_2: 'A right-angled trapezoid is defined as a quadrilateral having at least one pair of parallel

sides and at least one straight angle'. It is easily demonstrated that D_1 and D_2 are equivalent definitions and thus the cost of D_2 can be derived from the cost of D_1: $c(D_2,q) = c(D_1,q) = 2$ *ca*. The *CoD Method* is taught through a mathematical discussion (Bartolini Bussi, 1996), which Bartolini Bussi defines as a polyphony of voices (in Bachtin's sense) articulated around a mathematical object (concept, problem, procedure, etc.), which constitutes a motif of the teaching-learning activity.

Method

The experimental context was developed as part of the PhD project entitled *'Development of definitory thinking in geometry through the Geometriko Academy instrument'*. The meetings were managed by the curricular teacher, supported by our research team. The sample consists of a fifth class of an Italian primary school. The class examined consists of 17 students. The class has already studied the theory of quadrilaterals with their teacher. The teacher adheres to a traditional pedagogical approach and asserts that a mnemonic method of definition is the only viable technique at the primary level of education. Furthermore, the teacher believes that children are not yet equipped with the cognitive abilities necessary to grasp the concept of definition. The teacher's traditionalist views of the teacher was what determined the choice of this class for the experiment. The *Teaching Methodological Cycle* comprised four phases: firstly, an entrance test was administered; secondly, a frontal dialogue lesson on the concept of definition was conducted; thirdly, the *CoD Method* was applied using the mathematical discussion method; and finally, the exit test was administered.

Results and analysis of results

The analysis of the results was qualitative and will be carried out by examining the transcripts of the *mathematical discussions* and through the comparative results of an entrance test and an exit test. In this paragraph, some excerpts from the mathematical discussion are given which can help us to answer the question research of this study. The researcher plays the part of the teacher.

010.	Teacher:	Consider the following definition of a trapezium: 'A quadrilateral is defined as a trapezium if and only if it has at least one pair of parallel sides.' This definition costs 1 *ca* and is a minimal definition, or as many say, an economical definition. Let's look at a more complex definition, denoted as D_1: 'A quadrilateral is defined as a parallelogram if and only if it has opposite sides parallel, opposite sides congruent, and opposite angles congruent.' The definition D_1 costs 6 *ca* and is a non-economical definition. What do you think I mean by the *cost of a definition*? What determines the *cost of definitions*? We *pay* in *ca*, which is our official currency used for definitions. So, what is 1 *ca*? In this context, 1 *ca* represents the cost assigned to each *critical attribute* used in a definition. Each attribute, such as parallelism, congruence of sides, or congruence of angles, is assigned a cost of 1 *ca*. Therefore, the overall *cost of a definition* is the total number of independent *critical attributes* it uses. A *minimal definition* is one that achieves the intended concept using the least number of attributes, thereby having the lowest cost in terms of *ca*.
011.	Francesca:	So the number of lines in the definition has nothing to do with it...
012.	Filippo:	No no... We don't have to count characters or words …
016.	Domenico:	I get it! In my opinion money is *critical attributes*... *ca* is the initial letter of the words *critical attributes*! I guessed it teacher?
017.	Marialuce:	True! I also think the coin is the *critical attributes*! In fact in the definition of the trapezium they are because... it's only one... 'at least one pair of parallel sides' and it only costs 1 *ca*. The second definition... that of the parallelogram costs so much because it has so many *critical attributes*... It costs 6 *ca*...

018. Vittoria R. This is also the case for me …
019. Teacher: Well done! Marialuce explained well why the definition of trapezium I chose costs 1 *ca*. Can you explain to me why the definition I have called D1 of a parallelogram costs exactly 6 *ca*?
020. Aldo: We have to count the... the things that the parallelogram has... One... two... three and... after three I don't understand! Why six?
021. Licia: The properties we mention… but I don't quite agree… teacher, I count three!
022. Angela: That's true, I also count three… There are three…

Many children use their fingers to count and raise their hand with three fingers up, almost to reinforce that number. Licia, however, is not convinced and recounts once more out loud:

023. Licia: Teacher, I still count 3! So… 'opposite sides parallel' costs one *ca*, 'opposite sides congruent' costs another *ca*, making 2 *ca* and the last one, 'opposite angles congruent,' costs yet another *ca*. Altogether, it's 3 *ca*, not 6 *ca*!
024. Giorgia: I don't understand… Teacher, why does it cost 6 *ca*? I think it is worth less...
025. Teacher: Let's count them together. If we want to *buy* the definition: 'Opposite sides parallel,' how many *ca* does it cost?
026. Matteo: One *ca*!
025. Teacher: Are you all in agreement? What does 'opposite sides parallel' mean?
027. Lucrezia: Well… 'opposite sides parallel' means that two opposite sides are parallel, and then… and then the remaining ones are also parallel… So…
028. Domenico: So, it costs 2 *ca* because… we first spend one *ca* to obtain what Lucrezia said, 'two opposite sides parallel' and then spend another *ca* to obtain the property that the remaining sides are also parallel. So overall, it costs 2 *ca*.
029. Carlo: That seems like a correct reasoning…
030. Filippo: But if what Domenico says is right, 'congruent opposite sides' also costs 2 *ca* and not 1 *ca* as it seems...
031. Marialuce: Right! So we have to spend 2 *ca* for parallel opposite sides, another 2 *ca* for congruent opposite sides and again 2 *ca* for …
032. Francesca: ... for congruent opposite angles! Two, two more and two more... that's 6 *ca* in all! Here we go at last, the numbers add up....
033. Teacher: In short, we count the properties of the sides and angles. The definition D_1 of a parallelogram is too expensive and we must try to save money. I propose a challenge: take the definition D_1 and, starting from it, can you create a new definition D_2 of parallelogram such that D_2 is cheaper than D_1? I suggest a strategy: we start from the given definition and remove one or more properties at a time and see if the new cut definition is still an unambiguous description of the parallelogram.

The teacher acts based on the teachings of Bartolini Bussi (1996). Their intervention in the discussion [033] occurs at a moment when it is necessary to guide the class in establishing meanings both at a local level (cost of definition) and at a global level (the meaning of a non-economical definition and its reduction to a minimal definition). This is done using a technique employed when a student provides a clear, relevant example or makes a positive contribution to the discussion. In this case, Domenico unlocks the situation [028], which had been stalled until then, and the teacher seizes the opportunity to paraphrase some general concepts related to minimal definitions.

A few minutes pass, and the children try drawing new quadrilaterals on paper. The drawing exercises enable students to test their definitions, leading to a deeper grasp of geometric concepts.

040. Domenico: I have removed a pair of congruent opposite angles and am now testing... Every attempt I always come up with a parallelogram...

041. Lucrezia: I am trying without considering congruent opposite angles. I have tried many times and the drawings are always parallelograms....
042. Carlo: Domenico saved 1 *ca*... Lucrezia saved 2 *ca* together …
043. Filippo: It's the truth! Lucrezia you're a genius, I hadn't thought of taking twin properties together...
044. Marialuce: Filippo, I'm also trying to remove two duplicate properties. First, I removed just one, and then while experimenting, I saw that the other one isn't necessary either. I did many drawings, and whenever I use opposite sides parallel and opposite sides congruent, I always end up with a parallelogram automatically. Opposite angles congruent are unnecessary. So, the new definition is more economical and only includes opposite sides parallel and congruent.
045. Teacher: Perfect! I see that many of you agree that the pair of properties asking for 'opposite angles congruent' are optional. Mathematicians refer to these as 'redundant properties'. Redundant properties in a definition are those that can be derived from the others. By removing the pair of properties asking for opposite angles congruent, definition D_1 is reduced to a more economical definition. We will call this new definition D_2. D_2 can be expressed as: 'A quadrilateral is a parallelogram if and only if it has opposite sides parallel and opposite sides congruent. Do we still have uniqueness? I'll give you 5 minutes to think about it. Take a pencil and graph paper, and draw some quadrilaterals with these properties. This exercise is called 'Find the Counterexample.' The winner is the one who manages to draw a quadrilateral with the properties of D_2 that is not a parallelogram.

This teacher's intervention constitutes an initial phase of institutionalization through a mirroring with integration approach (Bartolini Bussi et al., 1995), where the student's contribution [Marialuce, 44] is repeated with some improvements in the language, expressed in a more academic manner. The definition provided is not necessarily the final one—that is, the one that will be definitively institutionalized and later recorded by the students in their notebooks—because, although it is unique, it is not yet minimal.

Almost 10 minutes elapse during which the children rehearse with pen and paper.

046. Mattia: Teacher, I won the challenge! I found some quadrilaterals that have the properties of the definition D_2 but are not parallelograms. Here they are: a rectangle, a square… there are many more…
047. Angela: Me too... beyond I found the rhombus not to be a parallelogram....
046. Domenico: The cheapest definition doesn't work. I'll try removing something else.
048. Licia: What do we do now?

One by one, all the children raise their hands and present incorrect counterexamples due to serious issues related to a complete lack of classificatory thinking skills [046, 047, 048]. This reveals a clear absence of interplay between the figural aspect and the conceptual aspect, and consequently, the failure to form figural concepts (Fischbein, 1993). This analysis can help interpret the problems with classificatory thinking.

049. Teacher: Do the counterexamples you have drawn verify the D_1 definition?
050. Domenico: Yes, they check it …
051. Lucrezia: If they check D_1 are parallelograms, it is not true?
052. Vittoria R.: True! So we are all wrong... rectangles, rhombuses and squares are parallelograms …
053. Licia: So nobody won... D_2 is valid then!

054. Filippo: How nice if we use D_2 we save a bit!
055. Licia: So nobody won... D_2 is valid then!
056. Teacher: So… has anyone managed to draw a quadrilateral that satisfies the aspiring definition of a parallelogram, D_2, but is not a parallelogram?

This is a suggestive help question in the sense Bartolini Bussi et al. (1995) based on the interpretivist approach; in this case, the tone of voice suggests the answer, which in this case is negative. No one answers.

057. Teacher: Great! None of you were able to draw a quadrilateral with opposite sides parallel and congruent that is not a parallelogram because such a quadrilateral does not exist! We have a new definition. The original price was 6 *ca*, but what is the current cost of this item?
058. Carlo: In my opinion it costs two and two so four …
059. Domenico: That's right! It costs 4 *ca*!
060. Voices: Yes, yes it costs 4 *ca*.
061. Teacher: Perfect! This new definition costs 4 *ca*. Let's continue with the game… Now I'll remove another pair of properties and propose the following more economical definition, which we'll call D_3: 'A quadrilateral is a parallelogram if and only if it has opposite sides parallel.' Do we still have uniqueness? I'll give you 5 minutes to reflect. Again, take a pencil and graph paper, and draw all the quadrilaterals with opposite sides parallel that come to mind. Do you always end up with a parallelogram? I challenge you to find a quadrilateral that is not a parallelogram!

The discussion continues. The children, under the guidance of the teacher, understand (also empirically with the help of drawings) that the definition D_3 uniquely identifies a parallelogram and that its cost is 2 *ca*. The *CoD Method* seems to work. The teacher challenges the children with a further task, asking them to eliminate one of the two remaining properties (a pair of parallel opposite sides) and to check whether the resulting quadrilateral is still a parallelogram. The children immediately realise that this definition costs only 1 *ca* and that such a low cost is unacceptable because the property 'at least two parallel sides' is trivially satisfied by all trapezia. The children realise that the attempt to further reduce the cost of the definition of a parallelogram from 2 *ca* to 1 *ca* has failed. A few students try to use other properties of sides or angles, but fail to invent a definition of a parallelogram that costs only 1 *ca*.

After taking the entrance test, the children did not revisit it again until it was administered again in the form of an exit test. The assessment and the solution of the entrance test were never communicated to the pupils. It was decided to do the two tests the same (minus the order of the items and the order of the answer options) in order to have a homogeneous comparison of results. In addition, in order to prevent the children from remembering answers already given in the entrance test when completing the exit test, it was administered after a sufficiently long time (six and a half months). Figure 1 shows a comparative summary of the results of the entrance test and the exit test and as an example, the text of two of the five items (the first and fourth items). To verify the transfer of skills, it was decided to base the two tests on a different definition of quadrilateral (the rectangle) from those analysed during the mathematical discussion (the trapezia and the parallelogram). Item 1 is the one with the highest number of correct answers in both tests. Lucrezia's answer to item 4 is very interesting because she unconsciously applies the *Theorem of the cost of equivalent definitions*: 'The definition given is minimal because it costs 3 *ca* like the one the teacher gave us who wants at least 3 right angles to give us a rectangle. This also costs 3

ca because it asks us for a parallelogram which we know costs 2 *ca* and then it also asks for a right angle which costs 1 *ca* and so in total makes 3 *ca*'.

Item Number	Entrance Test (March 2023) - N=16		Exit Test (September 2024) - N=16	
	Correct answer rate	Incorrect answer rate	Correct answer rate	Incorrect answer rate
1	37,4%	62,6%	93,8%	6,3%
2	31,3%	68,7%	62,4%	37,6%
3	31,2%	68,8%	50,0%	50,0%
4	18,7%	81,3%	81,2%	18,8%
5	12,5%	87,5%	75,0%	25,0%

1. Andrea: "A quadrilateral is a rectangle if and only if it has all right angles".
☐ It is acceptable as a definition and is also minimal.
☐ It is acceptable as a definition, but it is not minimal. Why?
☐ It is not acceptable as a definition (it is not unique). In this case, draw a counterexample.

4. Francis: "A quadrilateral is a *rectangle* if and only if it is a parallelogram with at least one right angle".
☐ It is acceptable as a definition and is also minimal.
☐ It is acceptable as a definition, but it is not minimal. Why?
☐ It is not acceptable as a definition (it is not unique). In this case, draw a counterexample.

Figure 1: Summary of Entrance Test and Exit Test Results and text of items number 1 and 4

Conclusions

The findings indicate that the *CoD Method* significantly enhances students' understanding of geometric definitions. Through active engagement in discussions, students identified redundant properties and transitioned to more economical definitions. This dialogue effectively connects the results to the study's objectives, illustrating that students can comprehend complex concepts when equipped with appropriate tools. The iterative refinement of definitions—from D_1 to D_2, and potentially to D_3—demonstrates how mathematical understanding evolves through trial and error. These realizations about valid definitions signify significant growth in the student's mathematical reasoning. In the context of the *CoD Method*, teacher questioning is essential for enhancing students' understanding of geometric definitions. It clarifies concepts, encourages reflection, promotes engagement, and facilitates problem-solving. By asking strategic questions, the teacher plays a pivotal role in guiding students through the complexities of mathematical definitions, ultimately fostering greater conceptual understanding and confidence in their reasoning abilities. Consider adding relevant references to support the discussion on teacher questioning and the *CoD Method*. In conclusion, based on the analysis of the discussion dialogues and the comparative results of the two tests, we can reasonably confirm that applying the *CoD Method* in a mathematical discussion context can improve the meta-concept of minimal definition in primary school.

After a short adaptation period, the children seem to handle the *CoD Method* well; it is in line with the reasoning behind minimal definitions. It is assumed that the success of this method is due to the fact that it verifies the real need for each critical attribute within the definition and determines whether it is redundant. The student, in order to achieve the goal of minimal definitions, is compelled by the inherent dynamics of verifying the redundancy of critical attributes to thoroughly investigate the meaning of the definition and each of its properties.

Dimensions of conceptual knowledge and dynamic geometric constructions

Lukáš Vízek[1] and Libuše Samková[2]

[1]University of Hradec Králové, Czech Republic; lukas.vizek@uhk.cz

[2] University of South Bohemia in České Budějovice, Czech Republic

In this work, we focus on the kind of information on students' conceptual knowledge that can be obtained using dynamic geometry constructions of quadrilaterals. We designed an assessment instrument based on dynamic geometric constructions created in the same way as traditional Euclidean constructions with a pencil, a ruler, and a compass. The constructions are supplemented by printed answer sheets in which various properties of quadrilaterals are listed and, when relevant, asked to be justified. We show how such an approach allowed us to distinguish different dimensions of conceptual knowledge, which we illustrate through authentic examples of students' responses to the answer sheets. We also consider possible stimuli for the contribution to the development of students' conceptual knowledge and, in general, to the teaching and learning of geometry.

Keywords: Dimensions of conceptual knowledge, geometric constructions, dynamic geometry, properties of quadrilaterals

Introduction

In recent decades, conceptual knowledge has received considerable attention in mathematics education, along with procedural skills and flexibility, as they together can form the aims of teaching and learning mathematics (Verschaffel, 2024). Conceptual knowledge is generally regarded as an understanding of mathematical facts and relationships between them that results in a connected network of knowledge (Hiebert & Lefevre, 1986) and refers to a type of understanding whose quality is proportional to the depth of such connections (Star & Stylianides, 2013). In our previous research, we focused on students' reasoning about quadrilaterals (Vízek et al., 2023) and we compared its forms with van Hiele's levels of geometric thinking (van Hiele, 1986). We now follow up on our more recent study, in which we studied what information about the quality of student conceptual knowledge can be obtained using a set of dynamic geometric constructions (Vízek et al., 2024). We developed a diagnostic instrument based on dynamic constructions of quadrilaterals and using it as a data collection tool in qualitative analysis we were able to identify six different subcategories of student comprehension of plane objects. We connected them with the existing general model of conceptual knowledge (Nilsson, 2020), and elaborate on the model in a way that makes it applicable within dynamic geometry environments (DGEs). In this paper, we explain the model in detail and illustrate it by presenting different forms of student thinking that might appear while in DGEs.

We organise the text as follows: at the beginning, the possible distinction of the dimensions of conceptual knowledge is characterised, with the general background for the comprehension of geometric objects and for DGEs. Then the diagnostic instrument is described, and various modes of student understanding are presented through authentic data excerpts. Finally, we discuss the findings and possible implications for educational practice.

Theoretical background

Dimensions of conceptual knowledge

To assess the quality of student conceptual knowledge, Nilsson (2020) differentiates three dimensions of such knowledge in mathematics: *knowledge of classification*, *knowledge of structures*, and *knowledge of principles*. In that general setting, knowledge of classification means identifying a certain object and its properties, which is merely isolated or poorly connected to other facts in mathematics, knowledge of structures refers to an awareness of the interconnectedness of ideas that leads to mapping a conceptual structure of an object or a set of objects, and knowledge of principles represents the ability to connect identified ideas and their structures by establishing principles that are generally applicable and lead to conclusions to mathematical propositions.

To perform an assessment of conceptual knowledge, there are two main approaches to do so. Conceptual knowledge can be assessed implicitly according to students' preferences in solving mathematical problems, comparing different strategies, and evaluating them, or explicitly by letting students define mathematical objects, justify their properties, and explain the nature of solution procedures (Rittle-Johnson & Schneider, 2015). Both ways, but especially the second one, are typically based on assigning non-standard tasks to students, as this approach can lead the students to reveal or invent unusual solution strategies different from routine procedures (Braithwaite & Sprague, 2021).

Geometric objects

In geometry, different levels of understanding are associated with different modes of comprehending geometric objects. They can be grasped as isolated shapes, i.e. classified partially, or ordered in a structure according to their common properties, i.e. classified hierarchically (de Villiers, 1994). The partition classification belongs to primary school and typically describes geometric shapes by their initial definitions using the size of sides and interior angles. In that sense, a square is described as a quadrilateral that has all sides of the same length and all interior angles right, a rhombus has all sides of the same length, and a kite has adjacent sides of the same length.

At the lower secondary school level, individual components of the shapes are studied in detail, especially diagonals and their features. From that perspective, diagonals of a kite are perpendicular and one of them bisects the other (but not vice versa). By adding the requirement that the diagonals bisect each other, we get a rhombus. By adding another requirement that the diagonals also have the same length, we get a square. Therefore, a square can be comprehended as a special case of a rhombus, and a rhombus can be comprehended as a special case of a kite, which makes the structure of these objects hierarchical (de Villiers, 1994). The properties of these objects can be proved from their initial definitions, while such justifications lead to conclusions of general principles and can develop thinking in geometry at the upper secondary school level (Fujita & Jones, 2007).

Dynamic geometry environments

Proper comprehension of planar shapes and exploration of their properties can benefit from the use of DGEs such as Sketchometry or GeoGebra (Bebernik et al., 2022). Within these programmes, geometric objects can be created using points, lines, and circles, so they can be modelled on the same

basis as in traditional Euclidean approach with a pencil, a ruler, and a compass. However, in contrast to the static constructions performed on paper, the constructions in DGEs are not static as they have so-called free points which can be moved and the construction retroactively modified by the movement. This kind of movement is called *dragging* (Leung et al., 2013) and leads to a change in the position of lines and circles determined by the moved point(s). Such dynamic manipulations generate a whole *dragging family* of objects (Forsythe, 2015) with some mutual properties that are invariant to dragging. So, modelling the objects in DGEs can highlight what the shapes within the dragging family have in common, which may be, for example, certain properties of diagonals mentioned in the previous paragraph. In that particular case, the dragging family might comprise a kite, a rhombus, and a square.

It seems that the assessment of students' conceptual knowledge and theoretical understanding in geometry could benefit from tasks that would be designed accordingly in DGEs. In particular, dynamic modifications made to the construction through the dragging of free points can show the users common features of objects in DGEs as phenomena, i.e. on the basis of recognising invariant and changeable properties of the objects (Baccaglini-Frank, 2019). However, the challenge is to relate such phenomenological evidence to the nature of geometric objects that are determined by their construction in DGE and, so, enable to deductive reason about them (İmamoğlu et al., 2023).

The instrument

In the GeoGebra environment, we prepared dynamic constructions based on the compositions of points, lines, and circles that create certain quadrilaterals in exactly the same way as they would have been drawn with conventional hand-by-hand tools on paper. Selected free points from the constructions were given a green colour and each construction was accompanied by a printed worksheet with answer frames (Vízek et al., 2024). We assigned the constructions to the students with a prompt: "Drag the green points to find which different quadrilaterals ABCD occur in the construction. Fill in the printed worksheet for each type of quadrilateral you found." Thus, students did not have to generate their own construction. Their work in the GeoGebra environment required only dragging the prepared model but no previous experience with creating in such an environment.

To introduce the instrument in detail, we focus now on one of the constructions, namely the one containing a kite, a rhombus, and a square (see Figure 1). Its electronic version is available under the link https://www.geogebra.org/m/wgcbybfm. The construction is based on perpendicular lines AT, OP with their intersection S, the line segment BD with the midpoint S, which is part of the line OP, and the point C, which lies on the line AT. The properties of the construction are ensured by concentric circles m, n, and congruent circles k, l. The C and D points are the free points that were coloured green, that is, it is possible to drag them. The point C is movable along the line AT and the point D along the line OP. The default situation (which is also available through the refresh button) produces a quadrilateral ABCD, which is a kite because its diagonals are perpendicular to each other, and one bisects the other one. When point C is placed at point T, its diagonals already bisect each other, so ABCD is a rhombus. Finally, when point D is moved to point G, the diagonals have the same length, so ABCD is a square.

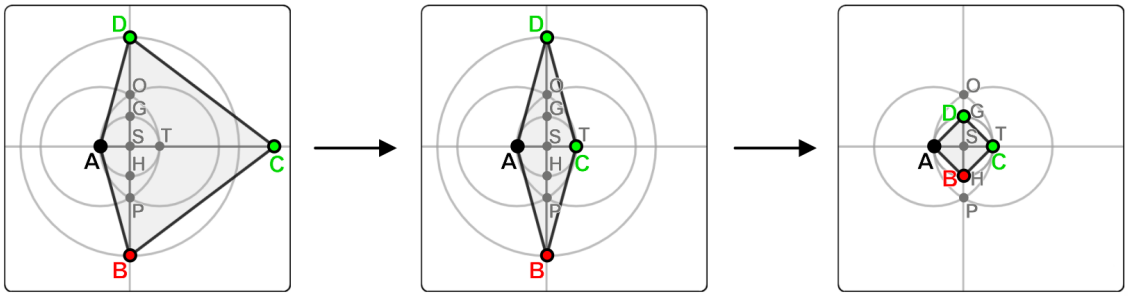

Figure 1: A kite, a rhombus, and a square appearing in the dynamic construction

The fact that a kite is a general quadrilateral in the sense of hierarchy in this particular construction, and a rhombus and a square are its special cases attainable by moving points C, D to specific exact places allowed us to prepare a universal assessment worksheet with answer frames suitable for all shapes appearing in the construction (Figure 2). For the purpose of the assessment, the worksheet is printed on paper, so that respondents can fully focus on the electronic version of the construction and fill in the worksheet at the same time. Each frame of the worksheet first asks respondents to provide the name of a quadrilateral found in the construction and to specify the exact locations of the green points that produce the quadrilateral. This unequivocally defines the shape the respondent is focusing on, and also shows whether the respondent knows the name of the quadrilateral properly. Then follows a list of various properties of diagonals intended for respondents to select and tick the ones that are relevant for the particular shape and fill in their justification besides each tick. In case a respondent noticed a property not listed, it can be specified and justified at the bottom of the frame.

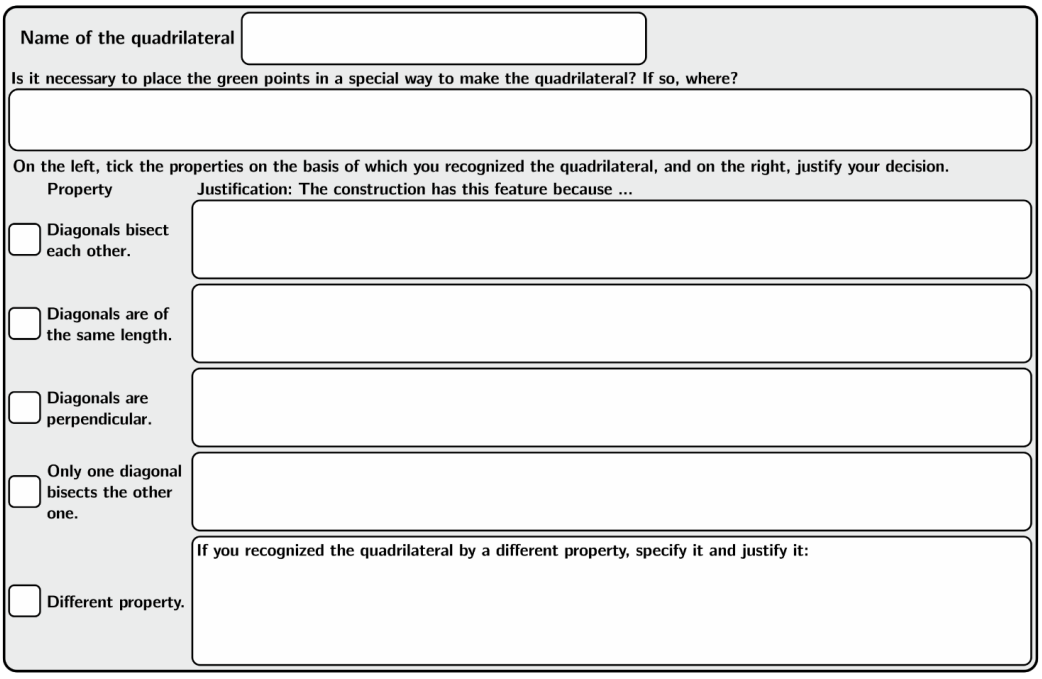

Figure 2: An answer frame for a construction based on properties of diagonals (Vízek et al., 2024)

In this paper, we focus on the kite construction because in the Czech Republic, where the study was conducted, this quadrilateral is not included in curricular documents provided by the Ministry of

Education, Youth, and Sports (MEYS, 2022, 2023). Therefore, working with kites implies a non-standard task and, therefore, the kite construction is suitable to assess the quality of students' conceptual knowledge. Our construction is also non-standard because the quadrilaterals in it are constructed on the basis of the properties of their diagonals and not on the initial definitions referring to the properties of sides and angles.

Student thinking revealed by the instrument

To capture the three dimensions of conceptual knowledge, that is, knowledge of classification, knowledge of structure, and knowledge of principles, we now show samples of authentic student thinking from the filled in answer frames. These samples come from five groups of respondents (labelled B to F); four of them (B to E) were participants of the earlier study (Vízek et al., 2024), the fifth one (F) is new, we included it to obtain a broader perspective. The groups are:

B – 16 future lower secondary school teachers, students of the master's degree program;
C – 27 future secondary school teachers, students of the bachelor's degree program;
D – 25 lower secondary school students of the age between 14 and 15 years;
E – 28 upper secondary school students of the age between 16 and 17 years;
F – 11 future lower secondary school teachers, students of the master's degree program.

To supplement the findings of the earlier study, we present only excerpts not published before. Code names of the respondents consist of a group letter and a randomly assigned order number (e.g. E19).

Knowledge of classification

Knowledge of classification is demonstrated in our context by identifying the quadrilateral contained in the dynamic construction and therefore writing its name at the top of the answer frame. This knowledge is further manifested in the description of its properties, and we distinguish between *a description of a property* and *an alternative explanation of a property*. A description of a property belongs to data excerpts where the respondent filled in a 'different property' at the bottom of the answer frame; however, this particular property was not given by the construction; instead, it just cited an initial definition of the shape based only on the size of sides and angles:

E19/Kite/Different property:	The adjacent sides are of the same length.
D01/Rhombus/Different property:	All sides are of the same length.
B15/Square/Different property:	All sides are of the same length, the angles at the vertices are 90°.

An alternative explanation of a property belongs to data where the respondent provided a justification of a ticked property by mere specifying the given property as such in a different way, without a connection to the construction. For example, some students stated that diagonals of a quadrilateral are perpendicular because they form a right angle or an angle of 90 degrees. Others presented how the ticked property translates to the shape.

F10/Square/Diagonals are of the same length: $|AC|=|BD|$

Knowledge of structures

Student statements that connect geometric shapes with their properties in a logical way represent the knowledge of structure. They can be expressed as an apprehension of *the structure of the shape* and/or

an understanding of *the structure of the construction*. The first of these perceives the shape separately from the construction, as if the lines and circles constructing the shape did not exist. However, individual elements of the shape and the way they are structured within the shape are addressed:

E01/Kite/Diagonals are perpendicular:	↔ DB is the axis of symmetry of the line segment AT => it is perpendicular
F06/Kite/Only one diagonal bisects…:	CS is the altitude of the isosceles triangle ΔDBC
F03/Kite/Only one diagonal bisects…:	Triangle ABD is isosceles, and by constructing the altitude to side a, the altitude = diagonal |AC| will pass through the midpoint of line segment |BD|

On the contrary, knowing the structure of the geometric construction ensures that the shape is perceived as an integral part of the construction, and the justifications reflect this fact by including the constructing lines and circles into the arguments:

C05/Kite/Only one diagonal bisects…:	The circles k, l ensure that BD is the axis of symmetry of AT and S is the midpoint of BD ⋀ AT, but generally |AS| ≠ |SC|.
E14/Square/Diagonals bisect each other:	The diagonals are the diameters of the circle m, bisected at the centre S.
F01/Rhombus/Diagonals bisect each o.:	m, n = concentric circles, common centre S, A, C ∈ n; B, D ∈ m; AC, BD pass through the centre S.

Knowledge of principles

When explaining the properties, *knowledge of principles* means that the student refers to statements which are generally applicable in geometry, that is, not restricted to the particular quadrilateral. These principles can be applied on the shape and its elements only, and/or on the constructing lines and circles. In our data, knowledge of principles was manifested by applying Thales's theorem (all angles above the diameter of a circle are right):

E01/Square/Diagonals are perpendicular:	Δ BCD is an isosceles triangle |DC|=|BC|. The circle m is Thales's circle of DH, where BCD = 90° → 1/2 = 45°.

or by applying the hierarchy of the shapes included in the construction, that is, by justifying a property using a reference to a justification of the same property already provided in a previous frame:

C19/Square/Diagonals are perpendicular: See kite.

Discussion and conclusion

The purpose of this paper was to connect the dimensions of conceptual knowledge to specific forms of student thinking in geometry that emerge when working with dynamic constructions. To complement and particularise our previous study (Vízek et al., 2024), we showed more data samples illustrating how a DGE construction containing a dragging family of quadrilateral shapes (a kite, a rhombus, and a square) can help to highlight and distinguish various quality levels regarding conceptual knowledge in geometry.

We posed the DGE construction as a non-standard task (Braithwaite & Sprague, 2021) by basing it only on the properties of diagonals and including a kite as a default shape, and this approach has paid off. The fact that the initial definitions with the size of sides and angles were not relevant for justifications allowed us to clearly distinguish between mere knowledge of classifications (especially,

knowledge of the name of the shape and its initial definition) and knowledge of structures (i.e. knowledge of individual elements of the shape, their relations, and/or their relation to the entire construction). That is, this approach allowed us to explicitly assess students' conceptual knowledge (Rittle-Johnson & Schneider, 2015). Compared to the dimension model of conceptual knowledge given by Nilsson (2020), we needed to be more specific in some cases, so the elaborated model has also subdimensions. The instrument allowed us to distinguish between students perceiving the shapes partially (especially, when they think about them as separate units) and hierarchically (especially, when they perceive the hierarchy as a general principle and utilise it in justifications), which particularise the meaning of the partial vs hierarchical classification given by de Villiers (1994).

From the perspective of task design, our instrument has a novel design which combines the benefits of DGEs, namely the process of dragging (Leung et al., 2013; Forsythe, 2015), which seems to encourage students to explore the features of the shapes included in the dragging construction (Bebernik et al., 2022); our data confirmed the encouragement aspect. Moreover, our instrument was constructed in a way that is in accordance with classical Euclidean constructions performed on paper. This particular design provides the solvers all relevant information about the constructed shapes, their structure, and the overall structure of the construction, which allows solvers not only to observe the properties of the included objects as phenomena of the dynamic construction (Baccaglini-Frank, 2019), but also to explain their properties in a logical way and, so, stimulate students' theoretical reasoning (İmamoğlu et al., 2023) by connecting the phenomena to their theoretical backgrounds. Future research will show whether the instrument could be also used for investigating the development of geometric reasoning in geometry at secondary school level (Fujita & Jones, 2007).

The role of perceptual clues in 3D enumeration tasks

Edgar Alstad[1] and Maren Berre[1]

[1]Nord University, Faculty of Education and Arts, Levanger, Norway; edgar.alstad@nord.no

Keywords: Geometry, spatial structuring, visualization, perceptual clues.

Background

This project explores the following research question: How can representations and perceptual clues support children's enumeration of 3D arrays?

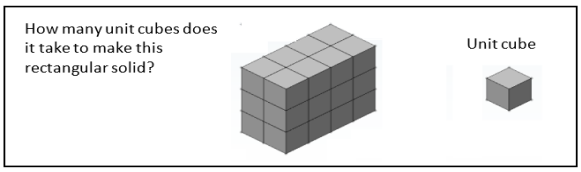

***Figure 1**: Task example from Ben-Haim et al.(1985).*

Research shows that students often struggle with visualizing tasks as exemplified in Figure 1, counting 2D faces instead of 3D units, leading to double or triple counting cubes (Battista & Clements, 1996; Ben-Haim et al., 1985). Battista (2004, 2010) identifies five cognitive processes crucial for enumerating units in 3D arrays: Units-locating, spatial structuring, organizing-by-composites, forming and using mental models, and abstraction. We consider an enumeration strategy as based on and a result of the students' cognitive processes.

Perceptual clues (PC) have shown to support students' enumeration strategies. PCs are a choice of design with the aim of drawing students' attention to a mathematical idea or strategy. For instance coloured cubes (fig. 2) can help students spatially structure the array in layers (Finesilver, 2017; Rupnow et al., 2022); spherical units (fig. 2) can reduce double and triple counting 2D units, thereby allowing students to discover more effective strategies (Alstad et al., 2023).

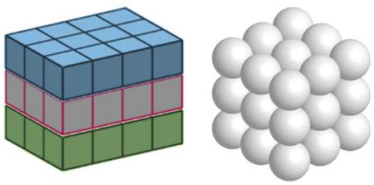

***Figure 2**: Coloured cubes and spherical units as perceptual clues*

Methods

During the fall of 2024 we collected data from 13 3rd grade students. The students were presented with four tasks in which they were asked to enumerate the units in a 3D array. The structure of the array remained consistent across the first three tasks (e.g. 3x4x4 array). Task 1, a 2D representation of the array of cubes; Task 2, a 3D representation; Task 3, a 3D representation with one out of three possible PCs, randomly assigned. Finally, Task 4 reverted to a 2D representation, in line with Task 1. Task 1 allowed us to identify whether students employed common erroneous strategies. Task 2 helped us determine whether children perceived the array differently when represented in 3D

compared to 2D. Task 3 enabled us to examine whether certain PCs supported students in seeing structures in the figure beyond any erroneous strategies. Task 4 assessed whether students could use their experiences and visualization from the 3D representations when encountering a new array represented in 2D.

Analysis and results

Firstly, students' strategies were analysed and categorized using Battista's five cognitive processes and Levels of Sophistication (Battista, 2004). We found minimal, if any, differences in students' strategies when moving from a 2D to a 3D representation. Nine out of 13 students counted squares instead of cubes with both 2D and 3D representations. Secondly, we analysed students' change of strategy after encountering a PC using the constant comparative method of analysis. Six out of 13 students changed strategies after exposure to a PC, indicating that the PC was supportive. The remaining seven students maintained their initial strategy. This variability in response to PCs suggests that PCs sometimes influence students' choice of strategies, though inconsistently. This variability is explained by the core category visuospatial responsivity. Visuospatial responsivity does not explain the underlying causes of these differences but provides a framework describing students' varying capacities to identify relevant figural units and adapt their strategies. We identified four levels of visuospatial responsivity: limited, growth, stable, and flexible.

Mathematics laboratory on geometric transformations at the museum

Michela Maschietto[1] and Beatrice Battilani[1]

[1]University of Modena e Reggio Emilia, Dept of Education and Humanities, Reggio Emilia, Italy; michela.maschietto@unimore.it

Keywords: Mathematical machines, geometric transformations, laboratory, museum.

Mathematics laboratory and mathematical machines

The idea of the mathematics laboratory has evolved over time in teaching and learning mathematics (Maschietto & Trouche, 2010). In Italian documents for mathematics curriculum (e.g., AA.VV., 2004), the mathematics laboratory is related to the construction of mathematical meanings and a crucial role is played by the use of material and digital artefacts. Mathematical machines are material artefacts related to geometric transformations, conic sections and perspective; they were built for didactic purposes, but they also are significantly related with the history of mathematics. Laboratory sessions based on the use of mathematical machines are designed within the Theory of Semiotic Mediation (TSM, Bartolini Bussi & Mariotti, 2008). They have been studied in educational research, mainly at upper secondary school (Maschietto & Bartolini Bussi, 2011); they are also proposed in out-of-school context laboratory sessions, such as at the university museum. We are interested in designing laboratory sessions for lower secondary school classes at the university museum (Laboratory of mathematical machines, www.mmlab.unimore.it), focusing on the mathematical machine for reflection (Fig. 1a). Our research questions concern: 1) How can the laboratory sessions implemented with upper secondary school students be adapted for lower secondary ones, 2) If the work on the mathematical machine in a laboratory session can foster the emergence of the meaning of reflection. In this poster, we aim to present the experimented laboratory sessions for 13-year-old students.

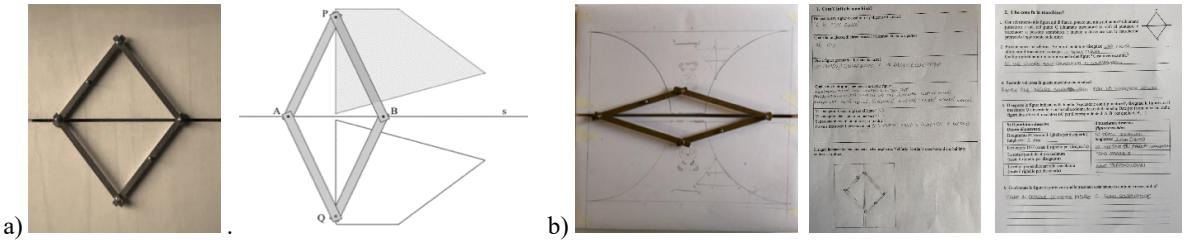

Figure 1: a) Machine for reflection, b) Students' drawing by the machine and worksheets

Methods

In previous research (Maschietto & Bartolini Bussi, 2011), the methodological elements of the TSM for teaching experiments in school have been adapted to a context beyond the classroom, where students go only once and are generally not familiar at all with mathematical machines. The exploration of the machines made through one worksheet and the final collective discussion has been maintained. To answer our first research question, we split the worksheet into two worksheets (the former concerning the description of the machine, and the latter guiding the identification of the reflection), considering linguistic issues, and added some support material to make the work with the machine easier and more pleasant for younger students. We also modified the structure of the

laboratory as follows: introduction of the geometric transformations; small-group work on the mathematical machine (Fig. 1a) guided by the first worksheet (Fig. 1b) with questions referring to the TSM ("How is the machine made?"); collective moment to share answers; group work on the machine with the second worksheet ("What does the machine make?"); collective discussion; final task. Each session lasts a maximum of two hours, including the visit to the exhibition of mathematical machines at the museum.

In spring 2024, we experimented with this new session with six classes of 13-year-old students. For each class, we collected the worksheets filled by the students, and the drawings they produced using the machine (Fig. 1b, left). Our analysis is based on these documents, as well as researchers' reports of collective moments.

Analysis of students' work

Regarding the first worksheet (Fig.1b, centre), students typically identified the rhombus and described its properties. In the last question of the worksheet, students were asked to represent the machine aiming to solicit their semiotic activity. The second worksheet (Fig.1b, right) asks students to draw using the machine and then to interpret/recognise the relationships between the obtained drawings. Although at the beginning of the session most students claimed that they didn't know anything about geometric transformations, words that characterise symmetrical figures ("*equivalent*", "*mirror*", "*same perimeter*", "*overlapping figures*") appeared little by little, as well as descriptions of corresponding figures ("*The fire drawn following the stencil is upwards, while the fire drawn on the sheet is downwards. They are congruent*"; "[the machine] *makes two figures superimposable by reflection*"; "[the drawings] *are the same thing but they are upside down or mirrored*"). In the end, most students correctly identified the transformation, although without providing any justification, with a few exceptions ("*because the diagonals of the rhombus are perpendicular and bisect each other*"). Even if the definition of reflection is not stated with the students, the whole work with the machine allows words and action consistent with the meaning of reflection to emerge in the worksheets and during the final discussion. This suggests a positive answer to the second research question, but it also provides elements to revise worksheets for future work.

TWG 05: Probability and Statistics Education

Reimagining Statistics and Probability Education in the Age of Data and AI: An introduction to the work of TWG05

Leader: Aisling Leavy (*Ireland*)

Co-leaders: Daniel Frischemeier (*Germany*), Sibel Kazak (*Türkiye*), Orlando Rafael González (*Thailand*), Luca Lamanna (*Italy*), and María Magdalena Gea (*Spain*)

Introduction

This report presents a summary of the activities and key outcomes of Thematic Working Group 05 (TWG05): Statistics and Probability Education at CERME14, held in Bolzano from February 4–8, 2025. The group brought together 30 participants representing 13 countries, who contributed through 18 paper presentations and 6 poster sessions. Guided by CERME's core principles of Communication, Cooperation, and Collaboration, TWG05 cultivated a dynamic and inclusive atmosphere that encouraged meaningful dialogue and constructive exchange throughout the week.

The CERME14 TWG05 team was led by Aisling Leavy (Ireland), with co-leaders Daniel Frischemeier (Germany), Orlando Gonzalez (Thailand), Sibel Kazak (Türkiye), María Magdalena Gea (Spain), and Luca Lamanna (Italy).

The week began with an ice-breaker activity, "TWG05 Colleague BINGO," aimed at encouraging participants to connect and form discussion groups. Sessions were structured to promote active engagement, with each paper allocated 10 minutes for presentation followed by 5 minutes for questions. Broader discussions then took place in small groups, each facilitated by a co-leader and including the presenter. The responsibility for chairing sessions was shared among the co-leaders throughout the week, spanning multiple sessions from Tuesday to Friday, including a dedicated poster session.

Key subthemes identified for discussion across all submissions included:

I. data science
II. visibilizing statistical concepts
III. teacher education
IV. probabilistic reasoning and risk literacy

The identification of these subthemes was the result of a careful examination of the accepted papers and their thematic focus. This mapping process was significantly informed by the themes identified as emerging from CERME13 (see Primi et al., 2024), which included "teacher education," "reasoning about data," "statistical and probabilistic thinking and reasoning," and "data science." Furthermore, it drew insights from two recent and influential research publications: Batanero and Álvarez-Arroyo (2024), and Burrill and Pfannkuch (2024). Batanero and Álvarez-Arroyo (2024) synthesized prominent research in probability education, highlighting areas such as children's probabilistic knowledge, the impact of visualizations on solving conditional probability problems, teacher

education, and probability modelling. Their work also emphasized the growing interest in the concept of risk and its pedagogical link to probability, and called for more research into teachers' mathematical and didactic knowledge of probability. Complementing this, Burrill and Pfannkuch (2024) identified four major emerging trends in statistics education research: data science, visibilizing statistical concepts, social statistics, and new contexts for learning. They underscored the importance of fostering statistical reasoning, argumentation, and the critical evaluation of data-based evidence, including aspects of risk, along with enhancing the accessibility of statistical concepts through interactive visualizations. Thus, the chosen CERME14 subthemes reflect these convergent and critical areas of contemporary research in statistics and probability education. Guiding questions were prepared to facilitate discussions on these subthemes, with groups assigning note-takers to document their discussions on task cards. An online shared space, Task Cards, was utilized to systematically document the content and focus of each session's discussions. This comprehensive documentation was critical for a successful and substantial concluding discussion on the final day of CERME14, where all insights gathered during the week were collectively summarized.

Data science

During the TWG05 discussions on Data Science, several key learnings and open questions emerged from the group conversations. Participants emphasized the importance of introducing data work and data literacy at an early age, acknowledging that children are already exposed to tools that use data. The consensus was that data literacy should be embedded within inquiry-based or problem-based learning, where skills emerge through answering questions. The group discussed the use of different types of data, agreeing that both "dirty" (messy) and "clean" real-world data are important for different learning goals, as real data incorporates a sense of "reality". It was suggested that learners could start by formulating questions and then be presented with existing data, and any disconnects could lead to modifying their questions. Familiar contexts, such as social media or sustainability, were deemed important for relevance, along with using examples like recommender systems to help students understand how their own data can be used for predictions, fostering an awareness of the world. Critical thinking and reflection were highlighted as essential components of Data Science activities. Regarding tools, it was noted that while non-coding applications and technologies can provide support, programming skills (e.g., Python) are important for understanding the "inner workings" of models and fostering algorithmic thinking.

The discussion also outlined the desired knowledge for an "ideal" 16-year-old learner in Data Science. Such a learner should: Be aware of algorithms' impact on their lives (e.g., in insurance); Understand that data-driven decision-making systems can have biases; Recognize that probabilities underpin these systems; Know that models and data are simplifications of the real world and that elements can be omitted; Possess critical thinking skills, asking questions about the data and what is presented to them.

Several open questions and areas needing further investigation were identified:

- Institutional Constraints and Teacher Support: How to overcome institutional limitations and address the vulnerability felt by teachers regarding Data Science education. The need to support teachers in using real-world data, perhaps by providing sample datasets and guidelines, was acknowledged, recognizing the significant responsibility placed on mathematics teachers.
- The "Black Box" Concept: When and how deeply to "scratch" or open the "black box" of algorithms. This includes understanding the underlying mathematics, acknowledging that some models are not fully explainable, and fostering algorithmic thinking through insights into the black box. It was noted that there might be both "pedagogical black boxes" (intentional simplifications for learning) and "real black boxes" (complex systems not entirely transparent).
- Distinguishing Data Science from Statistics Education: Clarifying the differences, particularly the role of context. In statistics, the context and potential models often guide data collection, whereas in Data Science, data and context are often pre-existing, and the task is to formulate questions based on them. The group emphasized the importance of teaching both perspectives.
- Teacher Education: How to effectively equip teacher education students with the necessary knowledge and skills to support Data Science thinking and learning. This includes rethinking the organization of Data Science lessons, potentially promoting more interdisciplinary teaching, and addressing constraints like the need for longer project work blocks.
- Tools and Activities: Developing and making available specialized tools that facilitate understanding, while also considering the benefits of general-purpose tools like Python for understanding inner workings. The challenge of ensuring learners gain insights into models when using simulations was also raised, along with the need for project-based work and activities that encourage reflection.

Visibilizing statistical concepts

Several key learnings and open questions emerged from the group conversations during the TWG05 discussions on Visibilizing Statistics Concepts. Participants emphasized the importance of fostering the ability to represent the same concept or data in different ways (i.e., transnumeration), using different types of representations, in both figural (e.g., scatterplots, tabular displays, decision trees) and non-figural form (e.g., verbal or narrative models, reflective statements, color schemes). Engaging learners in the creation or use of these visualizations, representations, or models of concepts must be done to fit the purpose of making visible previously unknown statistical concepts by the learners (like in the “modeling for” approach, which facilitates a deeper understanding of the underlying mechanisms and abstract ideas that the model represents), instead of adopting a correct/incorrect approach. The creation of visual models or graphical representations by learners, as well as their use of interactive visual data analysis tools (e.g., TinkerPlots, computer simulations), were reported by participants as effective ways to elicit and reveal students’ intuitive reasoning, conceptual processes, and informal notions of statistical concepts such as inference, sampling distribution, sampling variability, central tendency, correlation, enumeration, and uncertainty. Moreover, the participants agreed that learners’ interpretations of visualizations of concepts are socio-cultural and context-dependent, which allow teachers and researchers to delve into and understand more about not only about students’ intuitive reasoning and conceptions, but also about the

experiences and socio-cultural frameworks and schemas that they bring to visualizations (e.g., students' underlying values, norms and semiotic conventions), which are rooted in the learners' socio-cultural background and context.

From the discussion, the new learner's needs and roles in relation to data, and how Visibilizing Statistics Concepts can be instrumental in meeting those needs and roles, were outlined. Today's learners are *data consumers*, individuals who frequently interact with happenstance data or data and visual representations produced by someone else's efforts, usually using digital tools, Software platforms, interactive visual data analysis tools, and meaningful contexts. They are also *data producers*, because they frequently engage in empirical investigations, represent and interpret their own data, and communicate their findings and conclusions, usually making them visible. In addition to these roles, today's learners are also *data prosumers*, because they often have to engage in activities in which they should act as both data producers and consumers.

The participants also highlighted the important role currently played by technology-rich visual learning environments and software platforms that allow students to create, make sense and analyze visual models (e.g., TinkerPlots) in the learning of statistics. Participants also identified a high degree of interconnectedness between activities on Visibilizing Statistics Concepts and the following elements: data science, technology, teacher education, curriculum, affect, context (authenticity), and technology. The interconnectedness between Visibilizing Statistics Concepts and these elements opens new avenues for researchers to explore and gain better understanding of students' reasoning, actions, and conceptual development in learning statistics, while engaged in activities in which statistical concepts are made visible to them.

From the discussions, participants were able to pose several open questions, from which areas needing further investigation are identified:

- How can the interconnectedness of Visibilizing Statistics Concepts with different elements (e.g., technology, context) and domains (e.g., data science, mathematics) be included in the curriculum, in order to make it possible for students to be introduced much earlier to statistical and probabilistic ideas?
- How can the use of technology tools (e.g., TinkerPlots, simulations, case blocky programming with Scratch) be used to visibilize statistical and probabilistic concepts while enhancing both the computational, statistical and probabilistic thinking of students?
- How can AI and machine learning methods (e.g., Support Vector Machine [SVM]) be used to visibilize key mathematical, statistical and probabilistic ideas while contributing to AI literacy and demystification?
- How can simulations and modeling activities be used to make students transition from "modeling of" to "modeling for", while promoting students' reasoning with informal statistical models and probability modeling activities using technology-rich visual learning environments?
- How can researchers, teacher educators, and curriculum developers keep the pace of advances in technology, in order to be able to quickly respond to the current and future developments that will be relevant to students' needs and roles in relation to visibilizing data?

Teacher education

During the TWG05 group conversations on the theme of Teacher Education, one of the main insights was that, in order to engage meaningfully and make interesting use of statistics and probability, teachers should develop deeper contextual knowledge, e.g., in connection with other fields such as politics, medicine, or climatology - an aspect that clashes with actual, mostly outdated, curricula across the countries that do not offer much space for the exploration of real-world applications of both statistics and probability. Many of the presentations and discussions in TWG05 highlighted, on the other hand, concerns that most teachers possess limited statistical content knowledge and pedagogical content knowledge in statistics, largely because they themselves have likely not experienced high-quality teaching of statistics or probability. In connection with this, mathematics textbooks often fail to support interdisciplinary teaching - or, in general, link with other fields - and digital tools are still not widely available or easily integrated into real classroom settings.

A shared understanding emerged during the discussions that data science cannot be meaningfully implemented without the use of (digital) tools. This led to the recognition that, beyond statistical content knowledge and statistical pedagogical content knowledge, teachers also need technological pedagogical content knowledge (TPACK) to effectively incorporate digital tools into their teaching.

Another critical point concerned the need to shift teachers' beliefs about probability and statistics - from viewing them as isolated procedures to be memorized, toward understanding them as ways of thinking about data and context.

All in all, the need for more work towards the above-mentioned directions of research was highlighted, aiming at investigating the teachers' perspectives and knowledge, together with all the institutional setting and constraints, aiming towards a more meaningful teacher training and, in general, teaching of probability and statistics.

Several open questions and areas for further exploration were identified, both for practice and research. In terms of future research directions, there is a clear need for systematic investigation into the development of teachers' specialized content knowledge (SCK), pedagogical content knowledge (PCK), and technological pedagogical content knowledge (TPACK) - in both statistics and probability - building, in particular, on the foundational work of the ICMI study by Batanero et al. (2011). From a constructive and design-based research perspective, efforts should focus on developing textbooks and teaching materials that meaningfully integrate contextual knowledge, data, probability, and professional development. The goal is to create resources that support both classroom practice and in-service teacher learning. Additionally, affective aspects must be addressed, as inspiring teachers to rethink and transform their approach to teaching statistics and probability remains a key challenge -one that calls for further targeted research.

Finally, the following three fields were identified as future issues and points of contact for ways forward:

- Emerging curricular trends, such as data science and STEAM;
- Citizen and democracy education;
- Risk literacy.

Probabilistic reasoning and risk literacy

During the TWG05 group conversations on this theme, the key learnings centered around the topics, such as conceptualization of risk, recurring themes across different papers, and connection of probabilistic reasoning and risk literacy with the other subthemes. As part of stochastic education at school, risk literacy has become an emerging area. Conceptualization of risk from socio-constructivist and realist perspectives was highlighted as useful in fostering risk literacy, as they were found to be interwoven in students' reasoning. There was an agreement that risk literacy would aim at informed-decision making and assessing probabilities would be a crucial part of this process. It was noted that simulations can be used for inquiry-based learning to foster both risk literacy and probabilistic reasoning. When discussing the papers related to "probabilistic reasoning and risk literacy", the group emphasized the links with other topics, including data science (e.g., data generation through sampling or simulation), teacher knowledge to manage risk literacy in the mathematics class (e.g., open discussions, curricula constraints/possibilities), visualization/representation to identify and argue in (with) probabilistic concepts, and relevance of the context.

Several open questions and areas needing further investigation were identified for practice and research:

- Two questions, which are practice-related, were raised with the recognition that subjective interpretation of probability is left out since it is seen as non-calculable and risk literacy is new to mathematics education: How can we address subjective probabilities in school? How can we bring risk literacy into the school curriculum?
- Various suggestions were made in terms of research. Local theories for instruction on risk (e.g., levels of risk literacy and reasoning about risk) can be developed through design-based research. Specifying the conceptualization of probabilistic reasoning and risk literacy in terms of where they overlap and where they are different is needed. Designing meaningful tasks to foster risk literacy was discussed as a way to enable teachers to reinterpret mathematical concepts (e.g., expected value, conditional probabilities, and compound probabilities) already available in the curriculum through a risk lens by connecting them to decision-making under uncertainty. The group also emphasized addressing the emotional influences in students' perception of risk.

Conclusion

The Thematic Working Group 05 (TWG05) at CERME14 served as a dynamic and inclusive platform for exploring critical aspects of Statistics and Probability Education, uniting 30 participants from 13 countries for meaningful dialogue and constructive exchange.

The insights gained from these discussions underscore the imperative to equip learners with essential skills for the modern world. This includes fostering early data literacy and critical thinking within data science contexts, emphasizing the use of both "dirty" and "clean" real-world data, and understanding how data is used for predictions. Discussions also highlighted the importance of enabling learners to interpret and create diverse statistical visualizations**,** recognizing them as data

consumers, producers, and even "prosumers". A consistent focus was placed on teacher education, acknowledging the pressing need for educators to develop deeper contextual knowledge and technological pedagogical content knowledge (TPACK) to effectively incorporate digital tools and navigate these complex topics. Furthermore, the discussions on probabilistic reasoning and risk literacy reinforced their growing significance for informed decision-making in an increasingly uncertain world.

As we stand at the threshold of a new era profoundly shaped by data science, artificial intelligence, and advanced technological tools, this is indeed an exciting time for TWG05 and the broader field of probability and statistics education. While the challenges are substantial—including overcoming institutional constraints, providing adequate teacher support, and adapting curricula to rapid technological advancements—the possibilities for fostering deeper statistical and probabilistic thinking, enhancing AI literacy, and preparing learners to critically engage with data-driven realities are immense. We eagerly anticipate tackling these challenges and harnessing these possibilities to further advance the teaching and learning of probability and statistics.

Reconsidering Basic Resources for Modern Statistics Teaching and Learning: Opening the Dialogue

Dionysia Bakogianni[1] and Maria Meletiou-Mavrotheris[2]

[1]Karlstad University, Department of Mathematics and Computer Science, Karlstad, Sweden; dionysia.bakogianni@kau.se

[2]European University of Cyprus, Cyprus

This study discusses the findings of two distinct research efforts that explored how a specific resource, namely dynamic software tools for teaching statistics, was negotiated and integrated into teaching practice. Through a systematic analysis of the findings of these two cases, we draw conclusions about the significance of this resource and the conditions necessary for its effective use. Our findings indicate that dynamic software plays a central role in statistics education. However, challenges such as inadequate infrastructure, limited time, and insufficient opportunities for collaboration within the school setting are persistent barriers to the reform of statistics teaching. These issues highlight the need to reassess contemporary learning goals and reconceptualize the basic resources needed for teaching statistics. Additionally, we discuss how redefining these resources could promote equal opportunities and democratize statistics education in an era dominated by big data.

Keywords: resources, statistics teaching, dynamic software tools, innovative practices

Introduction

In recent years, the teaching and learning of statistics has become a central focus in curriculum reform efforts worldwide (Bargagliotti et al., 2020). These reforms emphasize stochastic reasoning and thinking as key curricular goals, shifting classroom statistical activities towards investigative and model-eliciting approaches. Alongside these curriculum changes, significant efforts have been made to develop effective professional development programs that equip teachers with the necessary knowledge, skills, and competencies to implement the latest guidelines for teaching and learning statistics (e.g. Burril et al., 2023). However, despite systematic research, development of instructional materials, and teacher training initiatives, the practice of teaching statistics often remains entrenched in traditional models.

In Greece, over the past 15 years, there have been two major attempts to reform the school mathematics curriculum. Both reform efforts significantly enriched and strengthened the statistical content within the mathematics curriculum, placing a special emphasis on the development of statistical reasoning and thinking. By adopting a more innovative approach to teaching and learning statistics, statistical inquiry has gained a central role in school statistical activity, while software tools have become essential in supporting this inquiry. During these years, efforts were also made to provide professional development for teachers. Despite these advancements, the integration of modern statistical teaching practices still faces considerable resistance.

Over this period, we have had the opportunity to study the development of practice within different groups of teachers. These studies spanned various time points, different reform efforts, and distinct collaborative contexts. The current study examines these two studies (Bakogianni & Potari, 2019; Bakogianni & Meletiou-Mavrotheris, 2024), both of which share a common focus: the utilization of

dynamic statistics educational software. Specifically, the two studies explored how the software was utilized by participating teachers in designing instructional tasks and in developing teaching practices.

The objective of this discussion paper is to analyze the findings of two distinct research efforts to address the following questions:

1. How were dynamic software tools for teaching and learning statistics negotiated and integrated into teaching practices within two different research contexts?
2. What conditions appear to facilitate or hinder the effective utilization of such tools to advance reforms in statistics education?

Through a systematic examination of the findings, we aim to gain empirical insights into the contextual factors that support or obstruct its use. These conclusions can provide valuable perspectives beyond the specific resource, highlighting the broader role of basic resources that prove critical for advancing the reform movement in statistics teaching and learning.

Theoretical views

Current views on teaching statistics

Statistics stands out from other fields of mathematics because it takes uncertainty into account. The pervasive presence of variability and randomness in modern life enhances the role of statistics in contemporary mathematics education and creates the need to develop new skills for managing the uncertainty inherent in decision-making processes (Burril et al., 2023). The complexities of statistical activity, as well as the nature of statistical problems, are captured in the framework of Wild and Pfannkuch (1999) for statistical thinking in statistical enquiry. This multi-dimensional scheme of Wild and Pfannkuch was central in our conceptualization of DSTR practice (teaching for the Development of Statistical Thinking and Reasoning) in our first study (Bakogianni & Potari, 2019).

Today, the evolution of the field of Statistics and the rapid growth the Data Science domain, introduces new trends in Statistics Education. Contemporary goals for teaching statistics include computational skills, complex forms of data representation, critical risk perception, interactive data visualizations, among others (Burrill & Pfannkuch, 2023). In light of these developments, the American Guidelines for Assessment and Instruction in Statistics Education (GAISE) Report (Franklin et al., 2005), were revised in 2020. The new GAISE II framework (Bargagliotti et al., 2020) emphasizes skills required for navigating the modern world of big data, and key issues in current curricula. Among the topics emphasized in GAISE II were posing questions throughout the statistical problem-solving process, considering different data and variable types, incorporating multivariate thinking, utilizing probabilistic thinking to quantify randomness, leveraging technology, effectively communicating statistical information, and implementing assessments that gauge students' deeper understanding of statistical concepts and reasoning. GAISE II (Bargagliotti et al., 2020) provided the foundation and guiding structure for designing the course in the context of which we conducted the second study (Bakogianni & Meletiou-Mavrotheris, 2024).

A view to resources for teaching statistics

There is considerable discussion in the literature around resources, their use, and their conceptualization as artifacts, tools, instruments, etc. (e.g. Pepin, 2015). Adler (2000) adopts a broad

perspective on resources, considering them both as a noun and a verb. Within this view, she identifies basic resources, which are prerequisites for the practice of teaching (such as buildings, electricity, desks, chairs), as well as resources specifically related to the teaching of a subject. The latter include human resources (e.g. collegiality, everyday knowledge, networks), material resources (e.g. curriculum, technologies, everyday objects), and cultural resources (e.g. time, language). The study of resources *in-practice-in-context* recognizes the complexities of the context and the practice in which a resource is used, developed, or transformed over time (Adler, 2000). Both studies discussed in this paper consider teachers' interactions with dynamic software tools for teaching statistics as an important pursuit in their professional development. Dynamic software tools for data explorations contistute a prominent resource for statistical inquiry at school (Biehler et al., 2013), for their potentiallity to both support statistical reasoning and foster conceptual understanding of stochastic concepts and ideas (e.g. randomness, variability).

The significance of dynamic software tools in the teaching of statistics, along with the challenges they pose to the usual teaching practices, makes this resource central to the development of the studies under discussion and a focal point of the present study.

Overview of the two studies

Developing practice in a teachers' community

The first study (Bakogianni & Potari, 2019) utilizes a community of practice (CoP) context (Wenger, 1998). In this study, eleven secondary mathematics teachers, as part of a CoP, collaborated to explore resources supporting the teaching of statistics, with a focus on promoting the development of statistical thinking and reasoning. Through iterative cycles of exploring tasks, designing, implementing, and reflecting, teachers engaged with various resources, some of which became part of the community's shared repertoire. The role of the researchers in these studies was that of a facilitator, responsible for organizing the meetings, shaping the agenda based on teachers' needs and emerging issues, and providing appropriate materials (e.g., articles, educational resources, critical questions) to support the process.

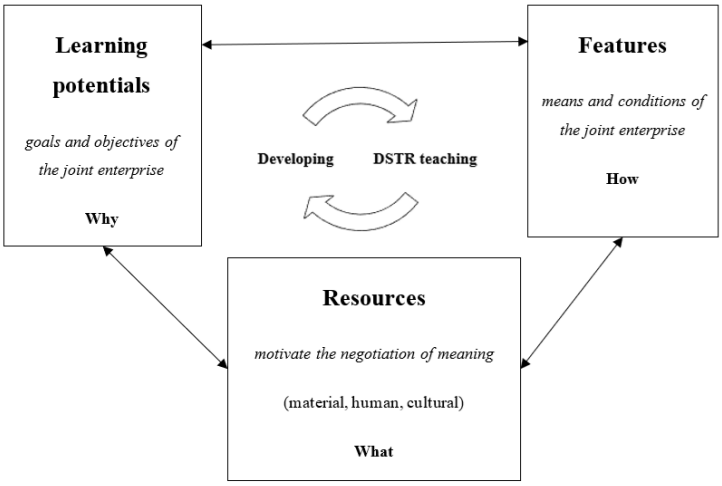

Figure 1: The conceptualization of statistical teaching for Developing Statistical Thinking and Reasoning (DSTR) (Bakogianni & Potari, 2019)

All the theoretical perspectives of this study are condensed in a dynamic triangle that captures three core elements of practice (see Figure 1). Locating this triangle inside a Community of Practice, we see the learning potentials as the purpose of the joint enterprise, the features as characteristics of the teaching that support the negotiated purpose, and the resources as the primary impetus for mobilizing negotiation of meaning.

Focusing on a particular resource – a dynamic digital tool for teaching statistics – the study identified three key phases in the re-sourcing process. The first is the *emergence phase* where the dynamic Software Tool for Statistics Instruction (STSI) is introduced to the CoP and becomes visible among its members. The second is the *exploration phase*, during which the STSI becomes a focal point for discussions and negotiations about its potential uses in the classroom. The third is the *immersion phase*, where the focus shifts to teachers' direct experiences using the STSI in the classroom. Moreover, our findings suggest that this immersion phase often facilitates the consolidation of the resource into the community's shared repertoire.

Progression through the three phases seems to be linked to the interconnectedness of the different elements within the teaching triangle of Figure 1. Particularly, the more explicit and robust these connections become, the more likely it is for the resource to be fully integrated into the practice.

Developing practice in a collaborative learning environment

The second study (Bakogianni & Meletiou-Mavrotheris, 2024) reflects on our experiences in a graduate course aimed at educating teachers in the teaching and learning of Statistics and Probability. Conducted approximately ten years after the first study, this research involved 20 participants—19 secondary mathematics teachers and 1 primary teacher – comprising roughly equal numbers of prospective and in-service educators. The teachers worked in pairs of groups (action team- reaction team) to design statistical projects aligned with contemporary ideas in Statistics Education. We investigated key factors influencing this design process. Unlike the first study, the course in this research placed special emphasis on the use of digital tools, providing students with ample opportunities to familiarize themselves with and experiment with TinkerPlots (Konold & Miller, 2005). Although there was encouragement but no explicit instruction to use the software for their project design, it is noteworthy that all groups chose to incorporate TinkerPlots into their projects. The authors of this article co-taught the course and participated as facilitators during the design phase, providing critical questions and additional resources to support the teachers where needed.

The study highlighted three main themes: the unique role of data in statistics, the importance of technology in fostering statistical reasoning, and the pedagogical challenges associated with teaching stochastic problems. Revisiting the findings, with the dynamic software tool in the center of our focus, we gained new insights into the teachers' experiences within an organized training program.

Synthesis of the key findings

Although the two studies were conducted at different times and within distinct collaboration contexts, they share a common focus on dynamic software tools for teaching statistics, and some implications for the development of secondary teachers' practices. This study draws on data from the reflection phase of the teachers following the design process. For the first study, the data consist of the transcription of a 120-minute discussion that took place after the teacher groups had designed and implemented a statistics activity in their classrooms. For the second study, the data consist of the

transcription of a 180-minute discussion during which the teacher groups reflected on their designs, incorporating feedback received from a peer review team. Using the triangle depicted in Figure 1 as a methodological framework, we explore the connections between the three elements of the triangle in both studies and reconsider our conceptualization of dynamic software tools in statistics education, as well as the integration of such tools into the practice. In the findings we refer with SA(1,2,..) to the participants of the first study and with SB(1,2,…) to the participants of the second study.

Linking Resource to Learning potentials

The establishment of particular links between the dynamic software tool and learning potential was successful and robust in both cases. The findings in both studies showed that all teachers were eventually able to articulate how the tool could effectively support specific learning potentials.

In the first study (Bakogianni & Potari, 2019), forming such connections was challenging and required multiple attempts of negotiating meaning, reading and discussing research papers, and experimenting in the classroom. Despite these challenges, teachers ultimately succeeded in explicitly linking the software tool to specific learning goals in statistics education. The following is a characteristic example of such findings, where SA1, directly linked the software tool to the learning potential of enhancing students' ability to create and understand sampling distributions;

SA1: I mean Fathom or some relevant software. I liked Fathom, I think it is very useful for students. The thing is to give students opportunities to explore the data on their own, to take the samples, to explore, to observe, but this… this requires time. But anyway, I prefer such activities from traditional teaching.

In the second case (Bakogianni & Meletiou-Mavrotheris, 2024), creating these links constituted a central goal of the course. Consequently, these connections were explicitly discussed in the classroom, and when teachers designed tasks as part of their course assignments, they were required to refer to such connections. Although it was not mandatory to use software tools in the course assignments, all teachers opted to integrate TinkerPlots (Konold & Miller, 2005) in their designs. The extract from the primary teacher below (SB1), not only explains why they made this choice, but also demonstrates the clarity with which they (SB1, SB2 and SB3) linked the software tool to the learning potentials.

SB1: For 4th grade students, it's very difficult to talk about probabilities. For example, when they get the same result 3 or 4 times, they start to believe that it's more likely. I had a hard time helping them understand what randomness is. The software helped me a lot in this case. It helped me explain it to them.
SB2: With the software, they become convinced.
SB3: Through the ability to perform multiple repetitions, the idea of randomness and variability becomes clear.

Linking Learning Potentials to Features

This type of connections concerns how specific learning objectives can be supported by particular features, that is, by specific means. For example, how a simulation might help illustrate the concept of variability, and how this feature, which is the engagement of students with simulation processes, is ultimately connected to the resource under study, which in this case is the dynamic software tool.

The last sentence of the previous extract illustrates how teachers connected learning potentials to specific teaching features. Here, SB3 refers to using multiple repetitions of an experiment, which have the potential to support students understand the concepts of randomness and variability.

Although establishing such connections was a primary aim of the course we offered, we found that these links became more apparent and were explicitly discussed by the groups of teachers during the design phase of a statistical task.

In the following extract, SA2 from the first study, discusses how the software's simulation tool allowed him to go beyond the limited data collected in the classroom, enabling him to explore the statistical significance of the result and make a statistical inference.

> SA2: So, the one group tries to recall words with meaning and the other group tries to recall words without meaning, and we note down the number of the words in each case. Then I calculate the mean value for the one group, then the mean value for the other group and I subtract the two values. The point now is to decide whether this difference is usual or unusual. Is it expected or unexpected? If it is usual, there may be many reasons for being usual, maybe it is the way we divide the people into two groups, whether we select them at random or not, etc? …This is where the technology comes.

Linking Resource to Features

This type of connection appeared to be the most demanding. What we sought in this case was to determine how the features of teaching could be linked to specific resources. These connections often depended on linking the features to a set of interconnected resources that are prerequisites for utilizing software tools. The predominant commonality between the two studies lay in the challenges associated with school resources, particularly technological infrastructure, time constraints, and human resource interactions, as key factors impacting the integration of these tools.

In the first study, inadequate technological infrastructure in schools frequently emerged as a barrier preventing teachers from implementing their planned activities in the classroom. In the second study, many teacher groups created alternative versions of their plans to accommodate teachers from schools lacking the necessary resources. However, these alternative scenarios were described as more simplistic: "To make it possible for someone without access to the software to apply it, at least at an initial level of exploration." The difficulty here was in linking these simplified plans with the teaching feature of engaging students in data explorations and randomizations processes.

Time limitations and curriculum constraints also surfaced prominently in discussions with the teachers in both studies. The majority of the designed teaching plans required 2-3 class periods, with all teachers agreeing that it is challenging to conduct a meaningful statistical investigation in just one teaching hour. In this case, the key teaching feature was supporting statistical inquiry to address a meaningful statistical problem.

Finally, one element that seemed to play a particularly significant role in the teachers' design was human resources—collaboration and interaction among them. Collaboration and interaction appeared to be crucial factors in managing the inherent uncertainty underlying statistical concepts and processes, and in addressing the challenges of uncertainty within the statistics classroom. This element was particularly evident in both studies and was noted by nearly all the teachers involved. The following excerpt from SB4 highlights this point:

> SB4: I had to think completely differently. In lesson planning, I always knew what I wanted and could anticipate to some extent what would happen in the classroom when I provided such a scenario. Here, things are very different. This completely took me

> out of my comfort zone. We needed to make up various scenarios, to share million ideas.

Discussion on the implications of the two studies

Biehler et al. (2013) liken statistical reasoning to "travelling" from data to conclusions, with computer tools making this process easier but with a "black box" effect, where some details are missed. Empirical studies have demonstrated that technology enhances students' statistical reasoning, even at young ages, by aiding data exploration and inferential reasoning (Biehler et al., 2013). Data exploration is crucial not only for statistical inference and statistical thinking but also for data science activities, linking statistics to the emerging world of big data, as pointed out in the GAISE II Report (Bargagliotti et al., 2020; Biehler et al., 2022).

The question arises: Is teachers' familiarity with technology and the development of specific learning objectives connected to it, sufficient to transform statistics teaching practices? Using the dynamic triangle of teaching (Figure 1), we aimed to explore how different elements of practice interacted during the process of integrating the tool in two studies conducted at different points in time.

Teachers' professional development and opportunities for negotiating meaning are crucial for developing connections within the dynamic triangle for teaching statistics (Figure 1). However, the implications of the two studies reveal that for the technological tool to be effectively integrated into teaching practice, some prerequisites that enable the connection of the resource with the characteristics and methods of actual teaching are necessary. When the connection between the technological tool (resource) and the teaching characteristics (features) is hindered, integrating the tool becomes more challenging, with negative consequences on the other elements of the triangle, namely, support for learning potentials and adoption of innovative features. Some common factors that seem to influence these links are the school's technological infrastructure, available time, and opportunities for teacher collaboration.

Conclusion

The systematic examination of the two studies helped us to get insights into key issues that appear both important and systematic for the negotiation and integration of dynamic software tools in the teaching of statistics. The explicit and strong connection of the resource with learning potentials prompts us to question whether modern learning goals in statistics can truly be achieved without utilizing such technology. If not, we may need to reconceptualize what constitutes basic resources for contemporary statistics education. For Adler (2000), basic resources constitute the minimum prerequisites necessary for teaching to take place. This prompts the question: What should be considered basic resources for a school where teachers aim to use software like TinkerPlots with their students? Our study highlights that the main and enduring barriers preventing teachers from using dynamic software tools in their classroom seem to be the school's inadequate technological infrastructure, time constraints, and limited opportunities for meaningful human interaction and collaboration.

How can software tools like TinkerPlots be made accessible for all students? How much time is truly required to support open-ended statistical investigations in the classroom? And how can school programs better facilitate ongoing teacher collaboration and student inquiry? These are critical questions that must be addressed to ensure the effective integration of dynamic software in statistics

education. Furthermore, these questions underscore that the reconceptualization of what constitutes a basic resource for school teaching, both generally and specifically in statistics education, also opens important discussions about equal opportunities and the democratization of statistics education. Moreover, as the concept of data evolves in modern society from simple datasets to vast arrays of big data, it becomes imperative for statistics education to clearly define the fundamental resources required to support sustained statistical inquiry at the school level.

How students justify the usability of self-built machine learning models

Using machine learning models is a part of the everyday work of many engineers. In this paper, we investigate how undergraduate engineering students use self-built machine learning models in a concrete application example. A qualitative analysis of excerpts from twelve student groups shows that despite similar models, the tendency to use the models in the application example differs. In addition, justifications for the use of the model are provided on two different levels. One level covers the resilience of the model itself. The other level relates to the applicability of the model statement, which is what we call the information that is obtained by applying a model to the new data set.

Keywords: Machine Learning, Model Building, Model Usability, Data Literacy

Theoretical Background and research question

Machine learning (ML) is at the heart of modern engineering and, through the use of mainly statistical methods and automated data processing, an interesting learning content in the context of statistical and data literacy (Engel & Martignon, 2024). ML can be used to optimize complex systems, to predict failures for maintenance, or to accelerate research by data analysis. Besides the building and the evaluation of ML models, which can be outsourced to other experts if necessary, justifying the usability of a model in an application situation is crucial (Bertolini et al., 2021).

The question of justifying the usability of a model in an application situation is closely related to the user reliance on recommendations from ML models. Due to the increasing use of ML-based methods using the label "AI", some relevant publications about reliance on recommendations from ML models also appear with the label "trust in AI" (Bach et al., 2022; Yang & Wibowo, 2022). "Trust in AI" is investigated in the context of various influencing factors on technological, organizational, contextual, social and personal level (Yang & Wibowo, 2022). Looking specifically at ML-based decisions, there is empirical evidence for different types of influencing factors related to the different levels. For example, on the technological level influencing factors can be the properties of a model, measured by different performance metrics (Yu et al., 2019; Yin et al., 2019). On a personal level, the difference between one's own ideas of a model and the model itself seems to be an influencing factor (Bansal et al., 2019). There is also the assumption that personal preferences and expertise regarding the ML-methods or a respective performance indicator have an influence on the reliance in ML-based decisions of users, i.e. laypersons related to model building (Chiang & Yin, 2022; Yin et al., 2019). Another interesting aspect is that trust in the ML-based decisions can be influenced by an appropriate visual representation of the ML-based decision process (Yang et al., 2020).

Our contribution enriches the field of research on user reliance on a recommendation of a ML model with a perspective that deals with a step prior to the recommendation: The usability of a ML model in a specific situation. The question is: *How do engineering students justify the usability of a self-built ML model?*

The situation in which we investigate students' justifications is characterized by two particular aspects: The investigation is based on the processing of a task in a teaching-learning environment in the context of a design research study (Bata et al., 2022). The task, which is described in the methods section, is an example of an engineering application that is intended to represent a situation from professional life, where students apply a ML model to a new data set. Furthermore, the students in our study use models that they have previously developed themselves, which means that they are explicitly not laypersons but beginners related to model building.

Method

Task

In the investigated task, the students have to apply a model to a new data set. The model was developed by themselves beforehand using the k-Nearest Neighbor classifier to predict steel quality (good quality / bad quality) based on two metric features (number of cracks / width of the biggest crack). In Figure 1 there is a visual representation of the models' prediction for the new dataset (containing samples of old and new steel): In the data set, half of the samples consist of old steel (white), and the other half of new steel (black). The background colors separate the areas classified by the model as good (blue) and as bad (red). The representation shows that all samples of the old steel are classified as of poor quality, and about 80% of the samples of new steel are classified as of good quality. Based on the application context and a visual representation such as in Figure 1, the students are asked to make a recommendation for the new steel in contrast to the old.

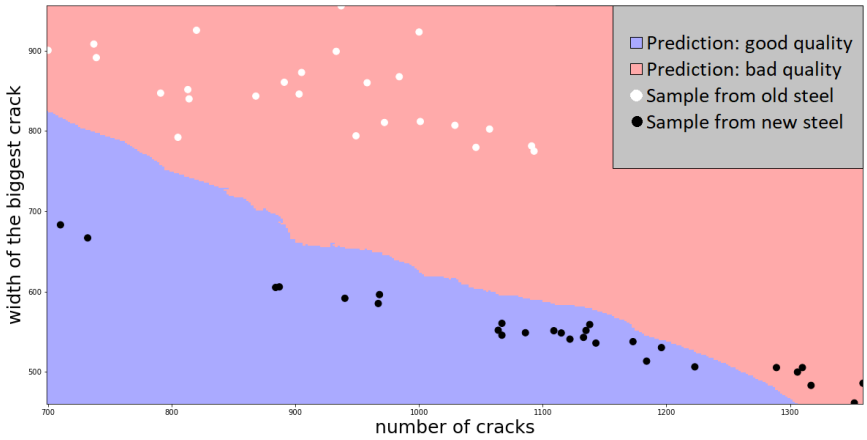

Figure 1: Visualization of a student-built model and the new data set as foundation for the decision

Data from the design experiments

To address the research question, we collected data from three cycles of design experiments in a laboratory setting (Gravemeijer & Cobb, 2006) involving twelve groups with a total of 29

participants. The participants were students from different engineering bachelor programs in the third to seventh semester at a German university, with no previous experience in machine learning. The different bachelor programs had minor discrepancies in the computer science and programming curricula, so a crash course in Python was given to some students before the introductory course started. This was useful in preparing the students for the programming tasks in the introductory course, which were completed using Jupyter Notebooks with Python.

The design experiments were conducted as follows: The twelve student groups were guided individually through the material by the lecturer, which is on top the researcher herself, via an online conference tool in three sessions each (Bata et al., 2022). The work on the material includes both presentation phases by the lecturer and group work on various tasks, one of which is the one described above. The three cycles differed only minimally in their prerequisites, the formulation of the task stayed the same. Each session of each group was documented by video recording.

Qualitative content analysis

The video recordings from the design experiments were transcribed in order to conduct a qualitative content analysis (Kuckartz, 2014). In the course of the qualitative content analysis we developed an inductive category system (Table 1), which was validated by means of consensual coding and by determining the intercoder reliability (Kuckartz, 2014). The intercoder reliabilities, which were calculated on a subset of the material coded by another researcher, of the three main categories range from 0.82 to 1. The value of one is achieved here because the subcategories of the first main category leave little to be interpreted. Taking into account the number of subcategories, the values correspond to a Cohen's kappa between 0.77 and 1 which means a good to very good agreement.

Results

The path from one example to the category system

We will start by showing an excerpt from a transcript of group 2, consisting of the students with pseudonyms Hanna, Wael and Bastian. They are talking about a recommendation looking at the visualization in Figure 1. Wael's statement is an answer to the question "Would you make a recommendation at this time?"

329	Wael:	So I would say, purely intuitively, no, we need much more training data (laughs). But maybe that's also my tic, I don't know.
330	Hanna:	But let's assume that we should now decide on the basis of what we have. Or we don't have no further budget available, then I would say, after 18,000 load changes, the steel, the new steel, is just still good in contrast to the old steel.
331	Bastian:	I think that because the result is so clear it is easier to make a recommendation than if it was a bit scarcer.

In this excerpt the students' decision to use the model for a recommendation is not clear. Two passages are coded regarding their decision, one in [329], coded by "Model is not good enough for recommendation" (C1.3) and the other in [330], coded by "New steel lasts longer / is better" (C1.2). Both codes are part of the first main category "Decision" (C1). This main category distinguishes

whether the students want to make a recommendation at all and if so, in favor or against the new steel. This category serves to frame the further coding with categories C2 and C3 (see Table 1).

Furthermore, we observe that the students provide justifications at two different levels. On the one hand, they give reasons related to the model itself like Wael in [329]. He says that he would like to have much more data to train the model. By mentioning the "Amount of data" (C2.6) he gives an aspect related to the second main category "Model resilience" (C2). Table 1 shows this and the other subcategories of C2. E.g. Students justify with traceability (C2.1), or they state whether their model is good or bad by using some performance metrics (C2.5). On the other hand, the students use justifications that are related to the "Usability of the model statement" (C3). A model statement is the information obtained by applying the existing model to the new data set, e.g. by looking into Figure 1 (all samples of the old steel are classified as of poor quality, and about 80% of the samples of new steel are classified as of good quality). An example for this is, when Bastian points out in [331] that the recommendation using the model is easier because the statement is very clear. This passage is coded as "Clarity of model statements" (C3.2). Table 1 shows the other subcategories of C3. E.g. Students justify with applicability or transferability (C3.3).

Table 1: Category system

Main Category	Subcategory
C1: Decision	C1.1 New steel is not good enough
	C1.2 New steel lasts longer / is better
	C1.3 Model is not good enough for recommendation
C2: Model resilience	C2.1 Clear / Traceable statement
	C2.2 Reality mapping
	C2.3 Parameter selection
	C2.4 Variance and bias
	C2.5 Performance metrics
	C2.6 Amount of data
	C2.7 CRISP-DM
C3: Applicability of the model statements	C3.1 Model quality
	C3.2 Clarity of model statements
	C3.3 Applicability / Transferability
	C3.4 Significance of data / features
	C3.5 Business perspective

Some examples of different subcategories

To illustrate further subcategories, excerpts from the transcripts of two other groups are shown below. First, we look at an excerpt from group 3 with the students Feline and Greta:

182	Lecturer:	[…] Then I have one more question. You wrote that you have a “reliable model”. If somehow, I'll say, something goes wrong in the process at the end. So now you've said we're using the new steel. And it's being used and then something goes wrong. (Greta: Hm (affirmative)). How would you defend that our model was reliable?
183	Feline:	(11) With the uhm criteria. So (..) we were given a data set on the basis of which we were supposed to build a model. And we tried to adapt the model so that the performance indicators were as good as possible and, above all, that the precision was as high as possible. And I would say that you could certainly defend it with that.

In this excerpt, a subcategory of C2 “Model resilience” is coded, namely C2.5 "Performance metrics" in Feline's statement in [183]. Feline explains that the group created the model beforehand with the aim of maximizing the performance metric values, especially the precision. Precision is emphasized here because in the application context, it places work safety above profit, as the students' considerations at another point in the processing show. Another thing, that this excerpt shows, is the lecturer giving a stimulus to motivate the students to give more justifications [182]. Impulses of this kind are discussed later in the paper.

The second excerpt is from group 12 with the students Dieter, Enno and Fabian:

122	Fabian:	[…] Yes, it just depends on the first question, what exactly they want, right? If there are almost no load changes with the steel and it's just permanently installed somewhere. (Enno: Hm (affirmative)) maybe it’s not worth it.
123	Enno:	Or does the company actually want the steel to be replaced as often as possible so that they can sell more parts?

The excerpt shows two subcategories of category 3 “Applicability of the model statements”, namely the two that are particularly broad and cover many different aspects. In Fabian's statement [122] he notes that the given data generated by the simulation of load changes on test components may not be meaningful for the application of the new steel. This formulates the aspect that the data used to build a model or to which a model is to be applied must fulfil certain requirements in order to be meaningful. The statement is therefore coded in category subcategory C3.3 "Applicability / Transferability”. Enno's subsequent statement goes even further than Fabian’s and questions whether the goal of material selection is high quality at all. The associated statement [123] should therefore be categorized as C3.5 "Business perspective".

Both examples highlight the variance in students' justifications, which could already be anticipated by the category system (Table 1): The justifications are at different levels (C2 “Model resilience” & C3 “Applicability of the model statements“) and within the levels concerning diverse topics (e.g.

technical things like performance metrics or contextual things like the business perspective). The next section provides an overview of the results of the coding across all groups.

Summary on the twelve groups

Although all groups start with slightly different models as a result of working with their self-built models, the model statement was mainly similar (most of the old steels as of bad quality and most new steels as of good quality, see Figure 2). The students tend to make a recommendation (C1.3 in only four groups) and when they do, it is more likely to be in favor of the new steel (C1.1 in only four groups), which is indeed the aim of the task. The groups that disagree about using the model or recommending the new steel can be identified by different codes in category 1 (as in the example shown). The disagreeing groups tend to use more and different subcategories in the other two main categories than the agreeing groups. Evaluating all passages coded with the main category 2, we see that not all groups use the resilience of the model (C2) in their justification. Some groups are not even able to do so when asked. A different picture emerges for category 3: The students show a wide range in their ability to justify the usability of the model statement (C3). Each group justifies at least once at the level of main category 3.

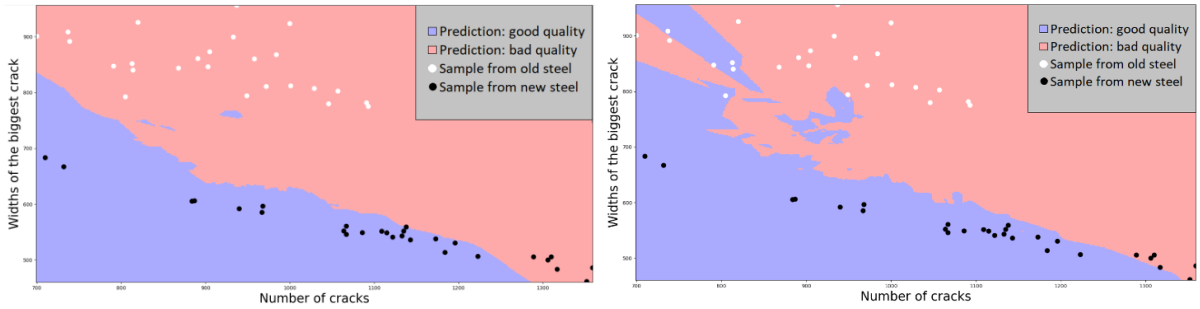

Figure 2: Two different models (group 5 & group 12)

Discussion

The developed category system (Table 1) opens the possibility to identify and analyze the students' justifications for the usability of ML models in an application context. It is interesting to note that although the question is about the application of an existing model to a new data set, the students argue at the C2 level ("Model resilience") in addition to the expected C3 level (**"**Applicability of the model statements"). However, this result is consistent with the existing literature, as the technical characteristics of the models, such as the specification of performance measures, increase the reliance on the model recommendations (Yu et al., 2019; Yin et al., 2019). This is true even when the modelling process has not been carried out by the users themselves in advance, which is the case in the present study. In contrast some groups are not able to argue at C2 level at all even though the lecturer has used a prescribed stimulus (as in the example from group 3) to motivate students to give answers from the category if they have not already done so on their own. Here it would be interesting to understand whether the partial lack of justification is due to the concrete task or to other reasons that lie in the model building processes beforehand (Bata et al., 2024) or in some basic understanding of ML. Despite the partial lack at C2 level, the results show a broad and diverse use of justifications, which is desirable when dealing with recommendations from ML models. This raises the question of

whether it might be useful to involve laypeople in modelling processes or at least to inform them about modelling processes in order to improve their reliance on the model results. This question, or assumption, is in line with Chiang & Yin's (2022) findings that short-term machine learning literacy interventions have an impact on laypeople's interaction with ML models and their outcomes.

Although only twelve groups with 29 students were studied to develop the category system, it is reasonable to assume that the subcategories of categories C2 and C3 are complete and transferable to other applications of supervised learning. This can be assessed from a technical point of view for main category 2, since the usual influences (data, parameters, structured generation) and evaluation parameters (performance metrics, variance and bias, comprehensibility and reality mapping) of supervised learning methods are represented. With regard to the main category 3, usual evaluation parameters of the application of ML models are represented. This is also due to the fact that the categories C3.3 and C3.5 are very broad and cover many different aspects. For example, in subcategory C3.5, the sections vary from “a steel has too long delivery times” to “what is the actual objective of the ordering company”. An investigation of the assumption of completeness in a different setting would be a desirable follow-up study and could expand the picture if necessary.

Although the subcategories of categories C2 and C3 can be assumed to be complete, looking at the differentiation of Yang & Wibowo (2022), there could be other main categories to justify the usability of a ML model. The justifications covered by the category system could, following Yang & Wibowo (2022) be sorted into the "technological" and "contextual" factors. It might be interesting to search intensively for further main categories that analyze the other formulated influences such as personal factors. However, it is quite probable that the learning situation or research format described above is not suitable for such an investigation.

From a design research perspective, there are three further considerations. First, there is the question of how to enable all students to argue not only at C3 level (“Applicability of the model statements”) but also at C2 level (“Model resilience”). Secondly, one could look more closely at whether one can artificially create the disagreement that, at least in the present sample, seems to lead to the use of more and different subcategories. The final consideration, also in relation to the results of Yang et al. (2020), concerns the way in which the model is visualized with the new data set (Figure 1). The question remains as to whether the visualization is suitable for providing students with a basis for justifying the usability of the model and, building on this, whether the type of visualization influences the students' justification.

A classroom experiment: the impact of teaching correlation and regression on students' knowledge of the equation of a line

Balázs Boller

Eötvös Loránd University, MTA-Renyi-ELTE Research Group in Mathematics Education, Budapest, Hungary; bollerbalazs@student.elte.hu

We present the results of a classroom experiment on teaching correlation and regression with 114 students and 6 teachers. The experiment sought to answer the question of how a 6-lesson course in correlation and regression helps students to better understand the equation of a line and to interpret slope. We have seen a general improvement, especially in tasks where the anticipated slope conceptualizations were geometric ratio or functional property. We also found that weaker students were more helped by being exposed to a new perspective on the equation of line. The feedback confirmed the importance for students of a topic that they could easily relate to everyday life.

Keywords: Experimental teaching, correlation and regression, equation of a line, slope of a line.

Introduction and previous research

In the Hungarian National Curriculum (NAT), there is currently no applicable purpose for the equation of a line (NAT). Students are only expected to know the formula $y = ax + b$. In our wider research, we are studying correlation and regression analysis as a possible secondary school application of the equation of a line, which could show students an understandable, everyday application. Previously, we examined the curricula of some European countries to see which approach fits best with the goals of the NAT (Boller, 2024). This research is the basis for the experiment that we present.

We were mainly interested in the impact of learning correlation and regression on students' knowledge of the equation of a line (Research question 1). Our second research question was about the extent to which this topic is accessible to students. The theoretical background for the main question is provided by Zoltán Dienes' perceptual diversity principle, which states that conceptual learning is more effective when learners meet the concept in different contexts and approaches (Dienes, 2015). In our case, we would like to approach the equation of a line from a new perspective of correlation and regression analysis.

Thesis point: "Although students can solve simple related problems, they have only a surface knowledge of the equation of a line, its applicability, the meaning of slope and intercept.

Hypothesis: By teaching correlation and regression analysis, students' understanding of the equation of a line will improve.

Several studies have been carried out on the teaching of correlation and regression analysis. Biehler et al. summarized the major research on reasoning about data. They mention correlation and regression from the perspective of covariational thinking and identify as a major challenge that data-based decision making is not a basic assumption for students (Biehler, Frischemeier, Reading & Shaughnessy, 2018) Gea and colleagues also have described, in the context of covariational thinking,

that the teaching of correlation and regression analysis is under-researched, although it is of great importance (Gea, Batanero, Lopez-Martin & Arteaga, 2016). It was found that some of the biases and misconceptions about the subject are resistant to traditional teaching methods, and the authors therefore proposed a methodological renewal of the subject. Even earlier Walker emphasized the importance of simulations in teaching regression analysis (Walker, 2004). He noted the benefits of simulations in improving understanding of concepts and encouraged interactions between students. As a result, simulations and group work using self-reported data can be found in the course we have developed. Further help was provided by the important research of Engel and Sedlmeier, who reviewed common errors and misconceptions about the concepts of correlation and regression and made four recommendations to avoid them (Engel & Sedlmeier, 2011). Their research shows that reasoning about correlation and regression is not always easy for the layperson, and even researchers sometimes struggle to interpret it correctly. Engel and Sedlmeier suggest helpful approaches to the subject, such as using real data and incorporating modelling experience and technology.

Among the research on the knowledge of the equation of a line, the literature on the interpretation and understanding of slope is significant. Research suggests there are 11 ways that slope can be conceptualized (Moore-Russo, Conner & Rugg, 2011). Linking them is not easy, as it was much more difficult for students to read slope from a graph in Birgin's study than from the algebraic form (Birgin, 2012). And based on the research of DeJarnette et al., the fact that students can quantify the value of slope does not mean that they can identify slope as a property of a straight line (DeJarnette, McMahon & Hord, 2020). In addition to the conceptualisation of slope, context also influences understanding. Planinic et al. showed that it is particularly difficult for students to interpret slope in context, and this is not due to a lack of mathematical knowledge (Planinic, Milin-Sipus, Katic, Susac & Ivanjek, 2012). Studies of university students and pre-service teachers have shown that they do not have an easy time understanding slope in a physical context (Styers, Nagle & Moore-Russo, 2020; Cho & Nagle, 2017).

Algebra and statistics have already been linked in the important research of Casey and Nagle, who showed that students' conceptualizations of slope play a significant role in their reasoning about the line of best fit (Casey & Nagle, 2017). In their study, they carefully investigate how reasoning about slope and the position of the line of best-fit changes in a more accurate way in the case of two students. Their results are important for practicing teachers and for us, as they have shown in detail that with the development of covariational reasoning, the functional and real-world conceptualization of slope has also improved (Casey & Nagle, 2017).

Methods and implementation

114 students participated in the research, with the help of 6 teachers from different areas of Hungary. Most of the students were in grade 11 (16-17-year-olds), except for one group, who were in grade 10.

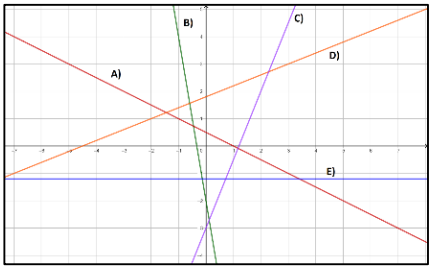
As the teachers participating in the experiment had not yet studied correlation and regression, we organised a one-day training course on the theoretical background, calculation methods and limits of correlation and regression. The structure of the course was in line with that previously described by Batanero (Batanero, Gea, Díaz, & Canadas, 2014). Their results suggested that teachers also have problems distinguishing between correlation and causation, but the activities they organised helped to develop teachers' knowledge of teaching correlation and regression and enabled them to find out,

for example, if a child draws the wrong conclusion from correlations. This also proved useful for the teachers in our experiment. In our course, we also described in detail the structure of the 6-lesson course and the individual lesson plans.

The experiment had three parts: in the preparation phase, the students wrote the anonymous pre-test, collecting information about their current knowledge of the equation of the line. One week later, the most active phase for the participants followed, when the focus of the lessons was on correlation and regression analysis for 6 lessons. Approximately 2 weeks after the active phase, the students wrote the post-test, also anonymous, in the final phase of the research. This test contained very similar tasks to the pre-test. At the end of the experiment, we received detailed written feedback from the participating teachers on the attitude of students and teachers, the methodology of each lesson and the use of the computing background. The students reported back to us in a student feedback form.

The pre-test was revised based on a previous pilot measure, resulting in the final form (Figure 1). The test consisted of 5 tasks. Tasks 1, 2 and 3, shown in Figure 1.A, measured basic subject knowledge, i.e. whether the student knew the formula and was aware of the basic meaning of the equation of a line (the slope is obtained by looking at how much the function moves along the y-axis while moving in the positive direction by unity on the x-axis). The second part of the pre-test assumed a deep (dynamic) knowledge of the equation of the line (Figure 1.B). This was measured through tasks that required an understanding of the constancy of the slope, and which required a degree of more complex thinking. The pre-test and post-test were both 5-point tests, with each task worth 1 point.

1.A) Task 1 – Find the equation of the line through the points $(-1;\ 3)$ and $(3;\ 11)$.



Task 2 – There is a line with the equation $y = -4x + 2$.

a) Does the line pass through the following point? $P = (-1;\ 6)$

b) The point $C = (x_c;\ -22)$ lies on the line. What is x_c?

Task 3 - Write on the line which line has which slope value.

Slope values: $10, 5, \frac{5}{2}, 2, \frac{1}{2}, 5, \frac{1}{4}, 0, -\frac{1}{3}, -\frac{1}{2}, -4, -6$

1.B) Task 4 - Answer the following questions! Give reasons for your answer. Line e has slope 12 and a point $A(27;\ 18)$.. Find the missing coordinates of the points $P(30;\ y_P)$ and $Q(x_Q;\ 14)$ that lie on the line without calculating the equation of the line.

Task 5 - The points $A(-3;\ y_A)$ and $B(3;\ y_B)$ are the points of the line f. What can we say about the slope of f if we know that the second coordinate differs by 1?

Figure 1. – The pre-test. Part 1.A) contains the basic tasks and part 1.B) the more difficult tasks

In terms of methods, we make two comments. First, we introduce the concept of average relative growth, which is used several times in the evaluation. For each student, the change in score on the pre- and post-tests is normalised by the score on the pre-test. This gives a relative improvement, which considers that, for example, a change of 0.2 points does not mean the same for a baseline score of 0 or 0.8. For each task, we calculated the relative growth of the student. The scores for the five

tasks were then averaged to give the average relative growth of a student. The average relative growth of the group was calculated from the scores of the students in the group (Figure 3.). We then looked at the relative growth in each task. And we averaged these values separately for each task, so we got the average relative growth of the students in a task (Figure 4.). The second comment concerns the drop-out rate of the participants in the experiment. The mortality is 11.4%. There were only two groups where the drop-out students scored on average better than the group average on the pre-test, so drop-out probably did not have a significant effect on the result.

The correlation and regression analysis course consisted of 6 lessons. The learning objectives of the topic were given by the conclusion of our previous research. We formulated goals that are in line with the objectives of the NAT. The lesson plans have been developed in a very detailed way so that the teachers can teach the topic in a similar way, exactly as described, and so that the students participating in the experiment receive the same kind of training as much as possible. The topic and the knowledge of the lessons are shown in Figure 2.

Title of the lesson	**Knowledge (concepts, principles)**
1. Introduction	Visualization of the topic. Relationships between variables (correlation vs. causality).
2. Correlation coefficient	Meaning and definition of correlation coefficient. Determination of different levels of correlation (pairing 'r' values with scatter plots).
3. The regression line	Illustration and purpose of linear regression. Drawing the estimated line by eye.
4. Theoretical background of fitting the line	Theoretical background of linear regression: least squares method (using computer software) Making predictions based on a regression line.
5-6. Application of the regression line in problems	Calculating regression line and correlation coefficient from own data (using computer software to forecast) Interpreting the results obtained by group. Exercise, summarise.

Figure 2 – The topic and the knowledge of the 6 lessons

A lot of basic knowledge was required during the course. The properties of the linear function were strongly relied upon, and the slope and intercept of the line were discussed in many exercises. For the prepared worksheets and lesson activities, we sourced textbooks from the Netherlands, Ireland and Luxembourg, based on our previous research experience, as well as the New Zealand IXL Learning site (www.ixl.com) (Boller, 2024). At the end of the process, students completed a feedback form where, in addition to their basic impressions of the topic, they were asked to rank how useful they found the topic and were also asked what prior knowledge they had to use most in lessons.

Findings

The first striking observation was an outlier group, shown in Figure 3. Most of the students in the experiment performed better on the post-test than on the pre-test, except for one group. The average relative growth of students in the higher-level group was -2%. The reason for this was found to be that members of the group had already scored very highly on the pre-test, with essentially no room

for improvement. In their case, therefore, it did not make sense to look at added value, so their data were not included in the rest of the analysis. The other students in the experiment scored significantly better on the post-test than on the pre-test ($\alpha = 0.05, \mathrm{F-and\,t-test}$).

Average relative growth in the participating groups					
A – grade 11 basic level	21%	D – grade 11 basic level	22%	G – grade 11 higher level	−2%
B – grade 11 basic level	10%	E – grade 11 basic level	9%		
C – grade 10 basic level	10%	F – grade 11 basic level	15%		

Figure 3 – Average relative growth in the participating groups

There was also an observed general improvement by tasks (Figure 4). Here we saw that the standard deviations of the mean of the pre and post tests are the same, with students performing on average $4 - 13\%$ better on each task. Despite our expectations, we observed an average growth of more than 10% in Task 2. This shows that in the post-test, students could calculate the corresponding x coordinate for a given y coordinate more skilfully. The smallest improvement was observed in Task 3. The reason for this is identified as the high input average of the task. The highest relative growth was achieved in task 4. In this task, the missing coordinates of the points of a line with a given slope had to be calculated without writing down the equation of the line, which requires a deep knowledge of the slope of the line. For the fifth task, a low 7% progress was observed, where the difficult wording of the task may have caused a more modest progress than expected.

The greatest improvement was in tasks 2 and 4, one of which we consider to be the basic tasks and the other the more difficult tasks requiring deeper understanding. What the two tasks have in common, however, is that the slope can be interpreted as a geometric ratio or a functional property.

required skills	mean of pre-test (standard deviation)	mean of post-test (standard deviation)	average rel. growth	Anticipated Slope Conceptualizations
Task 1: substitution into equation	0,34 (0,46)	0,37 (0,44)	7%	Algebraic ratio, Parametric coefficient
Task 2: fitting a point to a line	0,57 (0,49)	0,66 (0,47)	12%	Algebraic ratio, **Geometric ratio, Functional property**
Task 3: Pairing slope values with a graph	0,73 (0,30)	0,77 (0,29)	6%	Algebraic ratio, Physical property, Functional property, Behavior indicator

Task 4: calculate the missing coordinates of points on a line	0,39 (0,47)	0,46 (0,48)	13%	Algebraic ratio, **Geometric ratio, Functional property**
Task 5: determine the slope of a line from points with a given property	0,29 (0,40)	0,35 (0,41)	7%	Algebraic ratio, Geometric ratio, Physical property

Figure 4 – Skills expected in the input and output test tasks, average score and average relative growth

Another important finding of the experiment was the relationship between students' performance and their relative growth. Our sample shows a solid but weak correlation ($r \approx -0.32$). The sign of the slope of the fitted line was found to be significantly negative (α=0.05) by statistical methods, F- and t-test. This leads us to conclude that the weaker students made better improvements during the experiment than those who were more skilful in the beginning.

Another mentioned benefit was the introduction of the point cloud diagram in the mathematics lesson and the fact that standard deviation, which had previously had a poor fate, was now given a valuable place with regression analysis. Almost everyone considered that the use of computer software in class could be improved. Several teachers indicated that an extra lesson had to be added because of a lack of knowledge of Excel on the part of the students. Preparation for the lessons generally took a lot of time. As one colleague summarised:

"Overall, it was a very good insight into a very different world from what teachers and students think about mathematics. I love this game (reference to course - author's note) *and when I get the chance, I will definitely bring it to the next groups!"*

The students' feedback was also sought after the experiment. 74.7% of the participants gave a rating of 3 or more on a scale of 5 for how useful they found the topic. Students liked the lesson on correlation and causality the most (57%). Knowledge of the coordinate system (82.3%) and the equation of a line (75.9%) were the most important prior knowledge.

Conclusion and discussion

In our experiment, we investigated the impact of teaching correlation and regression on students' knowledge of the equation of a line. Our experiment supports Nagle and Casey's findings (2017) that the development of real-world examples and covariational thinking has had a positive impact on knowledge of slope (more broadly, the equation of a line). Inspired by their findings from personal task interviews, similar improvements were obtained in a classroom setting with a larger sample of students. Nevertheless, given the many levels of slope and covariational thinking, it is worth further exploring the connections between slope and covariational thinking.

We started from the assumption that students have only a surface knowledge of the equation of a line and the meaning of slope and intercept. From the low scores on the input measures, we saw that in many cases even the simpler problems were difficult to solve. In response to the research question, compared to our expectations, learning correlation and regression not only improved the

understanding of the equation among the participating students, but also led to a higher proportion of students solving the simpler problems correctly. Students performed significantly better on the post-test than on the pre-test. This was largely due to the types of tasks where the coordinates of a point on a straight line had to be calculated. These problems were also similar in that they could be solved with the same slope conceptualizations. We assume that this is related to the conceptualization of slope as a functional property, because in the 6-lessons course, students looked at the regression line as a function and often gave meaning to the slope in each context. We found that lower performing students made more progress during the new topic. Their relative growth was found to be significantly better than those who performed better on the pre-test. In addition to their higher development potential, and the fact that they have an even easier time formulating schemes of knowledge about the equation of a line may also play a role. This could be the subject of another research project.

Based on the experience of teachers and students who participated in the experiment, it would be desirable to place the correlation and regression analysis in an earlier grade. Contrary to expectations, much less knowledge of coordinate geometry was needed in the lessons. Another argument pro earlier publication is the introduction of statistics with standard deviation in grade 10, which may be worth adding. This is reinforced by the role of the higher-level group G in our experiment, where the group average did not improve because of the topic. This decision also includes the role of coordinate geometry, because even if not the concrete knowledge material, the perspective can add a lot to the understanding and the general mathematical skills that result from the maturity should be considered.

The topic of the experiment could be the subject of further research. It may be worth repeating the experiment on a sample 10th grade students with a control group. In the next period, we test our assumption that the teaching of correlation and regression has helped us to understand the slope as a functional property. To do this, we will identify general student misconceptions and model errors and carefully examine student responses to see which slope conceptualization they preferred.

The possible introduction of the topic in the curriculum will also require a rethink of teacher training, since, as the teachers wrote in the reflection, it is a very different world from the one they are used to. However, our experience has shown that the subject has great potential and a lot of interest, is accessible to students and, most importantly: Finally, it is easy to relate to everyday life and helps to make sense of real problems and today's issues, so it is worth engaging with.

Acknowledgment

Thanks to the colleagues who participated in the experiment and to my supervisors Csaba Csapodi and Ödön Vancsó. This study was funded by the Research Program for Public Education Development of the Hungarian Academy of Sciences (KOZOKT2021-26).

Risk literacy – a hybrid conceptualization

Marie-Theres Brehm[1] and Angelika Bikner-Ahsbahs[1]

[1]University of Bremen; Germany, mbrehm@uni-bremen.de

Given the current socio-ecological situation, marked by overlapping crises, the development of risk literacy is a relevant but under-researched topic in mathematics education. An appropriate conceptualization is lacking. We address this gap by elaborating a hybrid conceptualization of risk literacy for stochastics education in school. The concept combines mathematical risk competency with students' perception of risk, thereby combining a realist and a socio-constructivist approach. To illustrate this hybrid conceptualization of risk literacy, we draw upon examples from a design-based research study aimed at fostering risk literacy in stochastic lessons. These examples serve to demonstrate the usefulness of our conceptualization related to our task design. This is done by the method of empirically reconstructing students' interpretations of risk by tracking the social praxis of Game of Giving and Asking for Reasons (GoGAR) in the discourse of a situation of uncertainty.

Keywords: Risk, literacy, competency, instructional research, Inferentialism.

Introduction

The pandemic, climate change and other crises make it clear that citizens need to make well-informed decisions in risk situations that go beyond everyday scenarios. This emphasizes the significance of cultivating students' risk literacy from an early stage in their education (Pratt et al., 2011), but clear concepts of risk and risk literacy have not yet been elaborated in mathematics education (Eichler & Vogel, 2015). If we base risk literacy on Gal's (2002) model of statistical literacy, two components are crucial: statistical/mathematical knowledge and individual dispositions, such as attitudes or beliefs. Pratt et al.' (2011) confirm the relevance of these components in their educational study. They add that reasoning about risk as well as individual and social interpretations of risks are also relevant when risk literacy is to be fostered. However, fostering risk literacy has rarely been considered in mathematics education. Attention has rather been dedicated to risk competence and accessible visualizations of risk (Martignon & Hoffrage, 2019). Furthermore, the topic of risk is not prominently addressed in mathematics curricula (Burrill & Pfannkuch, 2024; Radakovic, 2015). As a consequence, the question of how to foster risk literacy in mathematics education at school remains an under-researched area, particularly for secondary level. To address these gaps, we conducted a design-based research study, named Risk-Design. The study focused on instructional design for developing risk literacy in stochastic lessons at grades 9 and 10. This article deals with a theoretical issue of the study; we develop conceptualizations of risk as a topic for stochastic lessons at school and of risk literacy to be fostered in these lessons. This will answer the first research question (*RQ1): What are the key aspects of risk literacy for stochastics education at school?* We are then going to show that our theorizing is empirically useful by providing two examples from the design study that demonstrate how we use the concepts of risk and risk literacy in our analyses to answer the second research question (*RQ2): How do students navigate risk, and how do they perceive risk thereby?* As this article makes mainly a theoretical contribution, we outline our methodological approach restricted to the analyses of the two examples. Finally, we discuss and reflect our results critically.

Theoretical framework

To elaborate risk literacy, we first conceptualize the term risk for stochastic lessons at secondary school level. This will result in a hybrid conceptualization, in which the two theoretical approaches, realism and socio-constructivism, which are not commensurable, are combined. Based on that, we will map out risk literacy as a hybrid conceptualization of the two approaches as well.

Conceptualization of risk

Although risk is considered in many disciplines, a clear definition of risk is missing in mathematics education (Eichler & Vogel, 2015). Hansson (2010) distinguishes between two perspectives on risk: a realist and a socio-constructivist perspective. The realist perspective assumes an objective world independent of individual and social interpretations. In this view, risk is modelled by probabilistic and statistical means, allowing risk to be treated as a measure of hazard that may help to mitigate risks objectively, for example using statistical data to minimize risk for a health treatment (see Pratt et al., 2011). However, risk decisions cannot solely be based on coordinating risky impacts with likelihood; they also need to encompass the complex conditions of people's lives and their perceptions and interpretations of the risks they meet. As demonstrated by the mathematician Fry (Medeiros, 2023), individuals facing cancer may opt for additional treatments with harmful side effects, even when the probability of positive outcomes is very low. It is the interpretation of risk as a *value-laden harmful event* that makes them decide for the treatment rather than against it based on the very small probability of a positive effect. While certain risks, such as nuclear power, are seen by people as unpredictable, other risks, such as cycling on busy roads, are accepted because risk-control seems possible. Such perceptions of risks cannot be captured by objective measures but rather by reconstructing people's interpretations of risk as it is conducted in socio-constructivist approaches. Hansson (2010), and Hansen and Hammann (2017) argue that both perspectives need to be combined to describe and understand people's handling of risks appropriately. Aven (2023) proposes to define risk as a situation with inherent uncertainty (U) about unwanted consequences (C), briefly (U, C), and distinguishes this from a measure that models risk. With this clarification in mind, we characterize risk as a cluster concept made up of five notions of risk. Related to a socio-constructivist approach, risk can be interpreted by people as a (1) value-laden uncertain and unwanted event, or (2) the cause of it (e.g., pathological gambling leading to financial loss). Related to a realist approach, risk can be understood as measurable, e.g., by (3) the probability of the occurrence of an unwanted event or (4) an expected value, namely, the sum of products of losses and their probabilities, and (5) the spread of a distribution. This cluster concept is particularly helpful for stochastics lessons at secondary school level because the different notions of risk can link the topic of risk to curricular requirements as well as providing space for the students' individual interpretations of risk situations that we have addressed in tasks. If necessary, this concept can be extended to include further risk measures.

Conceptualizing risk literacy as an aim in school

As part of *statistical literacy*, Gal (2012) describes probability literacy as the ability to access and handle "… probability-related information and ideas, in order to engage and effectively manage the demands of real-world roles and tasks involving uncertainty and risk." (p. 4). Here, managing tasks involving uncertainty and risks are crucial. According to Hansen and Hammann (2017), risk

competence is "... the abilities a person needs to address risk-related issues in a real-world setting" (p. 764), including the handling of risk-relevant issues in an individual's life. More concretely, Martignon and Hoffrage (2019, p. 31) explain how this handling can be conducted. For *risk-decision* situations, they distinguish four ways of *handling risks* that influence each other. These actions are not considered to be conducted in a specific order; instead, they clarify the ways in which risk-competent students should be able to handle risk decisions: they should (1) *identify risks*, (2) *analyze and model risks,* (3) *evaluate and compare different options,* and finally*,* (4) *take a decision*. It is not enough to practice these actions in just one context; various contexts should be included. This is considered by Niss and Højgaard's (2019) concept of *competency* from the KOM-project (i.e., *Co*mpetencies (KO) and the learning of *M*athematics (M)), which is the "insightful readiness to act appropriately in response to *a specific sort* of mathematical *challenge* in given situations." (p. 12, emphasis in original), here, situations involving uncertainty and risk. They distinguish three competency dimensions, that are necessary for developing competency: *the degree of coverage, the radius of actions*, and *the technical level*. "The degree of coverage of a competency is the extent to which all the aspects that define and characterize the competency are covered" (p. 21). We call these aspects facets of risk competency, encompassing the four actions introduced by Martignon and Hoffrage (2019), the cluster concept of risk, and all other risk-related mathematical aspects, such as risk-related representations and data handling. The radius of action means the variety of contexts or situations risk-competent people can address successfully. Finally, the technical level describes the "level of the mathematical concepts, results, theories, and methods" (Niss & Højgaard, 2019, p. 21), and risk reasoning that "the individual can bring to bear when exercising the competency" (p. 21). This definition of risk competency predominantly addresses risk from a *realist* perspective. Like Hansen and Hammann (2017) for science education, we also suggest adding a *socio-constructivist* perspective as a complement of risk competency to shape risk-literacy for stochastics education. For this, we use the term *risk perceptions* encompassing students' real-life experience. This hybrid view on risk literacy requires educational designs so that "personal experience and affective responses can be embraced rather than avoided" (Pratt et al., 2011, p. 344) in processes of risk reasoning.

In this elaboration, we answered the first research question by regarding risk literacy as an aim of stochastics education in school, that combines risk competency with risk perceptions, i.e., students' individual and social interpretations and handling of risks. This meets Gal's understanding of literacy and at the same time it allows linking the topic of risk to key concepts of stochastics curricula, i.e., probability, expected value, spread. In addition, the three dimensions of risk competency describe how students' risk competency develops. Fostering risk literacy means fostering risk competency and offering space for the students' risk perceptions by engaging critically and responsibly in risk reasoning and risk decision-making. Thereby, this approach takes up how students perceive, hence, value risk in context, socially and individually. In the next part we show how we have applied this concept in our design study and thereby provide a preliminary answer to the second research question.

Methodology and method

Our hybrid understanding of risk literacy is theoretically rooted in the concepts of statistical literacy, competency and risk-decision handling. We now substantiate our conceptualization empirically by two examples from our design study, beginning with methodological considerations. However, we

cannot describe the entire methodology of the design study, but rather elaborate a methodical account to make the examples accessible, by briefly providing the theoretical background for our focus on reasoning on risk decision-making, and, by a brief methodical description of our data analyses.

Investigating risk reasoning

Risk reasoning in situations of uncertainty, is the key to examine the students' risk notions and their handling of risk. For that we use the inferential approach based on Brandom (2000), which assumes that the meaning of a concept is determined by the ways the concept is used in collective discourses, which establish a *web of inferences of the concept with other concepts*. Brandom sees these collective discourses as an essential social practice (called the 'Game of Giving and Asking for Reasons' (GoGAR)), a process of social interaction towards mastering a concept by the "inferences it is involved in", i.e., by identifying "what follows from the applicability of a concept, and what it follows from." (p. 48). Notions of risk are stipulated in GoGAR related to the context and referring to other concepts. GoGAR is the process of reasoning, in which students may set up a claim, giving reasons, accepting or rejecting a claim while acting together in collaboration (Schindler & Seidouvy, 2019). By tracing inferences, GoGAR allows us to reconstruct processes of concept formation, hence, showing students' risk competency, their notions of risk and risk handling related to the situation.

Method

Our design research has two aims: developing an instructional design to foster risk literacy and theorize the results of the design experiments. The concept of risk literacy as well as GoGAR, both informed task design and data analyses. In the tasks, the students are asked to reason and make decisions in a situation of uncertainty to prompt GoGAR, activate risk competency, evoke risk notions and handle risks. Eight lessons (grades 9/10) were developed by four iterative cycles of revision (Brehm & Bikner-Ahsbahs, 2023). To capture collaborative discourses, video data were collected from two focus groups and the class discussions in each class. Data analyses were conducted in four steps. Step 1: identifying and summarizing episodes. Step 2: transcribing the relevant episodes. Step 3: sequential (turn-by-turn) analyses of the transcripts to *reconstruct* GoGAR, then coding terms of risk competency and the students' notions of risk, to finally build the web of inferences shown in the discourse. Step 4: interpreting/theorizing the results to answer the research questions.

Two empirical examples substantiating our theoretical elaboration

Two examples illustrate how we apply risk literacy and inferentialistic ideas in task design and data analyses (of step 3), how we interpret the results and thereby answer the second research question.

Example 1 (from lesson 1, grade 10): A tossing game (Figure 1)

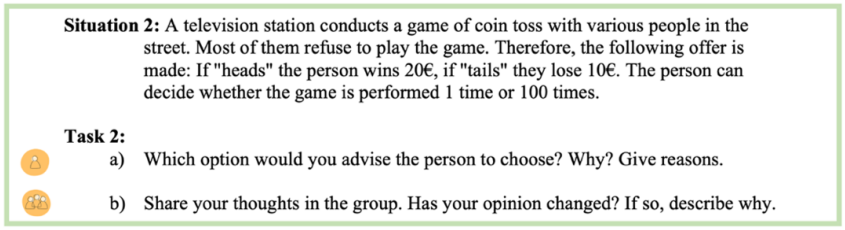

Figure 1: Heads or Tails – Task example 1 (Brehm & Bikner-Ahsbahs, 2023)

The students are familiar with the concept of *probability* experienced in game contexts. At stake in the task is the concept of the *expected value*, that is not yet introduced. The students may choose to play the game of coin tossing one time or 100 times. When heads are up, they win 20 € and if tails are up, they lose 10 €. The expected value is $\frac{1}{2} \cdot 20\,€ + \frac{1}{2} \cdot (-10\,€) = 5\,€$ per coin toss, which leads to an expected win of 500 € for a 100-fold coin toss in the long run.

23	Teacher:	What's riskier, doing it once or doing it 100 times?
24	Umut:	I thought that if I get only "tail", then I need 1000 € [to pay the loss].
25	Sina:	But I wanted to say that the risk is related to single play, then you only have the one-time chance, either you have it, or you don't have it.
26	Teacher:	Fritz and then finally Charlotte.
27	Fritz:	So, I would take one, because the probability is the same for both and with the second you can make more minus, but simply because (?)

As the students are unfamiliar with the Binomial Distribution, they reason informally, where we can observe *value-laden* relations expressed in their *risk notions*. E.g., Umut considers a *worst-case* scenario in the 100-times-play, making the 100 times play *feel riskier* (as he ignores the probability) (#24). Sina associates risk with the *unpredictability* of the one-off, stating, "either you have it or you don't have it" (#25). Implicitly, the risk seems to be more *incalculable* compared to the 100-times-play, in which winnings and losses can be equalized (#25). A similar decision is made by Fritz, but for a different reason, akin to the *worst-case* scenario (#27). Probability seems irrelevant to the decision, as the students can only grasp the probability of heads or tails in the Bernoulli experiment, hence, they state that it is the same in both options (#27). The *focus is the sheer possibility of losing more money* in the 100-times-play. When deciding which play is riskier, the students consider both, probability (#25, 27) and the amount of losses (#27), but coordinating both factors proves to be challenging, as also noted by Pratt et al. (2011). Some students adopt a risk-averse stance, focusing on *potential losses* (#24) and selecting a particular scenario, such as the *worst-case* scenario or the mere *possibility of losing* more money, associated with a particular *sense of high risk* (#27).

This example shows the value of our hybrid conceptualizing of risk literacy. Besides qualitative uses of probability (#25, 27), the students' perceptions of risk are expressed by three *notions of risk*: risk can be *the worst case*, the *possibility of losing much more money*, and unpredictable (*incalculability of risk*). The realist and the socio-constructivist perspectives are *interwoven*. Calculating risks did not appear by itself but needed to be more explicitly addressed in the tasks in the subsequent lessons.

Example 2 (from lesson 3, grade 10): Interpreting headings in the news (Figure 2)

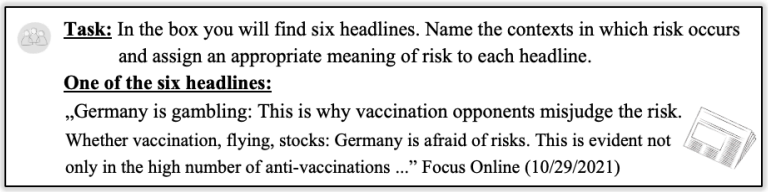

Figure 2: Risk addressed in a headline - Task example 2

The aim of the task (Figure 2) is to apply risk as a cluster concept thereby expand the radius of action and the technical competency level. Drawing on the methodical steps 3 and 4, we show that our conceptualizing of risk appears in the students' discourse, hence, turns out to be useful.

The example focuses on one of six risk contexts (sports, economics, health, workplace, society, climate change) using newspaper headings, thus contributing to expanding the radius of action. We expected two facets of risk competency be expressed: to *identify risks* through *analyzing* the context and *comparing* different risk situations. The following transcript illustrates how students master these facets of risk competency and the definition of the risk as a cluster concept.

1	Christin:	[…] I have cause, but I don't know if that's correct. Because the cause is that Germany is gambling away.
24	Christin:	[…] What do we do now with the headline?
25	Paul:	I have two [cause of an unwanted event].
28	Paul:	[…] "So Germany is gambling, that's why vaccination opponents are misjudging the risk". That is either the risk of contracting Corona or the risk of dying from Corona.
29	Christin:	Yeah. Sure.
30	Paul:	[…] Or the risk of dying from the vaccination, rather than from Corona, because after all, the risk of dying from Corona is much much bigger than dying from the vaccination.
31	Christin:	Ah no, wait, that's what's underneath it too. "Whether vaccinations, flies, stocks, Germany is afraid of risks". That shows, that's […] the unwanted event? Or cause. One of the two.
32	Paul:	Cause.
33	Christin:	Because Germany is afraid of risks. So risks are the cause, aren't they?
34	Paul:	Yes, we can say that.

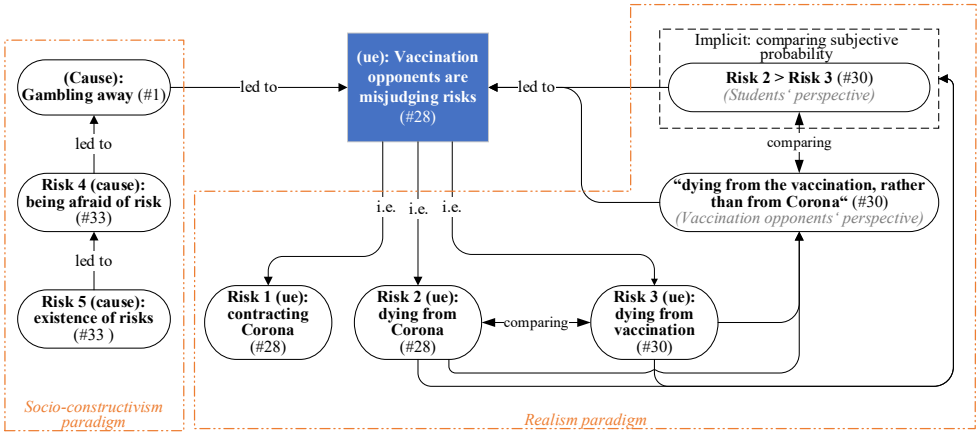

Figure 3: Web of inferences & facets (ue: unwanted event)

One student starts with "cause" as the claim (#1), found to be "Germany is gambling away" (see also Figure 3). The lack of resonance in the group leads to the *question* what to do (#24), *answered* by affirming the *claim* "cause" (#25) and then expressed with two claims (#28). "Germany is gambling away" is *identified* as the *cause* for vaccination opponents' misjudging the risk. This is clarified by *identifying* risks during GoGAR. Three kinds of risks as *unwanted and uncertain events* (ue) are *identified* contextually: "contracting Corona", "dying from Corona" (#28), "dying from the vaccination" (#30), comparing two of them in "dying from vaccination, rather than from Corona" (#30). This misjudging (of the vaccination opponents) demands further, more explicit *comparing* (#30), where risk takes the form of a *subjective probability* (a kind of implicit *modelling*) in "risk of dying from Corona is much much bigger than dying from the vaccination" (#30) as a reason that is given. These comparisons unpack the meaning of "misjudging" and as a consequence of "gambling

away" critically. Finally, being afraid of risks is *identified* as the *cause* underneath the unwanted events (#32), and by *comparing,* "risks" are *identified* as the deeper *cause* (hence risk) of being afraid of risks (#33) (see Figure 3).

In Example 2, the students master risk literacy by establishing a web-of-conceptual-inferences (Figure 3) joining both theoretical perspectives. This web displays two facets of risk competency that are activated: students handle risk by (1) *identifying*, (2) *analyzing and modelling risks* by comparisons. As this task is a reading task (reading headings), we do not find individual notions of risk as in Example 1 (see Pratt et al., 2011). Students rather unpack and interpret *the socio-cultural phenomenon of misjudging risks*.

Discussion and conclusion

We have answered Research Question 1 (RQ1) through theoretically elaborating a hybrid conceptualization of risk literacy by combining two theoretical perspectives as key aspects, a realist and a socio-constructivist perspective, and defining risk as a cluster concept for stochastic lessons in school. In both examples, the two theoretical perspectives come into sight and thus underpin the relevance of our conceptualizations. By analyzing the two examples, we answered how the students navigate risks and how they perceive risks thereby (RQ2). Consistent with Brandom's (2000) view on concept formation, Example 1 (a decision situation) shows that students' perceptions of risk (worst/unpredictable case, loss) arise from navigating risks by comparing them. Example 2 (a reading situation) displays that students navigate risks through activating risk competency, hence, risk literacy, and thereby decode a socio-cultural risk phenomenon within a web-of-inferences. How students navigate risks and how they perceive risks thereby, depends on the affordances of the risk situation confirming that risk must to be regarded in relation to the situation (Eichler & Vogel, 2015).

Gal (2012), Hansson (2010), and Hansen and Hammann (2017) proposed to consider both theoretical perspectives when risks and risk literacy are addressed. Therefore, our approach is not completely new. New is however, the way we have conceptualized risk and risk literacy for stochastics education in school. The added value of these concepts is their practicability for teaching and lesson design, their limitations are that the concepts are unusual and that two *incommensurable* theoretical views come together. Empirically, the two perspectives are interwoven, in research however we need to be aware, that we have hybrid concepts made of complementary, but incommensurable views. Whereas possible measures of risk can be learned and risk competency can be exercised, individual and social interpretations of risks that emerge in social interactions may not be measurable. These interpretations can neither be learned nor exercised. What can be exercised, however, is practicing GoGAR, which can sensitize for risks, help to manage risks and to reflect on risks and risk decisions critically.

Can you explain the surprising result? About students' arguments in the context of risk literacy before and after working with a simulation

Risk literacy as the understanding and evaluation of risks for informed decision making is increasingly relevant in today's society. Updating conditional probabilities based on new information, i.e., Bayesian reasoning, is fundamental for risk literacy as risks are understood as negatively connotated events and their corresponding probabilities. In this paper, we provide a novel approach to measuring Bayesian reasoning (and hence one aspect of risk literacy) by asking for explanations regarding surprising results. Our analysis includes three aspects: First, we introduce a coding system which can be used to categorize students' answers into misconceptions or adequate arguments with varying elaborateness. Secondly, we use this coding system to test if working with a computer-simulation affects students' arguments of the surprising results. The results are encouraging to infer that misconceptions can be reduced by using the simulation.

Keywords: risk literacy, Bayesian reasoning, simulations

Risk literacy and Bayesian reasoning

The probabilities of false-positive and false-negative test results along with their potential consequences, were central to the debate over the approval of HIV self-tests in Germany. These probabilities represent risks, with risks defined as negatively connotated events and their respective probability (Eichler & Vogel, 2015; Aven, 2023). Consequently, assessing these probabilities is crucial for risk literacy, which refers to the "ability to understand and evaluate risk, in order to support and make appropriate decisions" (Aven, 2023, p.1). Risk literacy is increasingly relevant in today's citizenship education (Geiger et al., 2023) and involves an internal view, i.e., including the ability for mathematical computations of probabilities, as well as an external view, i.e., putting the probabilities into the context and making sense of them (Eichler & Vogel, 2015). Therefore, risk literacy encompasses not only the ability of calculating probabilities, but also interpreting, communicating and arguing with probabilistic information of risk-related events (Hansen & Hammann, 2017; Operskalski & Barbey, 2016). Thus, measuring risk literacy requires tasks that go beyond the sole calculation of probabilities.

Different mathematical concepts are necessary for risk literacy (Hansen & Hammann, 2017). We focus on Bayesian reasoning in our study, a wide-studied mathematical concept with significant implications for risk literacy (Eichler & Vogel, 2015). Bayesian reasoning involves "combining conditional probability information and base rate information to update a posterior probability" (Reani et al., 2018, p. 63) In the context of HIV self-tests, the so-called sensitivity (e.g., 99.9% probability for an infected person to test positive) and false-positive rate (e.g., 0.2% probability for a non-infected person to test positive) are probabilities which are usually provided in the patient

information leaflet. Furthermore, the base rate refers to the probability that a tested person is infected with HIV and can be deduced from the prevalence of e.g., 0.1% for HIV among people at risk for HIV in Germany. However, users are often more interested in the probability that for instance a positively tested person is actually infected, called positive predictive value (PPV). The PPV, a posterior probability, can be calculated using sensitivity, false-positive rate and base rate information and is therefore an example of the process of Bayesian reasoning.

Estimating the PPV is error-prone. A meta-analysis found that only about 5% of individuals accurately calculate the PPV using sensitivity, false-positive rate and base rate information (McDowell & Jacobs, 2017). A typically erroneous strategy in this context is to assume certainty of the PPV based on the 99.9% sensitivity (Woike et al., 2023). However, despite excellent test-parameters (99.9% sensitivity and 0.2% false-positive rate), the PPV is only about 33%. This result–33% probability for being infected given a positive test result–is often precepted as surprisingly low (Gigerenzer et al., 2007), reflecting a failure to account for base rate information in updating the PPV.

Prior research highlights that translating probabilities into so-called natural frequencies helps improve understanding (McDowell & Jacobs, 2017). Figure 1 illustrates this, by translating the probabilistic information about HIV self-tests (see above) into a sample of 1,000,000 individuals. 1,000 out of these 1,000,000 randomly chosen people (i.e., 0.1%) are infected with HIV. Out of the infected individuals 999 test positive (sensitivity of 99.9%). However, 1,998 of the 999,000 not infected individuals erroneously test positive (false-positive rate of 0.2%). Therefore, a total of 2,997 (=999 + 1,998) individuals test positive, but only 999 of these 2,997 positively tested people (=33%) are actually infected with HIV. This result highlights the importance of the base rate: even a low false-positive rate of 0.2% still results in a large number of false-positively tested people (i.e., 1,998) as there are so many not infected individuals in the tested population. In this case, the false-positives (i.e., 1,998) even outnumber all infected individuals (i.e., 1,000) in the tested population.

Individuals	infected	not infected	total
positive test result	999	1,998	2,997
negative test result	1	997,002	997,003
total	1,000	999,000	1,000,000

Figure 1: 2×2 table with natural frequencies representing the information about HIV-self-tests

Previous research on Bayesian reasoning has primarily focused on asking for calculations of posterior probability, such as the probability of being infected given a positive test result. However, risk literacy entails more than calculation of probabilities only. Asking students to explain the seemingly counterintuitive results can assess how they communicate risks in a situation which requires Bayesian reasoning (Binder et al., 2019), thus using Bayesian reasoning as the mathematical content to measure risk literacy which goes beyond the calculation of probabilities. Figure 2 illustrates how such question can be asked. To date, no empirical studies have explored how students respond to such questions, making it unclear what arguments they provide and whether they recognize the role of the base rate.

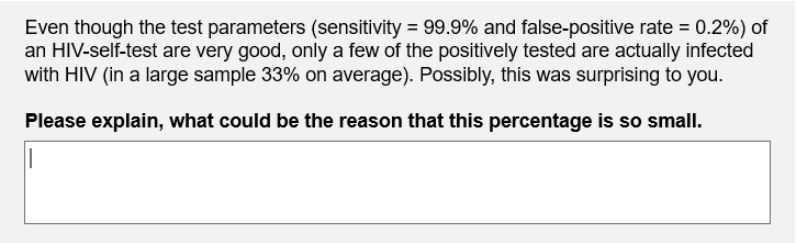

Figure 2: asking students to explain surprising results in the context of Bayesian reasoning

Simulations as a supportive tool

In the context of probability education, simulations are considered a supportive tool for learning (Maurer & Lock, 2016). They enable to re-enact stochastic phenomena (Erickson, 2010) and may also help to reduce misconceptions in the context of probability (Batanero et al., 2005). Particularly in the context of Bayesian reasoning, simulations may support a better understanding of conditional probabilities (Budgett & Pfannkuch, 2018; Engel & Martignon, 2015). Consequently, using a simulation, which imitates repeated testing with an HIV-self-test may be a supportive strategy additionally to the use of natural frequencies spelled out above.

Three characteristics of a simulation are central to our understanding of a simulation as a supportive tool. Firstly, a simulation imitates a (stochastic) phenomenon (Greca et al., 2014), in our case the repeated testing with HIV-self-tests based on the given probabilities. Secondly, a simulation is an interactive tool which "allows students to model and experiment" (Batanero et al., 2005, p.1) in the stochastic situation. Thirdly, a simulation has the purpose to illustrate processes which are otherwise hidden (Batanero et al., 2005; Greca et al., 2014). As such, a simulation (in the context of HIV-self-tests) should illustrate the influence of the base rate on the PPV which is otherwise often overlooked. The question arises, if a simulation with these characteristics can improve students' arguments for explaining the surprising results in the context of Bayesian reasoning.

Research questions

Asking students to explain surprising results in the context of Bayesian reasoning (see Figure 2) can measure understanding of risks and therefore risk literacy (see above). While it has been suggested before to ask this kind of question (Binder et al., 2019), empirical insights into how students answer this question are still missing. This leads to the following research questions:

- R1: What categories of arguments can be identified in answering this question?
- R2: How are different categories in a sample of statistically trained university students distributed prior to using a simulation?
- R3: Can working with a simulation improve the students' arguments?

For answering these research questions, we carried out two rounds of data collections (round 1 for R1 and round 2 for R2 and R3), which are described consecutively in the following.

Data collection and participants of round 1

In the first round, we asked 37 school students from grade 10 and 11 without prior training in Bayesian reasoning to explain the surprising results regarding the PPV in the context of HIV-self-tests. The

answers of the school students in the first round were used to develop a category system for the different arguments.

Data analysis of round 1

For identifying categories of arguments which students use to explain surprising results in the context of Bayesian reasoning we used a qualitative content analysis (Mayring, 2014) and formed categories inductively. The inductive approach was chosen as explaining surprising results in the context of Bayesian reasoning has not yet been empirically studied.

Results of round 1

Table 1 lists the categories of the school students' arguments, three categories were identified, out of which two reflect misconceptions (upper three rows in Table 1) and another category reflected arguments which correctly identify the influence of the base rate.

Table 1: category system for the different kinds of arguments to explain the surprising results

	Reason	**Definition**	**Example**
Misconception	Error of the test	Surprisingly small PPV is explained by errors of the test (e.g., false-positive rate).	"Because sometimes, the test is false-positive."
	Sources for errors of the test	Scenarios which may be the reason for an incorrect test result are stated.	"The test could be used incorrectly." "Possibly, another virus is mistaken for the HI-virus, because the test is not developed professionally."
	Sample size	The sample size is the reason for the small PPV.	"The value depends on how many people are actually tested, thus the sample size."
Identifying the influence of the base rate	Only mentioning the base rate	The base rate is mentioned without further explanation.	"Small probability for infection."

Data collection and participants of round 2

The second round of data analysis included 30 university students (prospective mathematics teachers). The university students participated voluntarily as part of their lecture. During the lecture, first, the university students received a worked-example on how to calculate the PPV followed by an exercise with feedback. This instruction and exercise are all prior training with regards to Bayesian reasoning of the university students. After the exercise, they were asked to explain the surprisingly low PPV in the HIV context (see Figure 2) and thus *before* using a simulation. Next the students were able to use a simulation for the HIV testing scenario for a total of 20 minutes to explore associations, e.g. between changes of the base rate and the PPV. After working with the simulation, they were asked again to explain the small PPV in the HIV context (see Figure 2).

Design of the simulation in round 2

A simulation needs to be carefully designed in order to fully embrace the (possibly supportive) characteristics spelled out in the theoretical background. Consequently, we have made deliberate design choices for the implementation of the simulation (http://bayesianreasoning.de/G1b.html) which we used in round 2 in order to answer R3.

In order to make the (otherwise hidden) influence of the base rate palpable in the simulation (third characteristic), we opted for three design choices. Firstly, we designed the simulation as a *stochastic* simulation. This means that the simulation's outcome depends on probabilistic parameter(s) within the simulation and therefore gathering observations does not always produce the same results (Greefrath & Siller, 2018). This implies that the probabilities inherent in the simulation are translated into (a sample of) frequencies which can be interpreted as natural frequencies which represent expected values. Like that, the support of natural frequencies spelled out above could also be exploited in using the simulation. Secondly, the simulation was set up in such a way, so that the frequencies are not represented all at once but can be sequentially gathered and observed. This may be promising as it has been shown that sequentially experiencing statistical information improves Bayesian reasoning (Schulze & Hertwig, 2022). Thirdly, the simulated frequencies representing the statistical information in the Bayesian situation are displayed in a visualization which is easily understood, in our case a 2×2 table. This choice is based on prior results that frequency-based 2×2 tables (as in Figure 1) are well-known visualizations easing inferences in the context of Bayesian reasoning (Böcherer-Linder & Eichler, 2019). For realizing the second characteristic of simulations (opportunity for interaction), we implemented sliders for the sample size which is drawn as well as for the value of the base rate. However, as interactivity in the context of Bayesian reasoning is not always linked to improved Bayesian reasoning (Mosca et al., 2021), we designed two versions of the simulation, version A in which only the sample size can be varied and version B in which also the base rate can be varied. Like that, version A was used in a first stage to get acquainted with the simulation and version B was used in a second stage, to allow more interaction and covariation of the PPV and the base rate to possibly understand its influence on the PPV.

Data analysis of round 2

For analysing the answers of the university students we used the category system from round 1. Yet, it became apparent that the last category (identifying the influence of the base rate) needed adjustment to reflect different levels of elaborateness in these arguments. While some students simply stated that the base rate was the reason for the surprising results without further explanation (fourth row in Table 1), others more elaborately explained the influence of the base rate on the different subsets (e.g., also including how the false-positives and true-positives were affected by the small base rate). These adjusted categories were used to code the answers of the university students by two authors of this paper and the inter-rater reliability was substantial with $\kappa = 0.76$.

For inferential analysis regarding R3, we carried out a Cochran's Q test to assess whether the distribution of the categories differs from before to after using the simulation. This is chosen based on the nominal outcome variable (category) and the repeated measures (McCrum-Gardener, 2008).

Results of round 2

With regard to R2 and R3, we provide the descriptive results of these categories of the students' answers before and after using the simulation in Figure 3. As evident in Figure 3, the category "Sources for errors of the test" was not used as an argument by the trained university students (and therefore may be unique to less statistically trained students).

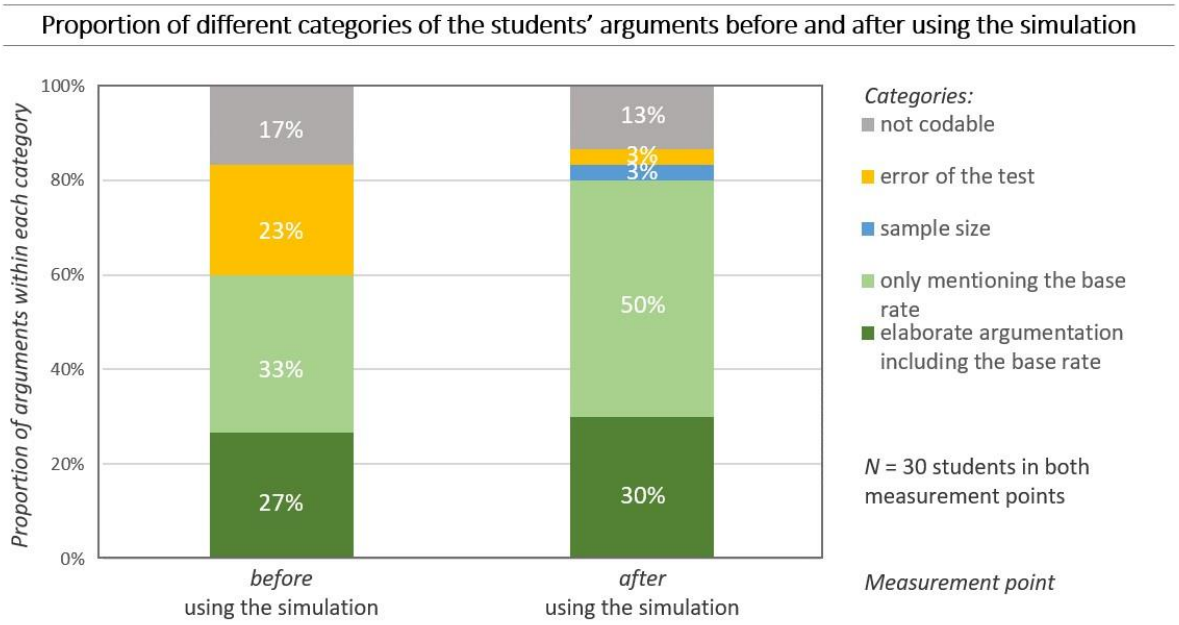

Figure 3: descriptive results of the students' arguments before and after using the simulation

Descriptively, there seems to be an improvement in the students' arguments as after using the simulation more students identified the influence of the base rate. The Cochran Q test is significant (T=18.6, df=1, p<0.01) implying that the distribution of the categories in the students' arguments significantly changed from before to after using the simulation.

Interpretation

The results have manifold implications. Firstly, in developing the category system for the data analysis we have identified misconceptions about the surprisingly small value of the PPV (i.e., attributing errors of a medical test or the sample size as reasons). This resonates with prior research results showing that the base rate is easily overlooked (McDowell & Jacobs, 2017). Secondly, these misconceptions seem to be rare among statistically trained people, but do exist. Thirdly, using the simulation we have designed seems to improve students' arguments, as after using the simulation hardly anyone expresses these misconceptions anymore and the majority (80%) correctly identifies the influence of the base rate. Still, in one case (=3% of the sample) a new misconception in the sample (attributing the small PPV to the sample size) occurs only after using the simulation. This may imply that allowing interactivity in the simulation with irrelevant features may hinder learning.

The presented research has limitations, as it cannot be ruled out that improvement in the students' arguments is based on repeated testing, as there was no control group. Future research could therefore study and compare, how working with and without a simulation changes students' arguments about surprising results in the context of Bayesian reasoning. Further, it would be interesting to study, how less statistically trained people, e.g., students in school, profit from working with the simulation. This is our aim in the larger context of the project siMINT (http://bayesianreasoning.de/br_simint.html) in which we study how working with a simulation can improve risk literacy.

Funding: The project receives funding from the Federal Ministry of Education and Research under the grant 16MF1070C – siMINT.

How do future teachers interpret a pupil solution to a probabilistic task involving proportionality?

Recent curricular programs worldwide include the teaching of probability from early levels. Consequently, teachers must have the necessary didactic-mathematical knowledge and competencies to solve probabilistic problems and interpret students' responses to these problems. Given the importance of proportional reasoning in solving probability tasks, this study investigates how future primary school teachers interpret mathematical practices in a fictitious student's solution to a probability task involving proportional reasoning. The research uses a qualitative approach to analyse how 133 future teachers interpret a student's solution based on proportional reasoning to calculate the composition of urns instead of calculating probabilities. The results reveal the participants' difficulties in correctly interpreting this strategy, although some improvement is observed compared to previous research.

Keywords: Probability, Proportional Reasoning, Teacher Education, Cognitive Processes.

Introduction

The integration of probabilistic and statistical content from the earliest levels of education requires comprehensive teacher training in probability and statistics. In addition to having the necessary knowledge and skills to solve the tasks they propose to their students, teachers must be able to interpret students' reasoning and effectively manage the challenges and obstacles they encounter with these contents (Franco & Alsina, 2022).

One of the fundamental components of probabilistic reasoning with which students have particular difficulty is proportional reasoning. Proportional reasoning, defined as the ability to establish multiplicative relationships between two quantities and to extend this relationship to another pair of quantities (Lamon, 2007), plays a crucial role in the analysis of the sample space and in the proportional quantification of probabilities (Bryant & Nunes, 2012). Thus, success or failure in the calculation and comparison of probabilities is closely linked to the recognition of the proportional nature of these probabilities (Begolli et al., 2021; Bryant & Nunes, 2012).

Specifically, recent research has analysed the strategies, difficulties, effects of problem variables and achievement levels of schoolchildren in solving ratio comparison problems (Castillo & Fernández, 2022), and to a lesser extent, proportional sharing problems (Yeong et al., 2020). Results indicate that students from primary to the end of secondary school have difficulties in identifying multiplicative relationships, comparing referents and understanding the concept of 'whole' (sum of parts) (Yeong et al., 2020). These difficulties are especially observed in the

probabilistic context, when students solve tasks involving the calculation or comparison of probabilities, often in the context of ballot boxes (Hernández-Solís et al., 2023). Although less attention has been paid to students' compression in sample space construction, it is observed that students with more advanced proportional reasoning skills show better performance in the construction of sample spaces (Hernández-Solís et al., 2024).

On the other hand, these difficulties are not exclusive to students. Thus, numerous studies reveal that both preservice and inservice teachers encounter difficulties with understanding and teaching the components of proportional reasoning (Buforn et al., 2018), as well as in interpreting students' responses in tasks involving proportionality (Fernández et al., 2013). Specifically, trainee (Batanero et al., 2015) and practising primary school teachers (Vásquez and Alsina, 2015) encounter difficulties in correctly identifying the proportional reasoning involved in solving probability problems, as well as in recognising and effectively addressing students' errors in this area (Burgos et al., 2022a, 2022b, 2023). Burgos et al. have specifically assessed the knowledge and skills of preservice primary school teachers in interpreting students' responses to probability comparison (Burgos et al., 2022a, 2022b) and fair play (Burgos et al., 2023) tasks, analysing how they identify proportional reasoning or its absence in the mathematical practices of schoolchildren.

The results show that future teachers have difficulties in identifying possible erroneous strategies behind students' incorrect answers, as well as in detecting proportional reasoning in their answers. In the case of secondary school, Dröse et al. (2022) asked future mathematics teachers to analyse a real solution to a conditional probability problem together with an excerpt from a student dialogue (vignette) to assess their teaching competences. The results revealed that, although preservice teachers could identify procedural errors, they failed to recognise the underlying conceptual difficulties that caused these errors.

In this paper we focus on how future teachers recognise the role of proportional reasoning in constructing sample spaces to create equal probabilities (Supply et al., 2020) when analysing a fictitious student's solution.

The research is framed in the model of categories of Didactic-Mathematical Knowledge and Competences of the mathematics teacher (Godino et al., 2017), which proposes six categories for the didactic dimension of knowledge (epistemic, cognitive, affective, interactional, mediational, and ecologic) to facilitate the categorization and assessment of knowledge and competences and the design of training actions with future teachers to develop such knowledge and competences. In this framework, knowledge is strongly related to the notion of competences. In this paper, we specifically focus on cognitive analysis competence, which allows teachers to interpret students' mathematical practices, i.e., comprehend students' procedures, identify personal interpretations, and recognize any misconceptions that may arise during problem-solving activities but focusing on the presence of proportional reasoning in a probability task.

In this line, we propose to investigate the cognitive analysis competence of future teachers through the interpretation of the mathematical practices in a pupil's solution to a probability task. The research question is: how do future primary school teachers interpret the mathematical practices in a fictitious pupil's solution to a probability task involving proportional reasoning?

Methods

The research follows a qualitative methodology with a descriptive approach. A total of 133 future primary school teachers (ages 20-21) from a Spanish university who had taken a mathematics education course participated voluntarily and in an informed manner. At the time of the intervention, they had already received previous didactic-mathematical training on statistics and chance, including epistemic (main concepts, properties and stochastic procedures), cognitive (analysis of errors and difficulties in the learning of probability) and instructional aspects (design and sequencing of tasks, materials and resources for teaching probability). The task, along with others not analysed in this report, was included as part of a midterm evaluation with an impact on the final grade of the course.

The task proposed to the participants, with a fictitious primary school pupil's solution, is presented below in Figure 1. The task asks future teachers (FTs) to interpret the practices developed by a fictitious primary school pupil and to evaluate both their solution and their justification, providing reasons for their evaluation. This assignment model focuses explicitly on the cognitive facet and has been previously used in research with future teachers (Burgos et al., 2022a, 2022b, 2023). However this particular task has been designed ad hoc to study the competencies of participants to recognize aspects of proportional reasoning involved in a situation of creating equivalent ballot boxes. The proposed fictitious solution is based on reflecting on the proportional composition of the content of box B with respect to box A, assuming that in box A there are only 4 balls, thus calculating the ratio between the white balls and the black balls in box A, a ratio that must also be respected in box B containing 20 balls. Then, the fictitious solution presents a notational error by indicating the multiplication between a fraction and an integer instead of equivalent fractions (1/3x5 as 5/15). The ratio chosen in this solution is different from the calculation of the classic probability as the ratio of favorable cases to possible cases with the Laplace formula, so FT should recognize the particularity of this solution and identify the proportional reasoning behind it.

The task proposed:

We have two boxes, box A and box B, containing both white and black balls. In box A there are three black balls for each white ball. There are 20 balls in box B (black and white). How many balls of each colour are there in box B if it is just as likely to draw a white ball as in box A?

A fictitious primary school pupil's solution:

1/3 **A** i.e. for every 4 balls, 1 white and 3 black

20 balls **B** is just as likely to draw a white ball as box A.

Let us suppose that in box A, there are only 4 balls. If there are 20 balls in box B, then there are 5 times more balls then in box A. Then we multiply 1/3x5 and get 5/15, i.e., for every 5 white balls, there are 15 black balls. If there were 20 balls in box B, then there are only 5 white balls.

Assignment for the future teacher:

Do you think the response given by the pupil is correct? What mistakes has she made? Justify by analysing the pupil's response.

Figure 1: The task proposed to the future primary school teachers

To minimize subjectivity biases, the authors together with an external expert contributor participated in the analysis through a cyclical process of defining, validating, and refining the category system. The three researchers independently analyzed portions of the data (the FTs' written operational and discursive practices), identifying types of responses in the interpretation of the pupils' solutions (Bardin, 2002). They then shared their results, unified the observed response types, and reached a consensus on the emerging categories. This process was cyclically repeated with additional data until all the data had been analysed. Finally, in order to facilitate the visualization of the categories described and the proportion of responses in each one, the information has been synthesized in a frequency table.

Results

The emerging categories identified in the future teachers' responses are described below:

- *Adequate connection between probability and proportionality*. In this category, the future teachers identify and explicitly mention the connection between the use of the ratio and the (equi)probability, demonstrating a correct understanding of the pupil's procedure, so this is a correct interpretation of the pupil's solution.

  FT24: La respuesta es correcta, ya que comprende las relaciones de proporcionalidad a partir de fracciones equivalentes. En ambas [cajas] la probabilidad de una y otra es la misma, aunque varía el número de bolas.
  Translation: *The answer is correct, as she understands the proportionality relationships from equivalent fractions. In both [boxes] the probability of one and the other is the same, although the number of balls varies.*

- *Adequate solution without relation to probability*. In this case, the pupil's solution is considered correct, but it is explicitly indicated a missing relation with probability. We assume that the FTs expected the use of the Laplace rule, which they did not find in the pupil's resolution and they did not understand the pupil's use of proportional reasoning.

  FT11: [La alumna] entiende la resolución del problema a base de fracciones equivalente y supuso la caja B en función de un supuesto de la A. Comprende estos conceptos pero no su relación con la probabilidad.
  Translation: *[The pupil] understands the solution of the problem based on equivalent fractions and assumed box B based on an assumption of box A. She understands these concepts but not their relation to probability.*

- *Correct use of probability*. In this category, the use of probabilistic procedures and concepts is highlighted, due to the use of typical terms of the probabilistic domain, such as favourable cases, possible cases, etc- when in fact the pupil does not make reference to these concepts.

  FT88: [La niña] ofrece tanto una respuesta correcta como una justificación correcta ya que muestra que entiende el concepto de probabilidad diferenciando los casos favorables y posibles.
  Translation: *[The pupil] provides both a correct answer and a correct justification as she shows that she understands the concept of probability by differentiating between favorable and possible cases.*

- *Error with fractions*. In this case, the operation mistake is correctly detected, pointing out that the error lies in the execution of the multiplication of a fraction by a whole number. However, in this interpretation the identification of proportional reasoning is missing.

FT122: Encontramos un problema con el planteamiento de la resolución debido a que la multiplicación 1/3x5 el resultado obtenido no es el que ha contestado la alumna.
Translation: *There is a problem with the approach of the resolution because the result obtained from the multiplication 1/3x5 is not the one the pupil has answered.*

- *Inadequate solution due to absence of probability*. Here, it is found to be an error the lack of use of probabilistic terms or formulas or misunderstanding in the probabilistic reasoning. It seems that the use of probability calculus was expected but did not occur in the pupil's resolution.

FT104: Respuesta y justificación incorrecta. No razona de la probabilidad sino de la cantidad de bolas
Translation: *Incorrect answer and justification. Her reasoning is not based on probability but on the quantity of balls.*

- *Error in the use of the ratio 1/3 for 1/4*. In this case, the use of the ratio 1:3 is considered a misunderstanding in the use of the Laplace formula to calculate the probability of drawing a white ball in box A. The FTs do not identify the fraction as the ratio; therefore, they consider that the error is in the identification of the number of possible cases.

FT64: No es correcto. Aquí el error que comete es identificar que de cada 4 bolas una es blanca, y 3 negras como 1/3 cuando debería ser 1/4.
Translation: *It is not correct. Here the mistake she is making is to identify that out of 4 balls one is white, and 3 black as 1/3 when it should be 1/4.*

- *Incorrect assumption of 4 balls in A*. Here, the particularization made by the pupil in supposing that there are 4 balls in box A is considered erroneous, although it is explicitly stated that this is only an assumption.

FT38: Se ha equivocado ya que parte de una suposición errónea, que es “la caja A tuviera 4 bolas”.
Translation: *She is wrong because she is working on the wrong assumption, which is “box A had 4 balls”.*

Finally, there are two more categories to identify inconclusive responses when FT do not provide any information about their understanding of the strategy used by the pupil and missing answers, when the FT does not give any answer. Here an example of inconclusive response:

FT75: Su respuesta es correcta ya que razona bien el ejercicio.
Translation: *The answer is correct as she reasons the exercise well.*

The following Table 1 shows the frequency distribution (percentages) of FTs' responses according to the categories described. The results reveal that a high proportion (24.81%) of responses are classified as "inconclusive", suggesting considerable difficulties in formulating clear and substantiated interpretations. This may reflect a general struggle with the underlying concepts or the application of proportional reasoning in probabilistic contexts.

The FTs had difficulties to properly interpret the role of fractions in the fictitious pupil's strategy considering, for example, that for the pupil, 1/3 is the probability of drawing white ball in A. It is worth noting the misunderstanding generated by using a different ratio than expected in the classical probability calculation (1/3 instead of 1/4) which has been detected as erroneous by a 15.04% of the participants, as well as the identification of the procedure as erroneous only because the probability is not calculated by a 14.29% of the participants. Despite having purposely avoided

asking FTs for prior resolution of the task, several of the identified categories refer to a prototypical response expected by the FTs that does not correspond to that of the pupil.

Table 1: Frequency distribution (percentages) of FTs' responses. In bold the correct interpretation.

Categories	Frequencies (percentages)
Adequate connection between probability and proportionality	18 (13.53)
Adequate solution without relation to probability	5 (3.76)
Correct use of probability	5 (3.76)
Error with fractions	17 (12.78)
Inadequate solution due to absence of probability	19 (14.29)
Error in the use of the ratio 1/3 for ¼	20 (15.04)
Incorrect assumption of 4 balls in A	12 (9.02)
Inconclusive	33 (24.81)
No reply	4 (3.01)

These results seem to confirm a tendency of future teachers not to go deeper into the analysis of the pupils' answers, preferring to compare the procedures with a single correct expert solution, as already observed in Burgos et al. (2023).

Moreover, this indicates a lack of multiple or relativistic perspectives needed to understand different possible solutions (Buforn et al., 2020), and could be due to a limited or incomplete knowledge of proportional reasoning and its role in the probabilistic context. Actually, only a small percentage of responses (13.53%) managed to establish an adequate connection between probability and proportionality, an essential aspect for a correct understanding of the pupil's solution.

Errors related to fractions, seen in 12.78% of the responses, and incorrect assumptions about the number of balls in A (9.02%) further suggest that future teachers struggled to integrate proportional reasoning effectively, since, although they detect other inconsistencies, they do not focus on what is really important in the pupil's response. The high number of inaccurate and inconclusive responses in interpreting the mathematical practices of the fictitious pupil points to a limited or incomplete understanding of both the probabilistic and proportional concepts involved in the task, indicating the need for a more nuanced and comprehensive approach to teaching these ideas.

Conclusion

A mathematics teacher's ability to interpret the reasoning of his or her students is fundamental to ensuring that both teaching and learning take place with quality. This ability helps teachers identify student understanding and difficulties. In the task analysed, both proportional and probabilistic reasoning play a fundamental role. Compared with the results of Burgos et al. (2022b), a lower percentage of participants recognize the presence of proportional reasoning in the pupil's solution but, in contrast to the results of the mentioned research, when they refer to proportionality, they do it in a correct way, in some cases explicitly mentioning the multiplicative relation between the composition of the two boxes.

The competences of future teachers to recognize and identify pupils' strategies and errors have an impact on the quality of teaching. Thus, it is of great importance to address these didactic cognitive analysis competences in teacher, mainly when unexpected solutions were given and unforeseen

proportional relations -different from the traditional ones involved in formulas- were indicated, thus allowing for a diversity of reasoning (Buforn et al., 2020).

Since many of the interpretations were inconclusive, it would be beneficial in further researches to supplement the data with interviews and follow-up sessions where the FTs can explain their assessments of the students' responses. This could help identifying if deficiencies in mathematical knowledge could be among the causes of these inconclusive or inaccurate interpretations. The study's results may be influenced by the participants' early training stages and limited experience in probability, which affects the generalizability to more advanced groups. Despite our efforts to conduct a rigorous analytical process, the qualitative data analysis retains a degree of subjectivity. These limitations require further research with diverse samples and methods to verify these findings and deepen our understanding of teachers' probabilistic and proportional cognitive competencies.

Statistical literacy in middle school students' performance of speech acts when reacting to data-based arguments on social media

Christian Büscher

University of Duisburg-Essen, Germany christian.buescher@uni-due.de

In order to adequately deal with possibly misleading statistical information on social media, students need to develop statistical literacy. Especially important for formulating replies to data-based arguments is the communicative component of statistical literacy. However, research provides only little guidance for how to develop this component. This study draws on the framework of communicative rationality for statistical literacy to inform the design of a learning environment on communicating about data-based arguments on social media. The empirical results show that the learning environment can elicit communicative rationality and it shows the variety of the students' communication about statistical information. These insights also motivate a further direction for research, as the students' performance of speech acts when formulating refutations of statistical arguments come into view.

Keywords: Statistical literacy, communicative rationality, disinformation, social media, design research.

Introduction

In today's online society, online media play an increasingly central role for citizens' access to news and the processes of forming opinions on political matters (Tucker et al., 2018). Only about 22% of people in many countries get their news from news media publishers, most people get their news from social media or direct messaging (Newman et al., 2024). Generally, there is a large distrust of online information and 59% report to be troubled with identifying real from fake information online (Newman et al., 2024). This distrust in media poses a challenge for democratic countries, as studies show that heavy social media use is associated with a growing distrust in political institutions (Lorenz-Spreen et al., 2023).

Most of such discourse focuses on the impact of disinformation, meaning false information that is intentionally introduced by an actor to harm the public (Freelon & Wells, 2020). Yet, information shared on social media often also contains data and graphs that can also be used to promote possibly misleading arguments, even if they are rooted in a factual basis. For traditional online news media, Gal & Geiger (2022) show the high critical demands on statistical and mathematical knowledge needed to adequately understand and interpret the news items. The shift from traditional media to social media increases the complexity of the required mathematical and statistical knowledge, as citizens on social media have the opportunity, and possibly the duty, to *react* to the shared information. It therefore becomes an important area of research to identify and to foster the knowledge needed for citizens not only to identify possibly misleading statistical information, but also the knowledge needed to engage in communication on statistical information shared on social media. This study draws on a framework proposed by Büscher (2024) to conceptualize this knowledge needed to communicate about statistical information. Afterwards, insights into the design

of a learning environment are provided to show how task design that uses social media posts can elicit communicative reactions showing students' statistical literacy.

Theoretical framework

Communicative rationality for statistical literacy

Understanding and criticising statistical information on social media requires statistical literacy, for which Gal's (2002) definition specifies two components, which Büscher (2024a) relates to as the (1) *interpretative* component and the (2) *communicative* component: (1) an individual's ability to understand and critically evaluate statistical information (i.e., news articles or social media posts making some quantitative argument) and (2) an individual's ability to communicate their understanding and criticism of such information. The communicative component becomes important for the case of statistical information on social media, as citizens that want to participate in public discourse on social media have to be able to formulate their support or their objections to statistical information.

To conceptualize such a view on communication on statistical information, Büscher (2024a) adapts Jürgen Habermas' works on communicative rationality, which "secures for the participating speakers an intersubjectively shared lifeworld, thereby securing at the same time the horizon within which everyone can refer to one and the same objective world" (Habermas, 1998, p. 315). Communication understood in this way is a process during which interlocutors reach a common understanding of the world. This common understanding might prove especially difficult to reach in the case of statistical information, where contradictions can arise between seemingly objective data-based arguments.

Communicative rationality is exercised by an interlocutor that evaluates an argument based on different *validity claims*, which provide different reasons for why the argument should be accepted or rejected (Habermas, 1998). For the case of data-based arguments, Büscher (2024a) provides a topic-specific adaption of communicative rationality for statistical literacy that specifies four different validity claims. (1) A data-based argument that does not align with conventional rules for formulating statistical arguments, that provides incorrectly drawn graphs, or that misses crucial information on sampling or base percentages might be rejected on the grounds of *comprehensibility*. (2) If the argument is not related to the objective world, if the used data do not adequately describe the underlying phenomenon, or if there are datasets known to the interlocutor that directly contradict the argument, the argument might be rejected on the basis of *truth*. (3) If the interlocutor suspects a hidden manipulative agenda behind the argument or if the reader suspects a lie, the argument might be rejected regarding the validity claim of *truthfulness*. And (4) if the argument violates social norms or ethical standards, it might be rejected because of its missing *rightness*.

Additionally, a Habermasian framework can illustrate that communicative reactions to statistical information posted online are not simple statements that are conducted in a social vacuum. Instead, they can be considered *speech acts* with which the reacting person hopes to achieve specific aims: (1) to inform others that one holds a specific view (a locutionary speech act), (2) to convince others to rationally agree with one's own view (an illocutionary speech act), or (3) to manipulate others into acting or thinking while hiding this intention (a perlocutionary speech act) (Habermas, 1998). An

investigation into the statistical literacy exhibited by students' replies to statistical information on social media thus needs to pay attention to the intended speech acts.

Eliciting and fostering the communicative component of statistical literacy

Empirical studies on students' statistical literacy and on design principles for fostering their statistical literacy are relatively scarce in mathematics and statistics education research. Studies show that statistical literacy seems to be relatively low in middle schools, but that it also can be developed (Callingham & Watson, 2017; Yolcu, 2014). Regarding ways to foster statistical literacy, Büscher (2024b; 2022) illustrates design principles that revolve around using critical contexts, engaging with statistical information that is based on models, and to provide scaffolds for reflecting on statistical information. Yet, these empirical results and design principles focus mostly on the interpretative component of statistical literacy. Regarding the communicative component of statistical literacy, Büscher (2024b) provides some first starting points by illustrating tasks in which students are provided with scaffold criteria for evaluating statistical information. More insights are needed regarding the question how to specifically elicit and foster the communicative component of statistical literacy. This paper engages with following research question: How do students address different validity claims and how do they engage in speech acts when communicating about statistical information found in social media posts?

Method

This study continues earlier work on identifying design principles and investigating students' learning processes on statistical literacy (Büscher, 2024a; 2024b). Earlier studies illustrated students' use of validity claims when criticizing statistical information (Büscher, 2024a), but without focusing on the speech acts committed when reacting to social media posts. This study intensified the work on the communicative component of statistical literacy by designing and investigating a learning environment that uses social media as the arena of statistical arguments.

Design of a learning environment

For this study, a learning environment was designed for use in Grade 7 in Germany. The learning environment consisted of a sequence of four lessons (each 45-90 minutes), during which the students engaged with real-world examples of extremist positions on immigration that are argued on social media using statistics. The lessons were designed by the teacher with the goal of providing the students with the necessary goals for 'debunking' statistical information that one the one hand does have a basis in real data, but on the other hand provides a misleading and manipulative argument.

A full account of the developed materials cannot be given here due to the available space, so that only a short overview is possible. Several design elements were provided in each lesson: (1) A social media post under investigation. (2) A worksheet that instructed the students to analyse the post. Here, students were asked the following questions: "What are your first thoughts on this post? What is the claim of the statistics? How are the data presented? What do you notice?" While working on this work sheet, the students had access to various scaffolds: (3) a list of sentence fragments for scaffolding the students' communication on the social media posts. Sentence fragments included "The statistics shows, that …", "Clues for/against this perspective are…", "If you look closer, you

can notice that…", "my personal opinion is that…", and many different fragments more. (4) A list of 'worry questions' (inspired by Gal, 2002) including "what is fact, what is opinion?", "are there numbers missing?", "is there an intention to mislead?", "what is being described and what is impossible to infer from the statistics?", "are there any events that were not included as a possible reason?". Following work on the work sheet, a whole-class discussion took place. Afterwards, (5) the students were provided with a work sheet for drafting a reply in the form of a social media post.

In the whole sequence of four lessons, three different social media posts were investigated. This study only focuses on the first of the posts, which was the object of the second lesson. Figure 1 shows a reconstruction of the social media post, whose original form that was investigated in the lesson was posted by a far-right group and is reconstructed and anonymized here. This post uses allegedly real data provided by official sources to make a claim that half of asylum seekers in Germany live on social welfare, which is portrayed as very negative and used as an argument for calling for additional measures against immigration. Reasonable rejections of such a claim would pose high demands on statistical literacy, as the post itself seems to be provides an explicit source (i.e., it can be considered *true*) and does not exhibit obvious mathematical errors (i.e., it can be considered *comprehensible*). Students that argue against the *truth* or *rightness* of such a claim could draw on external knowledge of Germany's welfare or immigration systems. For example, they could argue that asylum seekers have a moral right of support (thus challenging *rightness*) or draw on knowledge of the phenomenon by arguing that asylum seekers in Germany actually often are excepted from taking on jobs while their status is being evaluated (thus challenging *truth*).

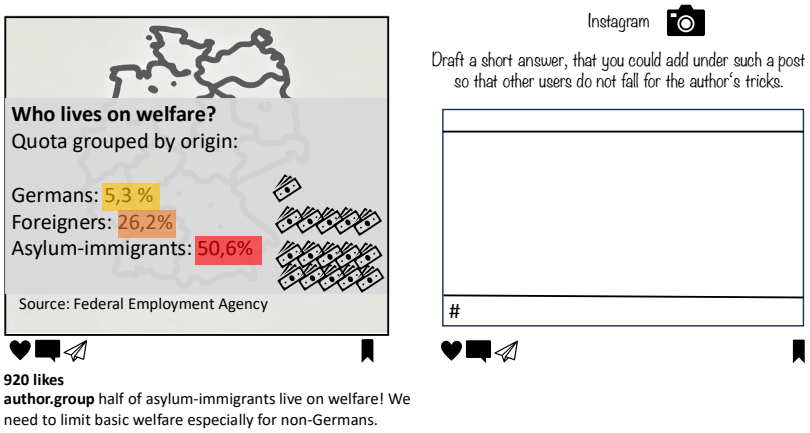

Figure 1: Reconstruction of social media post (left) and work sheet for drafting a reply (right)

Participants

The teaching sequence was carried out with two classes of Grade 7 students in May 2024, with a total of 43 students who participated in the design experiments. The participants were attending a school in a very low-income metropolitan area with an almost 100% rate of family immigration background, which meant that the students were emotionally highly invested in the context and in 'debunking' the social media posts. This means that a lot of care has to be given surrounding the use of this learning environment: care of the teacher to create an environment where students can safely engage with possibly emotionally disturbing content, and care of the researcher to be wary of sharing sensitive

information and of generalizing from highly subjective experiences shown by the students. However, the students' subjectivity is very much the point here: the real-word demand of social media is that students need to be able to adequately express their subjective position regarding statistical information that is possibly perceived as insulting and disturbing.

Data collection and data analysis

Data collection included the students' written replies to the social media posts, as well as videos of small-group discussion and whole-class discussion. For this study, only the written replies of the first class of students were used and only for the first social media post investigated by the students (Fig. 1). Thus, this study illustrates the effects of the design of the learning environment using 16 written replies. These replies do not provide insights into individual students' statistical literacy, as they are in part a product of small-group and whole-class discussions. Nevertheless, they allow insights into the differences in students' communication about data-based arguments that can be elicited by the design of the learning environment.

The written replies were analysed with regard to the students' use of validity claims using the framework for communicative rationality for statistical literacy (Büscher, 2024). Additionally, the written products were compared and contrasted to inductively generate categories for describing the differences in the students' speech acts shown while formulating replies that address different validity claims.

Empirical results

The written replies to the social media post that were created by the students after the whole-group discussion show a high variety of addressed validity claims and speech acts, although there are some commonalities between the students. In the following, translated examples are provided to illustrate the results. Where possible, translations were attempted that were consistent with the numerous orthographic and grammatical difficulties encountered by the students when responding to statistical information.

Some students purely address aspects of percentages and illustration:

S1: The statistics is wrong the percentages do not add up to 100% and the bank notes do not fit the percentages at all.

S2: It is claimed that asylum-immigrants get the most welfare. It is noticeable that the percentages were illustrated wrongly. The darker the colour, the more percentage it is. In summary you can say that it is a bad example because 20% are missing.

S1 and S2 both note that the given percentages do not add up to 100%, which they argue is a mathematical error. S2 also notes that higher percentages are presented in a darker colour, although it remains unclear why exactly S2 considers this wrong. Additionally, S1 argues that the bank notes do not fit the percentages. While the exact reason why S2 thinks this are unclear here, this is often the point of criticism in the whole dataset. These students treat the illustration of bank notes as an algebraic problem: If 5,3% correspond to a single bank note, then ten bank notes should correspond to 53%, not 50,6% as in the post. In this way, both students address violated formal rules of forming and illustrating statistical arguments, making this a criticism of *comprehensibility*.

It is notable that under the perspective of the statistical expert, the students' refutations are not convincing. It is not a mathematical error that percentages do not add up to 100%, because they do not describe the fractions of group members for all people living on welfare, but only the fraction of people living on welfare within each of the three groups – although it is possible this confusion is intended by the authors. A slight vagueness in the meaning illustrations like the bank notes is also often a necessity for creating concise illustrations and can be disregarded. Another notable difference is the level of elaboration of the replies, showing S2's use of the language scaffolds.

Other students focus on different aspects:

S3: [The author group] tries to manipulate us with this post to vote for [far-right party] AfD. The numbers also are not complete because they do not add up to 100 percent. […]

S4: The statistics show that asylum seekers and foreigners apply for a lot of welfare and it doesn't even add up to 100%. [The author group] is just xenophobic and only posts fake posts about foreigners. I also know a lot of refugees who want to work but it is being forbidden. Because of that it does not make sense that [the author group] posts that refugees apply for such and such welfare, if they are not allowed to work they of course have to apply for welfare.

Both students also address *comprehensibility* through the same argument of missing 100% as S1 and S2, but add additional aspects. S3 addresses a suspicion of the author group's intention: they created the post solely to mislead, manipulate and to influence elections. Likewise, S4 posits that the author group is xenophobic. In this way, both students base their evaluations not on validity claims such as truth or comprehensibility, but on issues of the subjective intentions of the authors, and therefore address the validity claim of *truthfulness*. S4, however, also adds knowledge of the social phenomenon of refugees and welfare. Because S4 knows that refugees are often forbidden from working, S4 calls into question whether the statistics adequately represent the phenomenon. By relating to additional knowledge of the phenomenon, this is an evaluation of the *truth* of the data-based argument.

In the replies of both students, speech acts can be observed. S3 appeals to the readers of their reply by making an explicit distinction between *we*, the collective own group of readers, and *them,* the author group who tries to manipulate 'us'. This we-them-framing can be considered a part of a *perlocutionary* speech act, as it provides a subtle way of drawing the readers to one's own side that is not rooted in rational agreement to validity claims. S4 engages in an *illocutionary* speech act through an explicit appeal to personal knowledge of the situation ("I also know a lot of refugees") as a proof of the *truth* of this statement. Other students are very direct in their use of speech acts:

S5: The post is incorrect. If you add up the percentages it doesn't make 100%. Please do not fall for this trick.

In these ways, S3, S4 and S5 seem to attend to the social nature of replies on social media posts by orienting their reply towards an audience.

Still other students provide a more differentiated evaluation of validity claims:

S6: If you add up the numbers it results not in 100% which means that it's wrong. In summary, it is right but also wrong because as mentioned it does not result in 100%.

S7: Actually I think that it would look very different if we would finally let foreigners or 'asylum immigrants' work, because the numbers would look completely different. Finally I want to emphasize that there are numbers missing. About 10-20% are missing. In my opinion, if you want [to influence the elections] then you have to show the full statistics. On the other hand, the numbers are correct. Therefore it would be better to show a real diagram.

Again, both students address the *comprehensibility* of 100%, with S7 adding remarks on the *truth* of statistics that are not taking into account the situation of legal work for asylum seekers. Additionally, both students grapple with the idea that the argument is "right but also wrong" (S6), that "the numbers are correct" (S7) but still objectionable. These students show their ability of understanding parts of the original post while still holding disagreement in other validity claims. These examples, however, also show the difficulties of expressing such a differentiated view, as even S7 – who shows probably the most elaborate and well-formed reply of the whole group – is unable to explicitly and concisely point out what exactly is correct, and what exactly showing a "real diagram" would entail.

Discussion

The students address various validity claims and engage in different speech acts for evaluating data-based arguments on social media. Noticeable is the high frequency of students making a faulty argument regarding supposedly missing percentages. The prevalence of this argument could indicate some kind of automated way of addressing manipulations in data that is carried out without a strong understanding of percentages. In general, the students in this study did not often address validity claims besides understandability. This could indicate a lower grasp on the communicative component of statistical literacy. In contrast, in an earlier study with Grade 5 students, a richness of validity claims was observed (Büscher, 2024a). A reason could be the present study's students' more limited understanding of context and data, as the lesson did not include personal investigations of data. However, requiring students to formulate replies on social media seems to have prompted some students to explicitly engage in illocutionary and perlocutionary speech acts. This was not observed in the earlier study. As such, the results of this study could indicate that designing for the communicative component of statistical literacy should include students' investigation of context as well as explicit formulations of replies to social media posts that make data-based argumentations.

Conclusion

Misinformation and disinformation on social media can erode the trust into democratic political institutions (Freelon & Wells, 2020; Lorenz-Spreen et al., 2023). But besides disinformation, there is also statistical information to be found on social media that literate users need to understand and react to. This requires the communicative component of statistical literacy, which in turn requires communicative rationality (Büscher, 2024). Research provides no guidance on how to develop this component for students and how students engage in speech acts regarding statistical information.

This study provided insights into a learning environment that used real-world social media posts showing positions on immigration as a focus for students' reactions on statistical information. The empirical results show that the designed materials could elicit reactions showing differences in the students' communicative rationality for statistical literacy. Additionally, it could be observed that the students had different success in performing speech acts that could capture an audience on social

media. These results point out an aspect so far undertheorized in research: conceptualizations of statistical literacy such as Gal's (2002) do not seem to include knowledge of forms of discourse on statistical information, of how to form a refutation and how to employ rhetoric. Neither does the framework of communicative rationality for statistical literacy developed by Büscher (2024a). This could be a promising direction for further research.

Facilitating elementary school students' transitioning from statistical modeling of to statistical modeling for

Michal Dvir

University of Haifa, Faculty of Education, Haifa, Israel; dvirmich@gmail.com

The pedagogical potential of the practice of statistical modeling has gained increased interest. However, the practice may be inaccessible for young students who had not yet developed familiarity with the necessary formal probabilistic tools. Engaging young students with informal corollaries has led to promising results, but the reasoning they express is often void of a deep appreciation of the stochastic behaviour of the model that formal probabilistic tools are used to estimate. Encouraging students to engage in modeling for examining the model's underlying stochastic mechanism, rather than solely engage in modeling of the investigated phenomenon, can facilitate the development of its appreciation. I offer a collective case study of three pairs of students' modeling progressions to illustrate how an innovative learning sequence can facilitate young students' transitioning from modeling of to modeling for, and subsequently elicit more mature reasoning with statistical models.

Keywords: Statistical modeling, Informal statistical modeling, Probabilistic reasoning.

Introduction

The pedagogical potential of the practice of statistical modeling has become a main focus of statistics education (Pfannkuch et al., 2018). Despite ongoing discussions, there is much more to elucidate. Specifically, while novices can be supported to develop models to represent what they see in the data, the data representations they create are often not accompanied with a mature probabilistic mechanism (Lehrer, 2017), which is a key characteristic of statistical models. In line with insight from mathematical modeling research, novices tend to engage in modeling *of* a specific phenomenon, rather than modeling *for* developing a deeper appreciation of the more general underlying mechanism of the models they use (Gravemeijer, 2002). This research designed an innovative activity sequence intended to support novices to transition from statistical modeling *of* to statistical modeling *for*, and examined how novices' reasoning with statistical models and modeling can mature throughout it.

Background: Statistical modeling of and for

With the goal of examining how young students can reason with statistical models and modeling, I have adopted the rudimentary view of models as purposeful representations (Hesse, 1962), simplified versions of a more complex phenomenon (Lehrer & Schauble, 2010). The simplification represented by the model may be found to be ill-suited for its intended purpose (Hesse, 1962). Therefore, a model should be continuously re-evaluated and refined. The process of model creation and renovation is what I refer to as modeling. The purpose of the model is key in distinguishing it from a mere representation, and in classifying the type of model. For example, mathematical models can be seen as intended to address a mathematical purpose, while statistical models are intended to address a statistical purpose (Dvir & Ben-Zvi, 2023).

While definitions vary, mathematical models are generally abstract constructs depicting characteristics of a structure or pattern (Lesh & Harel, 2003). The mathematical modeling process

centres on "mathematization", a process in which the original, often real-world, phenomenon is gradually depicted mathematically (Gravemeijer, 2002). The modeling process is iterative, and throughout it the forms of use of the model can transition (Gravemeijer, 1999): the initial use of the model, serving as a model *of* the phenomenon, is intended to identify the underlying mathematical features or structure of the specific real-world phenomenon. However, the model itself and its mechanism can become the subject of interest and investigation. The latter, referred to as modeling *for*, facilitates a deeper understanding of the abstract ideas that the model represents, and its reusability to explain *other* real-world situations with similar underlying mechanisms. This depiction of the mathematical modeling process can similarly apply to statistical modeling.

As statistical models are often formally depicted mathematically (Dvir & Ben-Zvi, 2023; Wild et al., 2018), statistical and mathematical models have similar traits. However, while the purpose of mathematical models is to deterministically describe or explain a structure or pattern, statistical models are intended to represent both a pattern or signal (systematic variation) as well as the noise around the noise (non-systematic variation, Dvir & Ben-Zvi, 2023; Konold & Pollatsek, 2002). The statistical model thus includes a stochastic mechanism (Davison, 2003) that accounts for the sources of the non-systematic variation, formally requiring familiarity with probabilistic tools. These are often not introduced in elementary school. Supporting young students to reason with *informal* alternatives of statistical practices (Makar & Rubin, 2018), involving little or no formal mathematical notations, can serve as an earlier introduction to their formal corollaries.

Various pedagogies have been developed to support novices' reasoning with informal statistical models and modeling. For example, Exploratory Data Analysis (EDA, Tukey, 1977) pedagogies that centre on engaging novices with data investigations, typically focus on seeking patterns in the data. EDA is therefore particularly well-suited to support novices' creation and refinement of deterministic verbal or visual (e.g., graphs or drawings) representations that serve as context-specific informal models *of* the investigated real-world phenomenon. However, the modeling process that EDA activities elicit, seldom leads emergently to students' transitioning to modeling *for* the purpose of examining the underlying stochastic mechanism through which the data were generated (Lehrer, 2017), which could then be applied to additional contexts. This is likely due to the typical engagement with only one real-world sample, whereas appreciating the probabilistic mechanism calls for envisioning all other samples that could have been generated by the same population (Lehrer, 2017). Similar constraints also characterize novices' engagement with Informal Statistical Inference (ISI, Makar & Rubin, 2018) activities, in which the novices' data exploration is guided by the purpose of generalizing beyond the data at hand. The request to formulate generalized claims often leads students to express some uncertainties. These expressions can be considered as initial reasoning with some aspects that would be formally represented stochastically. However, the models that the students generate still tend to be used as models *of* the specific examined phenomenon, and are not used *for* developing a deeper understanding of their underlying stochastic mechanism.

Complimentary, probability modeling activities (Franklin et al., 2007) are well-suited to support novices' creation and refinement of purely stochastic representations. However, these activities typically focus on non-realistic scenarios characterized by basic probabilistic mechanisms (e.g., a repeated coin-toss), challenging to apply to real-world phenomenon. To foster more applicable

insight, some have recently advocated for integrating probability modeling with EDA or ISI (Pfannkuch et al., 2018). Integrated approaches advocate for learning sequences that begin with students' modeling *of* real-world phenomenon, as they engage first with EDA or ISI activities. Probability modeling activities are then introduced related to the real-world phenomenon (e.g., Kazak, et al., 2018). In this study, I focus on a specific Integrated Modeling Approach (IMA, Manor & Ben-Zvi, 2017), in which the probability modeling activities focus on examining the model that the learners had created to represent their real-world ISI by conducting simulations of repeated sampling from it. By doing so, the learners are encouraged to transition from the initial use of the model as a model *of*, to using it as a model *for* examining its underlying stochastic mechanism, even if they are as yet unaware of its existence. To examine if or what shifts in their reasoning occur as a result, in the context of an IMA activity sequence, I examined: *How can novices reason with informal statistical models and modeling as they transition from model-of eliciting real-world activities to model-for eliciting probability modeling activities?*

Method

This study was conducted as part of Connections, a longitudinal design and research project. I employed a collective case study approach (Stake, 1995) to provide multifaceted in-depth accounts of three pairs of sixth grade (11–12-year-olds) students' reasoning, whose classroom participated in the 2016 iteration of the project. The classroom participated in a 19 lessons-long activity sequence inspired by the IMA (Manor & Ben-Zvi, 2017). The sequence included three cycles of ISI-extended EDA activities and, in accordance with the IMA, each was followed by a probability modeling activity that focused on models that the students developed during the preceding real-world data investigations. I focus on the students' participation in the second IMA cycle, in which they examined a sample size 60 that they collected from students in two schools in their district. Their purpose was forming inferences about a larger population of all of the students in their district (n=1300). The students' real-world data investigation began by their formulating research questions and conjectures that served as the students' initial models *of* the phenomenon. The students then created various data representations using TinkerPlots software (Konold & Miller, 2015), again serving as models *of* what the data indicated about the phenomenon. Based on these, they ultimately formulated inferences, verbal representations of their refined model *of* the examined phenomenon.

The need to formulate generalizations led the students to express uncertainty regarding the representativeness of their sample. The follow-up probability modeling activity was introduced as a means to examine these uncertainties. The activity was facilitated by the Sampler TinkerPlots tool, allowing to visually design a population, and simulate generating random samples from it. The students were asked to design the Sampler model according to their refined inference, and by doing so, even if they were unaware of it, attach a stochastic mechanism to their current inferred model *of* the phenomenon. The students were then asked to generate multiple random samples size 60 from the Sampler model and compare between them. The goal was to engage the students in examining sampling variation, the effect of the underlying stochastic mechanism, thus engage in modeling *for*.

The participants, data collection and analysis

The multiple cases study focused on three pairs of students: Noa and Ido, Erez and Orr, Ami and Gil, selected as they communicated their reasoning openly and fluently, and collaborated well. All of the participants' actions were videotaped by two cameras during class discussions, and Camtasia software to concurrently document the students' computer screen and articulations during their pair work. All videos were transcribed and analysed microgenetically (Siegler, 2006), to identify any visual or verbal representation that the students created, used or referred to. If the students assigned a purpose to the representation, it was classified as a model. Using the Reasoning with Informal Statistical Models and modeling (RISM, Dvir & Ben-Zvi, 2018) framework, the models were then classified as either Data models (i.e., representation of what the students saw in the data) or Conjecture models (i.e., representation of what the students believed beyond the data). In the final tier of analysis, the purpose of each model was further examined to identify whether it was used as a model *of* the phenomenon (i.e., focusing on the real-world phenomenon) or as a model *for* (i.e., focusing on the abstract stochastic mechanism of the model). Key scenes and their transcripts were discussed and triangulated (Schoenfeld, 2007) amongst three members of the Connections team.

Findings

Each of the three focus pairs formulated different research questions and created different models whilst investigating them. However, a shared pattern was identified in all three modeling progressions characterizing the students' transitioning from modeling *of* to modeling *for*. To illustrate this pattern, for each pair I focus on one repeated model that they invented and refined throughout the learning sequence. I provide here a more detailed account of one of the pairs' modeling progressions, followed by an overview of the similar trajectory identified in the progressions of the other two.

Erez and Orr chose to examine the relation between arm span lengths and the number of rope-jumps per minute. During their real-world investigation, the pair's original conjecture model was an informal expression of a linear positive relation (holding the rope "near" would make it "more difficult for you to jump"). However, they gradually acknowledged that their data showed otherwise, and consequently formed a new, more data-based, conjecture: "it [arm span] helps", informally representing a weaker positive relation (the students with longer arm span can potentially be better rope jumpers if they practiced, Figure 1, left). To initiate the probability modeling activity, the students designed the Sampler model to represent their refined "it helps" conjecture (Figure 1, right). To do so, they designed two different distributions of rope jumps per minute for shorter and longer arm spans lengths (e.g., the range of the shorter arm span students' rope jumps was much more limited, 0-60, than the range of the longer arm students' rope jumps, 0-200). As expected, all of the models that the students expressed during these stages of the learning sequence served as models *of* the examined phenomenon. However, as the pair began generating simulated samples, they continued to utilize the "it helps" model as a model *of* what they saw in the data (e.g., Erez: "it [the simulated sample] proves that it [arm span] only helps").

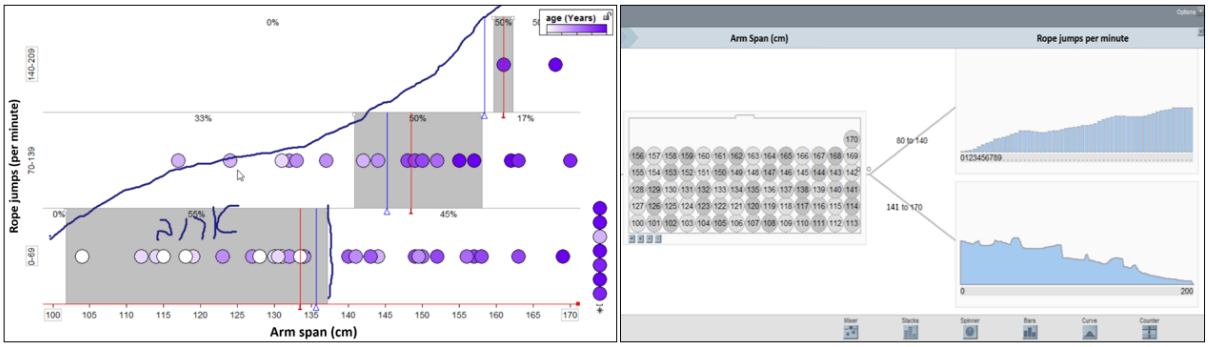

Figure 1: (Left) The real-world data representation of good, medium and bad rope jump results (three rows) according to arm span. The grey rectangles represent the original conjecture. The drawn line creating a triangle with the axis represents the "it helps" refined conjecture. (Right) The Sampler model representing the same "it helps" model, by assigning different distributions of rope jumps per minute to the shorter and longer arm span options.

Examining the initial simulated samples that they generated, the pair also created a new visual representation of a scatterplot, and emergently added drawings of circles, around some of the data but not all. This implies that the purpose of the circles was to represent the pair's "it helps" conjecture, thus again serve as a model *of* the phenomenon, rather than what the simulated data specifically showed. This was evident for example in Erez' explanation of the right upper circles (Figure 2, left):

> Erez: This [top left circle, Figure 2, left] is actually all of those that are, the arm span helps them jump but… they are not so good [rope-jumpers]… These [top right circle, Figure 2, left] are good [have long arm spans] and practice.

As the pair generated additional simulated samples, they continued to utilize the circles' representation. However, they began to articulate a different purpose for its use: comparing between simulated samples (e.g., Erez: "because of the circles that stay we can see it [a new sample] hasn't changed so much"). The shift in purpose is significant. Up to this point the students utilized the "it helps" model solely as a model *of* the real-world phenomenon, but were now starting to utilize it as a model *for* the data that its underlying stochastic mechanism can generate. The new use was further extended as the pair created a refined circles representation during the next lesson (Figure 2, right):

> Erez: We went through several samples and saw that it [the majority of cases] stays sort of in the same circles, it [the majority] doesn't go outside, here [in this simulated sample] it goes out [of the circles] a bit, the most that we have seen… but it is reasonable.

Erez' explanation implies another slightly different purpose of the circles model, representing areas where "it stays sort of in the same circles", meaning what the pair considered stable, or "reasonable" across the multiple samples that they "saw". Although based on what the pair "saw" in their data (multiple simulated samples), the behaviour Erez was now describing by the circles model was more general – "it doesn't go outside", thus serving as a conjecture model describing the limitations of the stochastic mechanism they have been examining and modeling *for*. Erez also utilized the insights gained about the mechanism to evaluate the current simulated sample: although "it goes out a bit",

even “the most that we have seen”, the pair considered it to be “reasonable”, as it is within the scope of the stochastic behaviour that the pair had come to expect.

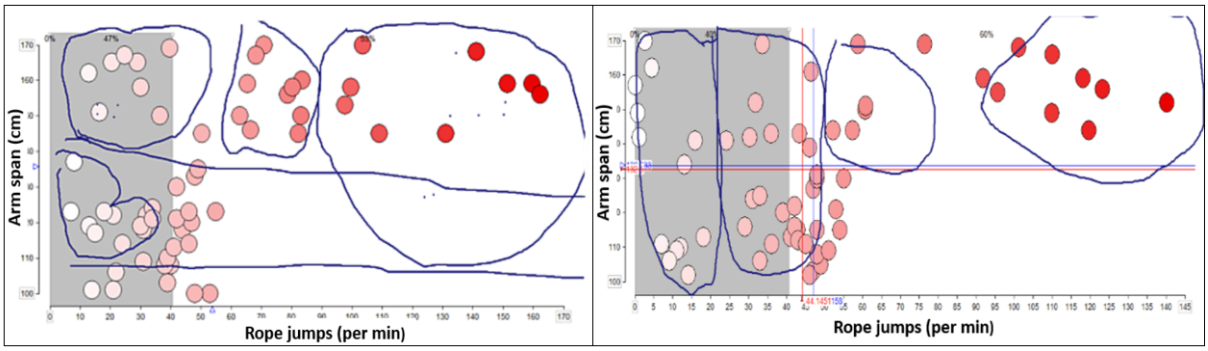

Figure 2: Representations of simulated samples, arm span according to rope jumps (color according to rope jumps) with the hand drawn initial circles model (left) and a refined version (right)

Ami and Gil examined a different type of question (“Who sleeps more, boys or girls?”) and developed a different type of repeated model to examine it. However, their model’s progression followed a similar path to that observed in Erez and Orr’s. Their repeated model focused on comparing between the shapes of the boys’ and girls’ duration of sleep distributions. Throughout the real-world data investigation, the model was only expressed verbally or using hand gestures. It was first visually represented by the shapes that the pair designed for each gender’s distribution in their Sampler model. Again, the model was exclusively used as a model *of* the examined phenomenon during these stages of the learning sequence. After generating their first simulated sample, the pair added drawings circumventing each distribution to represent the shapes they expressed earlier, still using the representation as a model *of* the real-world phenomenon (despite examining a simulated rather than a real-world sample). However, generating additional samples with varied distribution shapes, the pair started adding more circumventing lines (without deleting the earlier lines). The extended representation supported the adaptation of the initial model to a new purpose of comparing between simulated samples (e.g., Ami: “the blue line [I drew to represent the shape of distribution in this sample]… looks exactly the same as the other one”). The pair were therefore beginning to use the model as a model *for* examining the underlying stochastic mechanism. The pair also utilized a further extended version of the representation to summarize their insight about the mechanism, by drawing dots to represent the maximum variation they now expected from the original shapes.

Noa and Ido also examined a different type of question (“Is the stigma that girls run slower than boys true?”) and developed a different type of repeated model to examine it. The pair mostly expressed their repeated model verbally, referring to two medians (the boys’ and the girls’ 600 meter running times medians) and comparing them to determine which of the two genders were better runners. Unlike the other two pairs, they did not utilize the medians representation when designing their Sampler model. This was possibly due to Noa’s persistence that the Sampler model should reflect *no* difference between the boys’ and girls’ running results, despite what the medians in the real data reflected. However, they did continue to use the medians model as a model *of* the real-world phenomenon, as they examined the first simulated sample (Noa: “our [the girls’] median is here

[relatively small], and their median [the boys'] is here [larger]"), as did the other two pairs. Furthermore, when examining their second simulated sample the pair similarly assigned the representation a new purpose of comparing between simulated samples (e.g., Ido: "our [the boys'] median is becoming closer to yours"). The shift in purpose was also accompanied by a shift in the model use – from comparing medians within a sample, to comparing the difference between the medians across samples. These indicate a transition from using the medians as a model *of* what the data indicated about the examined phenomenon, to modeling *for* its underlying stochastic mechanism. The pair also repurposed the model to summarize their insight on the stochastic (here unlimited) behaviour they discovered (e.g., Ido: "It [the difference between the medians] can always change").

Discussion

The commonalities across the three case studies elucidate general aspects of how elementary school students' reasoning with informal statistical models and modeling can transition from modeling *of* to modeling *for* (Gravemeijer, 1999), during an activity sequence that integrates real-world data explorations (Makar & Rubin, 2018; Tukey, 1977) with probability modeling activities (Franklin et al., 2007; Kazak et al., 2018; Manor & Ben-Zvi, 2017) that focus on the students' invented models. Specifically, the initial stages of the probability modeling activity (i.e., designing a Sampler model and generating initial simulated samples) did not elicit the transition. This aligns with prior insight on students' initial naïve views when engaging with a single sample and challenges to envision additional samples that the same population (or stochastic mechanism of the model) can generate (Lehrer, 2017). However, as the students generated additional simulated samples they were provided with a tangible manifestation of the effect of the stochastic mechanism. Although unsolicited, all three pairs utilized the tools, i.e., the models, that they had already developed during the real-world data exploration and extended them to perform the samples comparison task. By doing so, they gradually emergently extended their initial use of the model as a model *of* the phenomenon, to a model *for* examining, evaluating and ultimately summarizing its underlying mechanism (Gravemeijer, 2002). The latter reflected rather mature reasoning with informal statistical models and modeling, despite the students' lack of familiarity with the formal probabilistic tools.

Novice Students' Engagement with Big Data Modeling

Ronit Gafny, Michal Dvir, and Dani Ben-Zvi

Faculty of Education, University of Haifa, Israel; ronit.gafny@edtech.haifa.ac.il

In today's digital society, supporting students in reasoning effectively with big data has become an important pedagogical purpose. This article examines ways to incorporate big data analysis ideas into teaching, focusing on informal modeling with big data and introducing students to the predictive purpose of a model. We designed a learning sequence and implemented it successfully with a class of 15 tenth graders. An analysis of the students' engagement uncovered two modeling approaches: creating descriptive models that led to overfitting by focusing on detailed data and creating explanatory models that emphasized generalization but neglected crucial data, resulting in underfitting. After reassessment and testing with new data, both groups opted to build a hybrid model, reflecting a more nuanced understanding of balancing model fit and predictive considerations.

Keywords: Informal statistical modeling, big data, predictive modeling.

Introduction

In today's data-driven world, reasoning effectively with and analyzing large datasets has become a crucial skill. The advent of data science has transformed how we approach problems, make decisions, and derive insights from data. With the proliferation of user-friendly tools enabling data exploration and analysis without requiring coding expertise, data science has transformed into a field accessible to non-experts. Consequently, there is a growing need to adapt educational strategies to equip students for this dynamic and evolving landscape. Traditional statistical methods and educational approaches have often focused on classical inference practices, which emphasize understanding underlying data distributions and hypothesis testing. However, in recent years, there has been a significant shift in practice toward predictive modeling techniques, prioritizing predictive accuracy and leveraging large, complex datasets (Breiman, 2001). This study explores a learning sequence that introduces students informally to the fundamental practices of big data analysis. The design is based on prior insights from statistics education literature on informal introductions to classical statistical practices (e.g., Informal Statistical Inference, ISI, Makar & Rubin, 2018), adapted to the different nature and purposes of central data science practices. As proof of concept, we present a learning sequence we designed to introduce a classroom of 15 tenth-grade students (15-16 years old) to the practice of big data modeling and illustrate its utility through the gradual maturation of considerations that the students expressed.

Literature Review

Reasoning with big data

In today's interconnected world, a vast amount of data is generated from diverse sources, such as sensors, smartphones, digital applications, and social media, often presenting unique challenges due to their incomplete, imprecise, misleading, or erroneous nature (Holmes, 2017). Unlike traditional educational statistical data, which is usually precise, comprehensive, and gathered through established sampling methods, this new data type plays an increasingly pervasive role in students' daily lives. Big data are characterized by the five V's: Volume, Velocity, Variety, Veracity, and Value. Volume reflects the sheer

amount of data generated by accelerated technology (Kitchin & McArdle, 2016), while Variety refers to the heterogeneous nature of datasets (Gandomi & Haider, 2015). Velocity reflects the rapid speed at which data are collected and analyzed, often in real time (Gandomi & Haider, 2015). Veracity addresses the reliability of data, focusing on their truthfulness, accuracy, and precision (Lukoianova & Rubin, 2014). Finally, Value pertains to the usefulness of the data, which, despite their typically low-value density, can yield significant insights when analyzed effectively (Gandomi & Haider, 2015). Due to these unique characteristics, reasoning with big data requires distinctive approaches compared to traditional data handling, centering largely on processes like data cleaning, organization, feature examination, and visualization. Modeling with big data similarly has features that distinguish it from classical statistical modeling.

Modeling in data science

Statistical modeling is a powerful tool for developing and testing theories through causal explanation, prediction, and description. It can be categorized into three main types: explanatory, predictive, and descriptive modeling, each serving distinct purposes in scientific research. Explanatory modeling is predominantly used in many scientific fields, particularly in the social sciences, to test causal theories by applying statistical models to observational data (Shmueli, 2010). Predictive modeling, in contrast, focuses on forecasting future or new observations by using statistical models or data mining algorithms. This approach prioritizes high accuracy in predictions over the model's interpretability and is central to fields like machine learning and data science, where models, such as random forests, are used to predict outcomes without necessarily explaining the underlying causal mechanisms. Descriptive modeling aims to summarize and represent the structure of data in a compact form, without necessarily focusing on causality or prediction. While explanatory modeling is used to test theories and predictive modeling aims at precise forecasting, descriptive modeling provides a foundation for understanding the data's characteristics, supporting both explanation and prediction.

There are two primary cultures in statistical modeling, one based on stochastic data models and the other on algorithmic models (Breiman, 2001). Stochastic data models assume a specific probability distribution or data-generating process, typically chosen based on the researcher's understanding or intuition about the underlying mechanism. These models emphasize interpretability and validity and are mainly used in classical statistics for explanatory or descriptive purposes, such as generalizing from small samples to larger populations under controlled conditions (Gould, 2024). While classical models are adequate for understanding causal relationships, they often struggle with complex big data problems, where algorithmic models excel.

Algorithmic models, central to modern data science, do not assume a predefined data structure. Instead, they use computational techniques to discover patterns directly from the data, prioritizing predictive accuracy over interpretability. Methods like random forests exemplify this approach, where multiple algorithms metaphorically "vote" on predictions, and the prediction receiving the most votes is selected (Gould, 2024). The predictive power of the model is typically determined by testing it on a portion of the data set aside prior to the training stage of the model. The main risk stems from overfitting the model to the training data, evident when the model performs lower than expected on the test data (Shmueli, 2010). On the other hand, underfitting might also occur, also evident in poor performances on

holdout sets, indicating that the model is too simple to capture the underlying patterns in the data. Both overfitting and underfitting limit the model's generalizability. The practice of algorithmic modeling therefore differs greatly from the classical practices associated with stochastic data models. However, it is similarly central and representative of the disciplinary (data science) culture and engaging novices with this type of modeling can have great pedagogical potential. A main hurdle might be, however, the computational complexities of the formal practice, which may render it inaccessible for novices who have not yet mastered the necessary formal language and tools.

To address this challenge, we propose devising *informal* corollaries, as had been done before to facilitate novices' engagement with central statistical practices. For example, to raise the accessibility of statistical inference, many have advocated for an informal corollary, Informal Statistical Inference **(**ISI, Makar et al., 2011; Makar & Rubin, 2018), informed by the central characteristics of the formal practice. In more recent years, similar strides have been made to raise the accessibility of the practice of statistical modeling through engaging with Informal Statistical Models (ISMs, Dvir & Ben-Zvi, 2021). Informal models can be defined as purposeful representations. When a representation is used for a statistical purpose—such as describing, explaining, or predicting—it can be considered an informal statistical model (Dvir & Ben-Zvi, 2021). These informal adaptations of central statistical practices serve as a bridge between novice learners' current understandings and formal statistical reasoning. Inspired by these, we designed and implemented a learning sequence based on the *Hypothetical Integrated Data Modeling Learning Trajectory* (Gafny & Ben-Zvi, 2023) grounded in design research methodology (Plomp, 2013), which was initially tested with two students before being implemented with a full class. The learning sequence consisted of informal adaptations of central data science practices and facilitated our examination of the following: *What considerations can novices articulate during informal modeling activity with big data?*

Method

This study was conducted as part Connections, a longitudinal design and research project that examines young learners' statistical reasoning, collaborating with the Taking Citizen Science to School (TCSS) center. We focus on the 2023-4 iteration of the project, in which a 12-lesson-long learning sequence accompanied the participation of a tenth-grade class from a public school in Northern Israel (15-16-year-old students) in the *Sleep-a Third of Life* citizen science project. The students had no prior experience in big data analysis. The students' participation in the project included filling out questionnaires that constitute a "sleep journal" about their sleep habits, *which* comprises some pre-chosen questions formulated by the sleep scientists who accompanied the project and additional questions that the students themselves chose to add. The students were granted access to the data they collected about their class and later to the larger project-generated data set (the "big data"). This dataset was derived from over 1,000 students across Israel who maintained a 14-day sleep diary that recorded 20 key categorical and numerical attributes, including age, gender, and sleep duration. The combined efforts of 38 classrooms resulted in a comprehensive dataset containing approximately 16,000 cases. Due to TinkerPlots software (Konold & Miller, 2015) limitations, the students analyzed 5,165 cases, using 4,165 to develop their models ("training data"), and 1000 cases to later test the initial models they created ("testing data").

The learning sequence. The central goal was to encourage students to emergently articulate the predictive purpose that a model can serve, particularly in the context of big data analysis. Building on the students' prior experience with classical data modeling and their familiarity with descriptive purposes that are more characteristic of classical data modeling, the learning sequence sought to facilitate their gradual discovery that models could be used for prediction. To support these objectives, the first phase began with small samples of self-collected data, following the growing samples heuristic (Ben-Zvi et al., 2012). The activities in this phase were informed by three pedagogical frameworks: Exploratory Data Analysis (EDA, Tukey, 1977), Informal Statistical Inference (ISI, Maker & Rubin, 2018), and the Integrated Modeling Approach (IMA, Manor & Ben-Zvi, 2017). The second phase focused on exploring the big dataset. It began with preparing the data for analysis, followed by creating an initial informal descriptive model of the connection between attributes chosen jointly by the class (net sleeping time and morning alertness). The descriptive purpose was expected to elicit considerations of model fit and potentially overfitting models. Mimicking the formal practice of choosing the best model, the students then began "voting" activities to choose one model out of the seven (each pair produced one model) to introduce to the sleep scientists as the class's finding. The voting process was two-staged: first, we divided the class into two groups of three and four pairs, resulting in two final rivalling models. In the second stage, the entire class selected one of the two. In the first stage, a criterion for what constitutes a "winning" model was not pre-defined, and students were free to express their criteria, use it to advocate for their model to be chosen, and vote accordingly. In the second stage, the predictive criterion, as it was not suggested emergently, was introduced to choose between the two models. The students were asked to test the predictive power of the model they voted for using the 1000 cases set aside earlier, serving at this stage as test data. In a final whole class discussion, the predictive power of the two models was compared, and students were requested to select a "winner" accordingly.

Data collection and analysis. We videoed all the participants' pair work using Camtasia to document the students' computer screens and articulations concurrently. We documented class discussions with two cameras and transcribed and analyzed all videos using the interpretative microgenetic method (Siegler, 2006). This method allowed us to examine the models that the students generated and reasoned throughout their participation; it involves closely examining learning as it unfolds in real time, focusing on incremental changes to understand how and why thinking processes develop. Specifically, we identified any visual or verbal representations that the students created or articulated. If the representation was purposeful, it was classified as a model. The models were then classified by purpose and fitness to data. Key scenes were discussed and triangulated (Schoenfeld, 2007).

Findings

We provide an overview of the types of models that the seven pairs created and transformed throughout the informal modeling activity and the different considerations they expressed alongside their creation or use. We introduce these chronologically, according to the three stages of the activity: a) developing models based on training data; and b) the initial voting stage; and c) the second voting stage informed by testing the models' predictive power.

Developing models based on Training Data. During this activity, each of the seven pairs were asked to develop a descriptive model (i.e., a purposeful representation, meaning they were free to

develop representations in any manner they found appropriate) for the relation between sleep duration at night and the level of alertness the following morning, based on the Training Data. Using the various TinkerPlots visualization options, each pair chose different means and tools, resulting in a diverse range of data representations, each reflecting the pair's final model. Despite these differences, the seven models can be grouped into two groups based on central commonalities. Group 1 consisted of three models, all of which we classified as having a descriptive purpose in line with the explicit guidance that the students received. In addition, we classified the three models as overfitting the data, evident by: inclusion of all cases (even those clearly erroneous); data representations that are difficult to decipher (often due to scaling issues, related to the choice to include all extreme cases, e.g., Fig. 1); and representation mostly of the noise in the data rather than the signal (often obscured in the complex data displays). In contrast, Group 2 consisted of four models, all of which we classified as having an explanatory purpose, despite the explicit guidance they received. We also classified these models as underfitting the data, evident by an omission of a large portion of the cases (restricting the examination only to data considered to be "typical"); readable simplified data representations (e.g., Fig. 1); and a focus solely on the (clearly evident) signal.

The initial voting stage. In this stage, the students worked in two larger groups, divided based on the commonalities identified in the previous activity. We guided the groups to select one model out of the three or four each group had constructed based on a criterion of their choosing. The chosen models reflected the criterion on which they were based. Group 1 chose the overfitting model illustrated by a representation of the distribution of each alertness level across the entire possible range of sleep hours (0-24, Fig. 1). The inclusion of all of the data resulted in a representation in which a clear signal was harder to identify. The group did attempt to represent the pattern by adding a red line to the central clump of each distribution (sleep durations between 4-12 hours). However, in a written explanation they provided for their chosen representation, the students did not express an actual relation between the two attributes; the criterion for the choice of the model implied by the explanation was providing a comprehensive description of what the students observed in the data. Group 2 (Fig. 1) chose the underfitting model illustrated by a representation that focused on the central range of sleep duration, specifically between 3-12 hours. They completely disregarded the values they considered as extreme or atypical (0-3 and 12-24). To represent the pattern that the model focused on, they used averages, boxplots, and a hand-drawn trend line. The representation was chosen as it clearly illustrated that "for most teenagers, the more they sleep, the higher their level of alertness." Their criterion was implied by the focus on the pattern as well as the wording the students chose: the more one sleeps, the more alert they will be, providing a (causal) explanation for the observed pattern.

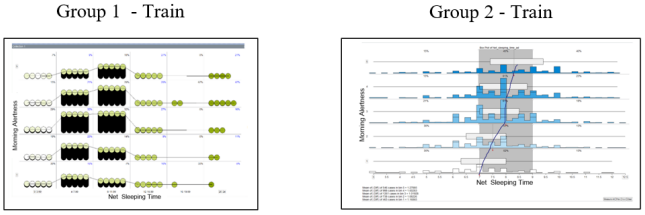

Figure 1. The model representations chosen by Groups 1 and 2, based on the Train Data, with the x-axis representing net sleeping time and the y-axis representing morning alertness.

The second voting stage. This stage was informed by testing the models' predictive powers. Each of the two groups presented their chosen model to the other group. Both groups were then tasked to vote on which of the two "winning" models should be presented to the sleep scientists as the classroom's final finding. A whole class discussion was conducted to consider additional criteria for the selection. The students continuously advocated for either descriptive or explanatory purposes and the overfitting or underfitting models they associated with each, each group advocating for one and dismissing the other. The researcher then suggested predictive power as an optional criterion, and the students accepted it as a reasonable "tiebreaker." The Test Data were then organized according to the two "winning" data displays (Fig. 2), and the students were asked to compare the train and test performance for each. This comparison led to a critical realization that neither model was fully adequate for predicting future data; one was overfitting, and the other was underfitting. This encouraged the students to agree that a hybrid model that could balance the strengths of both approaches—capturing significant patterns (signal) while reducing the impact of overfitting to noise—would better address the predictive purpose.

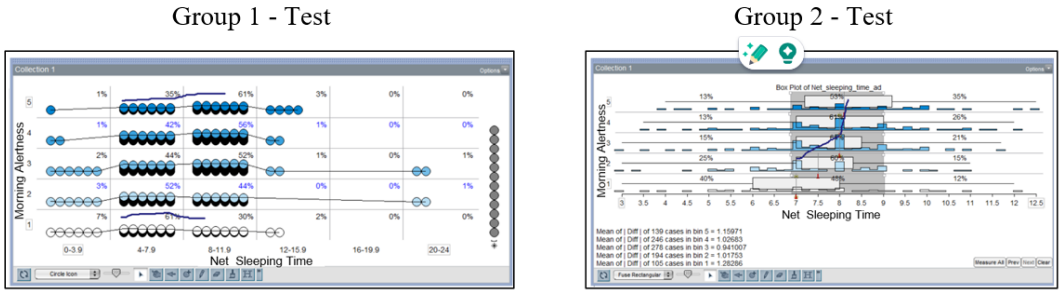

Figure 2: The model representations made by Groups 1 and 2 based on the Test Data, with the *x*-axis representing net sleeping time and the *y*-axis representing morning alertness.

Discussion

A comparison between the two groups reveals distinct differences in their modeling strategies. Although both groups were instructed to build a model to describe the phenomenon, their approaches diverged significantly. Group 1 focused on creating a descriptive model, prioritizing a detailed account of the phenomenon over generalization. They did not ignore the aspect of generalization entirely; for instance, they drew a red line to illustrate the model's prediction versus the actual data. However, their primary goal was to provide a thorough description, which led to an overfitted model that captured too much of the data's specifics (Shmueli, 2010). In contrast, Group 2 adopted an explanatory approach, focusing predominantly on generalization and the pattern while neglecting a significant portion of the data. It is possible that they were drawn to explanatory considerations due to the scientific context of their inquiry and in a different, non-scientific context, they would not have developed an explanatory model. Furthermore, their emphasis was on broad generalization rather than detail. When asked whether their model accurately represented the entire population of adolescents in Israel, they confidently claimed it did, without considering the need for adjustments to account for outliers or atypical cases. This approach resulted in an underfitted model with limited descriptive insight (Shmueli, 2010).

The connection between each group's purposes and their outcomes was evident: the first group's focus on a descriptive purpose led to overfitting, while the second group's focus on an explanatory

purpose resulted in underfitting. Encouraged to assess the predictive capability of their models, both groups discovered the limitations of their approaches. Group 1 recognized that their overly detailed account made their model unsuitable for new data, while Group 2 realized that their overly generalized account did not adequately account for new data. By agreeing to build a hybrid model, the students acknowledged its potential to address the shortcomings of their initial models. This decision demonstrated their evolving understanding of predictive modeling complexities and their readiness to explore more advanced strategies. The hybrid approach allowed them to navigate the trade-offs between overfitting and underfitting, providing them with deeper insights into effective modeling practices in data science.

Through the design of the learning sequence, the students informally experienced several key principles in big data analysis, including: (a) The practice of train and test - dividing data into a training set to teach the model and a test set to evaluate its performance on unseen data (Holmes, 2017). The students built the model with the Training Data dataset and evaluated its performance by comparing it to the results that came from processing the model on the Testing Data dataset. (b) Overfitting and underfitting models: Understanding when a model is too complex (overfitting) and captures noise from the Training Data, or too simple (underfitting) and fails to capture underlying patterns (Shmueli, 2010). The students, by comparing each group's winning model, were able to understand the benefits and limitations of each model in the context of overfitting vs. underfitting. (c) Balancing between model fit and predictability: striking a balance between a model that fits the Training Data well and one that generalizes effectively to new, unseen data (Breiman, 2001). The hybrid model suggestion expressed an appreciation that they can balance fit and generalization concepts. (d) The students' modeling selection – choosing between models based on accuracy and predictability: The process of selecting the best model by comparing different models and finding the one that offers the highest accuracy while maintaining good predictive power (Gould, 2024). The multi-models that the whole class created provided a tangible experience of the practice of building multiple models and "voting" on predictions.

We credit these learning outcomes to the fact that the design of the activity sequence was informed by the formal data science practices but made them accessible through informal adaptations. Specifically, we consider *informal predictive modeling* to be a potential gateway to data science, as stochastic modeling has been acknowledged as a gateway to classical statistics (Dvir & Ben-Zvi, 2021).

Informal conceptions of appropriate choropleth maps held by in-service East and Southeast Asian teachers

Orlando González

Assumption University, Graduate School of Human Sciences, Thailand; ogonzalez@au.edu

This paper examines how a group of 14 in-service East and Southeast Asian teachers reason about what makes an appropriate choropleth map, in the context of a task that required from them to choose an effective visual way to communicate the geo-spatial spread of the COVID-19 disease. The findings revealed that, while all the participants reasoned about the task using different visual map components mentioned in the literature (e.g., color scheme, number of classes, class limits, and administrative unit level), most of them focused on the color scheme and the legend's value ranges, and only one considered the administrative unit level. Moreover, contrary to what many specialists recommend on how to create appropriate choropleth representations, a red color scheme was found to be more appropriate for a map content related to a pandemic by the study participants, which may have a cultural connotation to it.

Keywords: Choropleth maps, conceptions, in-service teachers, geo-spatial data.

Introduction

When the COVID-19 pandemic started, a very common way for media to present the panorama of the disease in the world has been through choropleth maps, which have been extensively used by health professionals and general public to identify regional hotspots and to find geo-spatial strategies against the pandemic (Juergens, 2020). Choropleth maps (also known as geographic heat maps, shaded maps or graduated color maps) are graphical representations showing the distribution of statistical data over a geographic region, in relation to a quantitative or categorical variable (Camm et al., 2021). Choropleth maps provide a simplified method to visualize, using color codes, geo-spatial data[1] on how a measurement or attribute (e.g., the absolute count of confirmed COVID-19 cases worldwide) varies across a geographic area or show the level of variability within a region, and are particularly useful when analyzing epidemiological data. That is why the use of these artifacts has become so popular, since most of the public is not trained to read data-driven maps critically, which makes the visualization of the COVID-19 pandemic with easy-to-understand choropleth maps crucial. Moreover, Thai and worldwide health experts believe that the use of geo-spatial data, including representations such as choropleth maps depicting disease density, spreading area, disease prevalence areas, resource distribution, admission rate and COVID-19 distribution patterns, allows health authorities to synthesize large amounts of information that can then be used for the prevention and control of diseases and resource allocation (Laoluekiat et al., 2022).

Due to this growing presence and importance of choropleth maps in our daily life, teachers are expected to promote their students' statistical literacy skill related to this graphical representation.

[1] Geo-spatial data is defined as a composite of descriptive or thematic content (e.g., attributes characterizing a spatial entity) and spatial components (e.g., coordinate system and geometry; Juergens, 2020).

This demands from teachers a specific set of professional competencies, which depend heavily on their professional knowledge and their conceptions of curricular contents (Gal, 2002; González, 2021). Moreover, in the case of Thailand, the use of maps and geographical tools for searching, analyzing, drawing conclusions, and making efficient utilization of geo-spatial data is a key curriculum standard shared across many subjects (Ministry of Education of Thailand, 2008). However, the levels of graph competence and geo-spatial literacy of school teachers have been reported to be worrisome by many authors (see Groth & Meletiou-Mavrotheris, 2018, for a review of such works), and, to the knowledge of the author, there are no reported studies on in-service school Thai teachers in relation to their informal conceptions of choropleth maps.

Consequently, the following research question was posed to clarify aspects of the professional knowledge and conceptions of what makes an appropriate choropleth map held by in-service teachers from different East and Southeast Asian countries working in Thailand: How do in-service East and Southeast Asian school teachers working in Thailand conceptualize what makes an appropriate choropleth map, in the context of looking for an effective visual way to communicate the geo-spatial spread of the COVID-19 disease, and how these conceptions align with previous literature?

The importance of teachers choosing appropriate graphs for the learning of statistics

Reading and interpreting statistical graphs is an essential element in acquiring statistical literacy, which Gal (2002) described as the union of two related competencies: (a) interpreting and critically evaluating statistically based information from a wide range of sources; and (b) formulating and communicating a reasoned opinion on such information (González et al., 2011). Statistical literacy also involves the choice of an appropriate graph in relation to both the situation and the data being represented (González, 2021). Moreover, it is important to consider the possible biases that may be transferred to the graph, voluntarily or involuntarily, especially when choosing the scale or the administrative unit level in a choropleth map (Field, 2020; Juergens, 2020; Lane et al., 2022).

Choropleth maps, as well as other powerful data display artifacts (e.g., dynamic population pyramids or maps of commuter flow) have been reported to facilitate the conduction of statistical investigations, and hence the use of these graphs in the classroom by teachers is highly recommended, so they can engage and enrich student learning of statistics (Promodou & Dunne, 2017). Data visualization is a key pedagogical approach focused on helping students develop data analysis skills and engage with the investigative cycle in the process of exploring data. By using graphical artifacts displaying geo-spatial data, such as choropleth maps, teachers are able to select or create a map that allow students to search for data that may contain relevant information for their analysis task, search for a visual structure that is appropriate for the data, develop further insight, and then make an informed decision and take action (Promodou & Dunne, 2017). However, choosing or creating a task that will trigger the process of formulating a statistical question that can be answered with data, analysing the data with appropriate graphical and numerical summaries, and interpreting the results as they relate to the original question of interest has been found not to be easy for school teachers (Groth & Meletiou-Mavrotheris, 2018; González, 2021; Isoda et al., 2018).

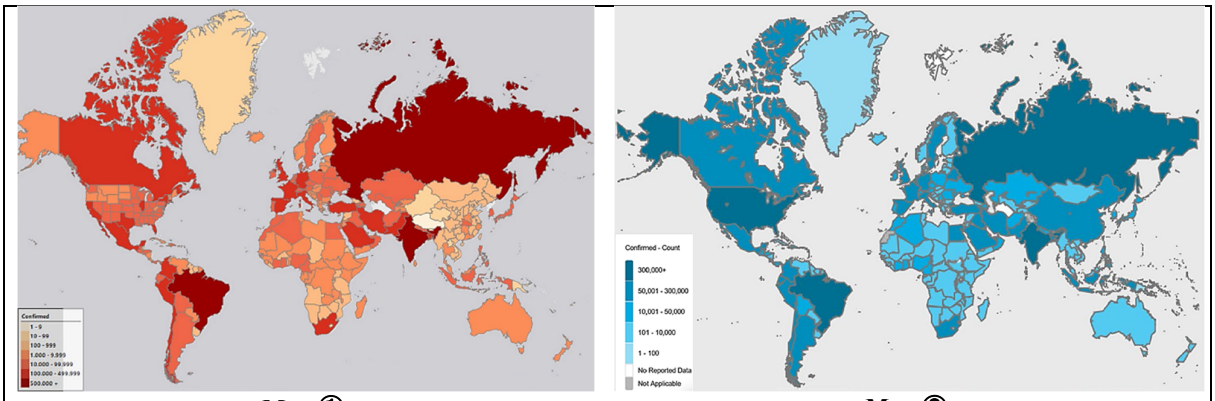
In order to exhibit graphical competence, a data user must be able to read between, beyond, and

behind the data displayed in different sorts of graphs and to interpret meanings from them; to select and create appropriate graphs for specific situations, with or without the support of technology; and to critically evaluate graphs and to distinguish the relative strengths and limitations of particular graphical representations of data (González et al., 2011). Therefore, teachers must master themselves graphical competence before fostering it in their students. Moreover, there is plenty of evidence in the literature of a tendency to underestimate the complexities of learning and teaching graphical representations by both pre- and in-service school teachers, their poor level of graph reading and interpretation skills, their tendency to fail to integrate graphical knowledge with problem context, and their trouble with graph selection and understandings of data types (Groth & Meletiou-Mavrotheris, 2018; González, 2021; Isoda et al., 2018). With the popularity of choropleth maps in media nowadays, it is crucial for teachers to be able to know the geo-spatial data literacy aspects of choropleth representations, and become a sort of cartographer or geo-information expert themselves (Field, 2020; Juergens, 2020), in order to support their students in achieving the educational goals and objectives of the official curriculum documents in relation to the teaching of the statistical contents.

Choropleth maps and COVID-19 visualization

In a choropleth map, each geographic region is color-coded to represent a quantitative value based on a scale with color variation intervals that go from a light tint for smaller values to a dark shade for larger values. This color code allows the reader to recognize the implication of the general patterns of light and dark shades in relation to the variable at hand. This approach makes the viewer's perception of the map's values immediate, since it is quite intuitive (Camm et al., 2021; Kirk, 2016).

Besides the color code scheme, there are other key components of a choropleth map, including the legend, number of classes used in each color code scheme, the class limits or value ranges for each color, and the administrative unit level for data visualization (e.g., school districts, emergency response districts, tax zones, cities, counties, provinces, states, or countries; Field, 2020; Kirk, 2016; Juergens, 2020; Lane et al., 2022)



If the quantitative measure being depicted is about, or related to, the consequence of more people living in an area, interpretations of the choropleth map may be distorting and misleading; so, in such cases, it is suggested to consider transforming data to per capita (or other spatial denominator) to standardize the analysis accordingly (Juergens, 2020; Kirk, 2016).

During the COVID-19 pandemic, choropleth maps were a common representation in media to depict the spread of coronavirus cases around the world. Choropleth maps are particularly appropriate for depicting standardized data like rates, percentages or densities, rather than counts or totals. Absolute counts usually increase with area size, and this can be misleading. Many maps for the pandemic have used absolute values to show the number of cases across a country with a choropleth mapping technique. This is known to lead to accuracy issues, as different areas have different numbers of people in it, which leads to inaccurate conclusions when looking at a choropleth map (Field 2020; Franch-Pardo et al. 2020; Lane et al., 2022). Another source of error for choropleth maps is when the map maker uses the "default" classification scheme for creating classes (or different patterns) for the map, instead of figuring out which type of breaks or classes make the most sense for what is being conveyed (Lane et al., 2022; Monmonier, 2018).

Population normalization can solve some of the accuracy problems of creating a choropleth map based on raw numbers (Field, 2020). It is achieved by dividing the number of cases by the population in a specific area to give a percentage of that area that has been infected. In order to make the COVID-19 cases comparable, one has to normalize them against the total population. A widely used rate is cases per 100,000 inhabitants (Juergens, 2020). Otherwise, when visualizing the data with only raw numbers, some areas can appear to have very few cases, but instead have a high percentage of infection if that area has a low population.

Methodology

The task for this study (see Fig. 1) was developed inspired on the discussion made by Juergens (2020) on how choropleth maps are used for effective visual communication of the geo-spatial spread of the COVID-19 disease, and how many map creators seem to forget about the fundamental principles of good and easy-to-read thematic choropleth maps, which requires geo-spatial data literacy. Two choropleth maps from Juergens' (2020) article were chosen, both showing the same information, but with different level of detail: the absolute count of confirmed COVID-19 cases worldwide as of July 6, 2020. Map ① was originally retrieved from the University of Virginia's COVID-19 surveillance dashboard, while Map ② was from the World Health Organization's COVID-19 dashboard. This task was designed to look at the participants' conceptions of what constitutes a good choropleth map, which in turn will reveal aspects of their geo-spatial data literacy and their ability to judge the reliability of spatial data (Field, 2020; Franch-Pardo et al., 2020; Juergens, 2020).

Map ① **Map ②**

Both Map ① and Map ② show the same information: the absolute count of confirmed COVID-19 cases worldwide as of July 6, 2020. Which map (Map ①, Map ②, both, or neither of them) would you consider the most appropriate to use in the classroom to explain the level of worldwide spread of COVID-19 on the given date to your students? Please justify your choice with as much detail as possible.

Figure 1: The task given to the study participants, adapted from Juergens (2020)

The subjects who participated in this study consisted of 14 in-service East and Southeast Asian teachers (four elementary and 10 secondary school teachers, two from Thailand, seven from China, four from Myanmar and one from Vietnam) who were taking a 15-week introductory graduate course in educational research methodology at a private university in Bangkok, Thailand. The main commonality in the statistical preparation of all the participants was their prior learning experiences

with measures of central tendency and variation. All participants were given the study task in mid-June 2024, at the beginning of the first session of the course, for completion in class, prior to any formal instruction or attention being explicitly given to the concept of distribution of a quantitative or categorical variable over a geographic space or within a data set. The task was not given as part of a formal evaluation for the course, but rather as a way of having the subjects show their initial informal thinking on what makes a good choropleth map. All participants completed the task within 30 minutes. The written responses to the task were collected and then transcribed by the researcher.

The study data, comprised of the written responses and transcriptions of the task shown in Fig. 1, were then coded by conducting an inductive content analysis using grounded theory (Strauss & Corbin, 1990), to examine the transcripts of the responses given by the study participants, group similarly-structured answers into categories for analysis, and organize such categories into themes.

Results

About 43% (6 out of 14) of the participants chose Map ① as the most appropriate choropleth map to use in the classroom to explain the level of worldwide spread of COVID-19 on the given date to their students. About 43% (6 out of 14) of the participants chose Map ② as the most appropriate one; about 7% (1 out of 14) chose both of the maps; and about 7% (1 out of 14) chose neither of the maps.

A qualitative analysis of the explanations supporting each participant's choice allowed me to identify different reasons for the choices made by them. Thus, in addressing the study's research question ("How do in-service East and Southeast Asian school teachers working in Thailand conceptualize what makes an appropriate choropleth map, in the context of choosing an effective visual way to communicate the geo-spatial spread of the COVID-19 disease, and how these conceptions align with previous literature?"), results are presented according to responses that focused primarily on color scheme, number of classes, class limits, and administrative unit level.

Color scheme

Out of all subjects, about 43% (6 out of 14) of the participants justified their map choice making reference to the color scheme, preferring the red scheme instead of the blue one. The exemplars that follow show the comments of some of the participants, followed by the initials of the subject.

HS: The color of Map ① indicates very alert for dangerous situation as most countries use red color as a sign of danger or reminding something's terribleness [...] But the color of Map ② is vague.

XY: I would like to choose Map ① because red color will draw your attention at first and the red color may metaphor an urgent situation of one thing. Actually, pandemic is a global issue, which is very urgent to every country. […] When you use blue to indicate the level of worldwide spread of COVID-19 which shows a peaceful vibe to people. They won't be alerted how urgent this pandemic is! When audiences go through Map ② without reading the descriptions, an audience member like me will think like this "Wow! It's more like a world map to indicate where is the water area and where is the land area." Somehow, when you look at the Map ①, I get a sense of something urgent is happening right now, I think I want to know more about it!

Number of classes

Out of all subjects, about 36% (5 out of 14) of the participants justified their map choice making

reference to the legend's number of classes. Both maps have the same granularity of their classes: seven classes each, although only five of those classes are numerical for Map ②. The exemplars that follow illustrate this category of responses.

CP: I would like to choose Map ②, because it […] reports some regions without reporting data and regions that are not applicable. In order to ensure the accuracy of the data, most of the information we can receive at present comes from official platforms and reports, but the data in some places cannot be collected or is not officially displayed. The Map ② marks this point, […] but there are no hints to indicate those areas that have not been reported in Map ①.

SL: Map ② also indicates the regions without reported data and the regions that are not applicable, which seems more rigorous and realistic.

Class limits

Out of all subjects, about 29% (4 out of 14) of the participants justified their map choice referring to the legend's class limits. The exemplars that follow illustrate this category of responses.

AY: The numbers of Map ① is somehow too detailed, and it is less meaningful as there must be mistakes and omissions in the process of information collecting.

SL: The number of people in each color area in Map ② is more reasonable and less complicated for readers.

Administrative unit level

Out of all participants, about 21% (3 out of 14) of them justified their map choice making reference to the map's administrative unit level (i.e., countries, or states or provinces within a country). The exemplar that follows illustrate this category of responses.

EZ: I'm going to choose Map ②, because Map ② is displayed by countries, which is simpler to analyze. Map ① depicts the cases in various regions and countries. There are excessive samples.

RS: Map ② is easier to look at initially because it does not divide US and Chinese states. Because of this, there seems to be some conflicting data on the maps; it appears that in Map ① the US has less cases than in Map ②.

Discussion and conclusion

The study participants were able to reason about important components of a choropleth map, including legend, color scheme, number of classes, class limits, and administrative unit level. From the data analysis, it was also observed that none of the participants mentioned the countries' population or the use of raw counts instead of using population normalization as an issue for making an appropriate choropleth map for displaying COVID-19 information (Field, 2020; Juergens, 2020). Only 1 participant expressed three different characteristics of an appropriate choropleth map, while most of the participants mentioned two. However, only two were able to realize the misrepresentation of spatial information in Map ①, which depicts simultaneously countries, US states, and Chinese provinces, instead of the US and China as countries. This may hint for a need for improvement of the geo-spatial data literacy skills of the participants, which is a key skill nowadays, when choropleth maps are very common in media to visualize and understand not only the geo-spatial spread of a disease, but also election results, population density, healthcare access, and climate patterns (Camm et al., 2021; Juergens, 2020). Moreover, being able to choose the appropriate graph and create appropriate graphs for specific situations, with or without the support of technology; and being able

to critically evaluate graphs and to distinguish the relative strengths and limitations of particular graphical representations, are skills associated to graphical competence and statistical literacy in general (Gal, 2002; González et al., 2011).

The informal descriptions made by the participants of what makes a good choropleth map align well with the characteristics of appropriate choropleth map representations found in the literature (e.g., (Field, 2020; Franch-Pardo et al., 2020; Juergens, 2020; Lane et al., 2022). For instance, map errors and misrepresentation of spatial information (e.g., depicting simultaneously administrative levels of different hierarchy, such as countries, US states and Chinese provinces) is a common way to "lie with maps", influence the reader's understanding in a certain way, and then lead to inaccurate analyses or results by the reader (Juergens, 2020; Monmonier, 2018).

In relation to the color scheme in choropleth maps, red is a common color to use for danger and urgency, that can influence a reader to feel more alarmed about the data (Lane et al., 2022). In fact, red color hues, which are known to be able to also cause anxiety, fear or danger on map readers, are often referred as inappropriate for choropleth map representations, particularly when the map content is related to a pandemic, which is an unpleasant topic by itself (Juergens, 2020). However, in the current study, it was found that all the participants who referred to the color scheme preferred the red over the blue one, claiming that this sense of urgency, alert and alarm about the data triggers the reader's attention to the map information. This conception could have some cultural connotations, since red has been the color of power, status, and repelling evil in Chinese and other Confucian heritage cultures, with copper-red hues having a meaning of difficulty attached to them (Stuart, 2016).

Since the Basic Education Core Curriculum of Thailand mentions as a common standard for many subjects the utilization of maps and geographical instruments for searching, analyzing, drawing conclusions, and efficient utilization of geo-data and information, as well as the ability to explain meanings of data from diagrams, maps and charts in search for data to analyze the physical and social characteristics of Thailand, Asia, Australia, Oceania and the rest of the world, it is necessary the promotion of statistical and geo-spatial data literacy in our teachers, and this ongoing research may shed light on the possible issues held by our teachers in relation to their ability to choose, critically evaluate, and create appropriate graphs for specific real-life situations. Therefore, more information is needed on the teachers' statistical literacy skills related to graphical representations of geo-spatial data, as well as their specialized content knowledge in a context of graphical representation of data, which will provide more evidence on the teachers' readiness to assist students in realizing errors, misrepresentations and (in)appropriate components in graphs, and in properly using their contextual knowledge of graphs (González, 2021).

Richness of reflective processes on algorithmic decision-making systems by prospective teachers

Susanne Hilger[1] and Carina Büscher[1]

[1]University of Cologne, Germany; susanne.hilger@uni-koeln.de

As Artificial Intelligence (AI), algorithms, and algorithmic decision-making systems (ADMS) play an increasingly important role in everyday life, it is crucial to incorporate the promotion of data literacy into teacher education. In a seminar for prospective math teachers the functioning of ADMS in general and decision trees in particular was explored. Since in mathematics learning reflection processes play a significant role, the material was designed not only to build basic knowledge on ADMS but to foster reflections on its appropriate use and the associated purposes. In this study the richness of the initiated reflection processes is demonstrated.

Keywords: Data literacy, reflection, learning processes, critical mathematical thinking, teacher education.

Introduction

Due to the steady increase of computing power and the availability of large amounts of data, the use of algorithms and AI-based technologies has significantly increased. As a result, algorithms are increasingly being used in decision-making processes. The use of such systems, called algorithm decision-making systems (ADMS), entails not only opportunities but also significant risks, for example, when personal data is processed and an ADMS makes decisions about individuals based on that data as access to credit, employment, medical treatment and judicial sentences (Castelluccia & Le Métayer, 2019). In the light of these challenges, it is crucial to educate the population to become responsible citizens, so they are not merely passive consumers but can actively shape the digital world through critical questioning. Teachers play a central role in the promotion of mathematical critical thinking and data literacy, as they have a direct influence on how future generations will interact with technology (Casal-Otero et al., 2023). An essential step in the inclusion of data literacy in classroom is therefore the promotion of data literacy among prospective teachers.

The research project presented here focuses on promoting algorithmic literacy among prospective math teachers as one component of data literacy, with a particular emphasis on fostering reflections on the use and purpose of ADMS.

Theoretical background and research question

One component of data literacy is algorithmic literacy (Büscher & Lengnink, in press). According to Lengnink (2020), algorithmic literacy includes, first, the "ability of an individual to interpret algorithmic processing and critically evaluate results generated by algorithms in various contexts" and, second, the "attitude to discuss reactions and opinions regarding such algorithmically obtained results and to critically question their implications" (Lengnink, 2020). Thus, algorithmic literacy is not limited to the understanding of a concept or method but also significantly includes diverse reflections on the significance and implications of concepts, methods, and results.

In mathematics learning, reflection processes are needed that go beyond the acquisition of mere knowledge and focus on the contextualization of this knowledge, as well as the possibilities and limitations of using mathematics (OECD, 2017). In the context of ADMS, this means that not only basic knowledge like a fundamental understanding of ADMS but also reflective knowledge such as the possibilities and limitations of ADMS must be learned.

Reflective knowledge, which refers to the "competence in reflecting upon and evaluating the use of mathematics" (Skovsmose, 1994), can operate on various levels. According to Skovsmose (1998) there are four kinds of reflection. The *mathematics-oriented* reflection focuses on the object (a concept or algorithm) itself. When the appropriate use of the object (relationship between the object and an extra-mathematical reality; validity of the model) is discussed, it is about *model-oriented* reflection. Reflecting on the actual purpose of carrying out the modelling (in the political, social or cultural context) is classified as *context-oriented* reflection. The fourth kind of reflection is the *lifeworld-oriented* reflection, which occurs when the significance of the topic for one's own life is considered.

A structure of various components of a holistic concept of competence can be found in the orientation framework for the learning area of global development (Schreiber & Siege, 2016). This framework lists the competence areas of *recognizing*, *evaluating*, and *acting*. In the area of *recognizing*, knowledge is purposefully acquired. *Evaluating* involves the critical ability to assess the suitability and value of different outcomes, information, or sources. *Acting* entails making (well-founded) decisions and transforming acquired knowledge into responsible actions.

Materials that can be used to learn about the functioning of various ADMS can be found, for example, in the projects "AI unplugged" (www.aiunplugged.org) and "Data Science and Big Data in Schools" (www.prodabi.de). However, the focus of the material is often on conveying basic knowledge, i.e. the understanding of the algorithm itself. Reflections about the use and purpose of ADMS are less actively encouraged. Bilstrup et al. (2022) found in their literature review that reflective discussion with ADMS is underrepresented compared to the demonstration of the performance. Sanusi et al. (2023) identify a similar gap in teaching and research and request that societal and ethical aspects should be included when dealing with ADMS. Correspondingly, the reflective processes of learners in the context of ADMS have been little researched.

In response to this gap in teaching and research, Büscher and Lengnink (in press) developed a seminar concept on ADMS with the goal of initiating the areas of competence *recognizing*, *evaluating*, and *acting* (Schreiber & Siege, 2016) and the four levels of reflection *mathematics-oriented*, *model-oriented*, *context-oriented*, and *lifeworld-oriented* (Skovsmose, 1994) in reflection processes among students. With the help of material from "AI unplugged" (www.aiunplugged.org), knowledge about the functioning of decision trees is built up and reflections are initiated in discussions and written reflection tasks (more details follow in the "Method" section). The material was used in a seminar for prospective math teachers and the written products of the reflection tasks were qualitatively analysed with the aim of specifying the reflection processes in more detail.

In the follow-up study presented here, the material is re-used in a slightly modified version and the written reflection tasks will now be analysed with the focus on the richness of the reflection processes of the students. Specifically, the following research question (RQ) will be investigated:

> (RQ) What are the differences between the students' reflection processes?

Methods

Design of the teaching-learning environment

The teaching-learning environment concerning ADMS and reflections about ADMS developed by Büscher and Lengnink (in press) was slightly modified. In the following the design of the material is sketched.

After a short introduction into decision trees the students were asked to create their own one based on data taken from www.aiunplugged.org (see Figure 1 A). To initiate reflections, the students should justify their choice of features. A possible decision tree can be seen in Figure 1 B (taken from www.aiunplugged.org).

After that, students should validate their decision tree using test data and assess and interpret its accuracy. To foster deeper reflections on the choice of data and features, a monkey with yet unknown features (see Figure 1 C) is shown and the difficulty with the categorisation is discussed.

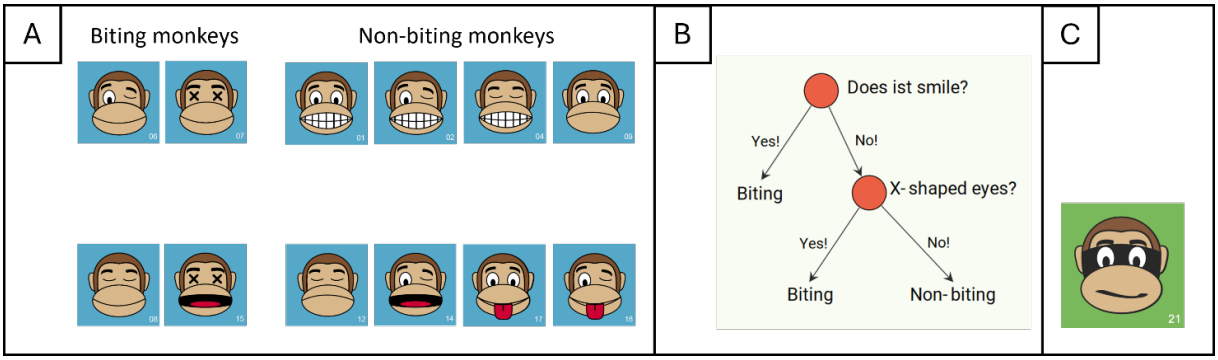

Figure 1: Training data (A), a possible decision tree (B), data with new features (C). Taken from www.aiunplugged.org by Annabel Lindner and Stefan Seegerer. It is licenced under CC BY-NC

Afterward, students were confronted with one real-world scenario where ADMS made decisions about individuals (likelihood of a criminal reoffending in court). The use of ADMS in these situations was to be discussed, and its impacts evaluated. The final reflection task (RT) which was to be discussed and answered in written was:

> (RT) An ADMS uses historical data for decisions that lie in the future. Discuss comprehensively: What are the opportunities and risks of such an approach?

Design of the study

The material was incorporated into a seminar titled "Content-based thinking before calculation and general education in math education" for students pursuing a teaching degree for upper secondary schools at the University of Cologne in the summer term 2024. The students worked in groups of two

to three persons. The reflection processes in the written answers of the students were analysed using a qualitative content analysis (Kuckartz, 2016) applying parts of the category system in Büscher and Lengnink (in press).

Büscher and Lengnink (in press) use the competence areas *recognising*, *evaluating*, and *acting* (Schreiber & Siege, 2016) to differentiate various types of <<reflective activities>>. If the object itself (e.g. the decision tree, the data, ADMS, …) is described, then the activity *recognising* is performed. If results or impacts are discussed (e.g. opportunities and risks of ADMS), an *evaluation* takes place. If a course of action is derived (e.g. discussing how risks of ADMS can be counteracted), the process falls into the category of *acting*.

Additionally, Büscher and Lengnink (in press) elaborate on a distinction between the addressed <<reflective objects>>. In their responses to the reflection tasks, students refer to various objects. If they talk about the data or the selected features, the object *basis* is addressed. When the algorithm, the decision tree, or properties of the model are discussed, reflection on the *process* takes place. The object *result* is coded when the students discuss the model's decisions or its properties. If none of the previously mentioned objects are referenced, but instead the use of ADMS is addressed in general, a *holistic view* is adopted. An overview of the category system is given in Table 1.

Table 1: Category system to capture reflective objects and reflective activities (taken from Büscher & Lengnink, in press)

	Name	Description
Reflective objects	*basis*	There is a reference to data or features.
	process	The algorithm, decision tree, or its characteristics such as accuracy are addressed.
	result	Decisions or their characteristics are addressed.
	holistic view	There is a reference to the use of an ADMS in general.
Reflective activities	*recognising*	Description of the object.
	evaluating	Criteria-based evaluation of the object.
	acting	Presentation of options for action or selection of a specific course of action.

A total of 14 groups participated and completed the reflection tasks. 10 of them answered (RT) and are thus relevant for our analysis. Their answers were deductively coded with the category system described above. The examples presented in this paper were translated from German to English by the authors.

Results of the study

The reflection task (RT) (see in "Method" section) requires the reflective activity *evaluating*, which was undertaken by all students. To uncover the reflective objects of the students, we will first list all addressed objects with their characteristics. Subsequently, the distribution of reflective objects among the students is presented and the richness of the reflection processes is illustrated by the answers of three students.

The students address the three reflective objects *basis*, *result*, and *holistic view*. They mentioned various aspects which were grouped in these categories (listed in Table 2).

Table 2: Addressed aspects in the reflective objects *basis*, *result* and *holistic view*

basis	*result*	*holistic view*
Injustice in the data	Incorrect decisions if the data do not match the situation	Support
Current / future developments not considered	Difficulty in understanding decisions	Objectivity, efficiency
Learning from the past		Cost reduction, resource conservation
Manipulation of data		Predictive accuracy
		Loss of control, job displacement, lack of individuality, injustice

It becomes evident that the reflection task brings forth numerous aspects. However, when looking at the responses of individual groups, a very different richness in their answers can be observed. In Figure 2 one can see that the reflective object *basis* is addressed by all ten groups, whereas the holistic view is mentioned by six and the result only by two groups (called Aaron and Beate).

	Clara	Henry	Marie	Nilas	David	Jakob	Kayla	Laura	Aaron	Beate
basis										
process										
result										
holistic view										

Figure 2: Distribution of the addressed reflective objects among the groups

To illustrate further the richness of the reflection processes we provide a detailed examination of the answers of the groups called Nilas, Laura and Aaron.

1	Opportunity: Past mistakes are not repeated.
2	Risk: Current circumstances are not taken into account (social change, current events such as the climate crisis, politics, war, etc.).

Figure 3: Nilas' answer to RT

The group Nilas highlights positively that "past mistakes are not repeated" (line 1 in Figure 3) but criticizes that "current circumstances are not taken into account" (line 2 in Figure 3). Both aspects are references to the reflective object *basis*.

The group Laura addresses two reflective objects, namely *basis* and *holistic view*.

1	Opportunities: Improved predictive accuracy, cost reduction
2	Risks: Data bias, overfitting to past pattern

Figure 4: Laura's answer to RT

In mentioning an "improved predictive accuracy" and "cost reduction" (line 1 in Figure 4), the group adopts a *holistic* perspective on ADMS. By warning about "data bias" and "overfitting to past pattern", it addresses the data *basis* (line 2 in Figure 4).

The group Aaron provides a very detailed answer to (RT) (see Figure 5).

1	As an assistance (basis) for human decisions;
2	Human vs. machine;
3	Manipulation of test data;
4	Situation does not correspond to the test data --> wrong decision;
5	When it comes to small irrelevant decisions, only minor/no impact;
6	If ADMS should make big decisions, significant impact (especially in case of errors);
7	Can simplify many work steps --> jobs may be cancelled;
8	Risk: People no longer make decisions themselves as they rely on ADMS;
9	"Dehumanization", loss of control;
10	ADMS should not be used in "system-relevant infrastructures" while possibly increasing efficiency;
11	Inequities between those who have access to the technology and those who do not;
12	Especially at the start of testing: good training opportunities for humans (e.g., in chess);
13	Further development in various areas, possibly minimizing anthropogenic errors.

Figure 5: Aaron's answer to RT

A positive *holistic view* in Aaron's answer can be found in the mention of "assistance" and "increasing efficiency" and "can simplify many work steps" resp. (line 1, line 10 and line 7 in Figure 5). Negative holistic aspects are considered in line 2 ("human vs. machine"), line 7 ("jobs may be cancelled", line 9 ("loss of control") and line 22 ("inequities") in Figure 5.

The reflective object *basis* is addressed by mentioning the risk of "manipulation of test data" (line 3 in Figure 5).

The *result* of an ADMS is discussed in line 4,5,6 in Figure 5; there, the risk of "wrong decision" (line 4) is mentioned and the distinction between "small irrelevant decisions" (line 5) and "big decisions" (line 6) is made.

Summary and discussion

To foster algorithmic literacy among prospective teachers, a seminar concept was designed (Büscher & Lengnink, in press) to initiate reflections on the model and the general use of ADMS. In the present study, the variety of reflection processes occurring among the learners is examined. Specifically, the

following research question is posed: “What are the differences between the students’ reflection processes?” A diverse richness can be observed in the students’ answers to the final reflection task: “An ADMS uses historical data for decisions that lie in the future. Discuss comprehensively: What are the opportunities and risks of such an approach?”. The written answers of this reflection task were analysed using the analytical tool from Büscher and Lengnink (in press).

While working with the reflection task, the learners address a different number of reflective objects, namely the data *basis*, the *result* of an ADMS and a *holistic view*. The aspects within these categories are very diverse. But this diversity is addressed by only a few students.

The reflective object *basis* is mentioned by all groups. This was likely elicited by the preceding seminar content and the question (RT) itself: The material on decision trees particularly encourages discussions about the selected features of the monkeys, and the question (RT) itself already hints at the use of historical data in ADMS. In this sense, it is not surprising that all groups address the basis; rather, it demonstrates that one objective of the teaching unit was successfully achieved.

No group discussed the role of the process in ADMS. While working on the decision trees, the model itself and possible changes in the process was indeed part of the discussions among the students, but apparently, this did not lead to comprehensive reflections in the end. In a further developed version of the material, the individual reflection tasks could be better linked.

Six out of ten groups mentioned aspects in the category *holistic view*, and only two groups addressed the reflective object *result*. This shows that the number of addressed reflective objects varies among the groups and illustrates how students can vary in their ability to reflect. This may, for example, stem from the fact that students have varying levels of prior experience with the topic and with reflection, thus leading to different capacities to develop reflective concepts. Another reason for this diversity could be that the teaching-learning arrangement does not equally stimulate the reflection processes of all students. Simply integrating reflection tasks into teaching-learning settings and discussing them in groups may therefore not be sufficient to initiate a certain variety of reflections in all learners. Further research should investigate how reflection processes can be more comprehensively encouraged.

What we missed in the responses was a connection to the students' own lifeworld. They primarily mentioned “generalities” without discussing the impact on their own daily actions. We would like to establish this connection in further developments of the teaching-learning environment.

The analytical tool developed by Büscher and Lengnink (in press) proved to be usable in this second slightly modified iteration of the seminar, indicating that it is quite robust to minor changes in the teaching-learning setting. It would be interesting to explore whether the category system can also be applied in other teaching-learning arrangements related to ADMS, which are further away in terms of the content from the original seminar concept. To address this empirical task, further materials need to be developed and employed, and the reflection processes of students should be further investigated.

Middle school students' objectification of probability in a computer simulation-based environment

Kjærand Iversen[1] and Amrit Bahadur Poudel[2]

amrit.b.poudel@nord.no

This study explores the development of students' probabilistic reasoning through their engagement with a computer simulation-based environment. Specifically, this development involves the interpretation of stochastic events, and the social and cultural aspects of the classroom setting are also investigated. Applying Radford's framework of knowledge objectification, we analyse and detail students' developmental processes as their knowledge of probability concepts develops and they conceptualise random events utilising mathematical symbols such as fractions and percentages. Their objectification of probability is analysed and described as processes of objectification: (1) experimenting with software and (2) making sense of symbols or systems.

Keywords: Probability, simulation-based environment, objectification.

Introduction

The development of students' probabilistic reasoning is currently understood as a progression from informal ideas and reasoning to incremental academic and formal interpretations and understanding of probability (Batanero et al., 2016). Effective lesson planning and the teaching of probability in schools necessitate a thorough understanding of students' informal probabilistic reasoning, which has been a significant focus of research for several decades. Typically, middle school students have already acquired an understanding of foundational aspects of probability through prior experience. For instance, they are often capable of identifying a comprehensive set of outcomes for a stochastic event. However, one cognitive challenge for middle school students lies in evaluating and comparing the likelihood of each outcome and utilising mathematical concepts such as fractions and percentages to express these probabilities.

In this study, we investigate 7th-grade students' interpretation of probabilistic reasoning when they encounter formal approaches to expressing their thinking in a school setting. The study is structured around several consecutive lessons focused on the basic concepts of probability, the relationship between theoretical and frequentist probability, and the modelling of compound stochastic events. Specifically, this study examines exploratory lessons to highlight students' initial reasoning and development, which is the primary focus of this article. To effectively analyse and describe students' probabilistic reasoning, we employ the theoretical framework of knowledge objectification proposed by Radford (2002).

Knowledge objectification as a theoretical framework

Radford (2002, p. 14) defines objectification as 'a process aimed at bringing something in front of someone's attention or view'. Building on this, Radford (2003) proposed that students become aware of *knowledge* embedded in a cultural space (e.g., a computer simulation-based learning environment),

a process he refers to as *knowledge objectification* – stating that 'to learn is to objectify something'. We denote mathematical objects as the 'reality of the entity being studied, created, constructed, or investigated by the mathematician, or otherwise of "concepts" when it is desired to emphasise the result of the act of thought [...]' (Iori, 2017, p. 276) during students' interaction within the computer simulation-based learning environment. This refers not only to abstract concepts, but also to culturally and historically created entities, representations, signs, and processes. We view participating students as young mathematicians engaged in the activity of objectifying probability concepts in a computer simulation-based learning environment.

During the objectification process, semiotic tools serve to make abstract mathematical concepts tangible and accessible. These tools – such as words, nonverbal clues, signs and symbols, diagrams, visual aids, and teachers' questions and interpretations – help students concretise abstract mathematical concepts. These artefacts are called *semiotic means of objectification* because they mediate forms of reflexive activity intended to raise awareness of mathematical objects. Semiotic means of objectification have been identified as follows:

> Objects, tools, linguistic devices, and signs that individuals intentionally use in social meaning-making processes to achieve a stable form of awareness, to make apparent their intentions, and to carry out their actions to attain the goal of their activities (Radford, 2003, p. 41).

When interacting with a simulation-based environment, students engage in actions and with artefacts, which facilitates the evolving social practices of doing, thinking, meaning-making, and relating to others and the world (Radford, 2014).

Objectification of probabilistic concepts in information and communication technology environments

Educational research leverages ICT environments to gain valuable insights into students' probabilistic reasoning, typically employing software that models stochastic devices or real-life artefacts in a simplified manner. For example, a study by Pratt (2000) utilises an ICT environment known as ChanceMaker, which is comprised of various gadgets analogous to real-life artefacts, such as spinners, dice, and frisbees. Another notable ICT environment is Probability Explorer, developed and utilised by Stohl and Tarr (2002), which facilitates the exploration of probabilistic reasoning among middle school students.

To investigate and comprehend middle school students' probabilistic reasoning, many studies involve their middle school participants in compound stochastic events. This approach is evident in the work of Pratt (2000), Stohl and Tarr (2002), Abrahamson and Wilensky (2005), and Iversen and Nilsson (2007), where the stochastic events consist of two independent subevents. For example, throwing two dices involves the subevents of each individual die being thrown. Modelling compound stochastic events by connecting two sub-events is typically challenging for students (English & Watson, 2016). To explore students' reasoning about compound stochastic events in depth, Fischbein (1975) developed a set of random devices in which the connection between subevents is particularly transparent. The random devices feature a structure through which one or more marbles traverse a system of crossroads, and each marble has an equal probability of moving either to the right or to the left at each crossroad. In our study, we employed FlexiTree software (Figure 1) to investigate the probabilistic reasoning of middle school students. FlexiTree software is a digital version of the random devices developed by Fischbein, with additional features. For example, FlexiTree can

simulate a large number of experiments, and the probability of going left or right at each crossroad can be set to values other than 0.5.

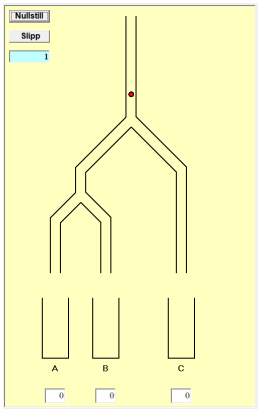

Figure 1: FlexiTree software – System 2

This study focuses on the role of artefacts or semiotic tools in students' objectification of probabilistic concepts. Specifically, the FlexiTree software is highlighted as a semiotic tool, as are the students' use of symbols and various numerical concepts such as fractions and percentages in their meaning-making.

Students and teachers interact to objectify probabilistic reasoning, with the teacher's questions serving as signs or symbols to guide students' thinking, engagement, and responses. Students express their thoughts using signs and symbols, such as percentages and fractions. Together, both teachers and students engage in knowledge objectification, using these signs and symbols to express and understand probabilistic concepts – thereby facilitating the objectification process. Similarly, students' interactions with the FlexiTree software influenced their objectification of probability.

Methods

Teaching probabilistic reasoning and randomness and developing probabilistic models to engage students and foster meaningful experiences are complex tasks. The participants in this study were a group of 7th-grade students who had received only a little prior knowledge of formal probability from school. We approached this phenomenon through well-developed teaching experiments designed to explore and understand the dynamics of how students interact with a semiotic objectification system in a simulation-based learning environment. The teaching experiment comprises a series of lessons that include both whole class discussions and students working in pairs with a computer, as well as teaching episodes and individual interviews during which researchers and teachers closely observe the development of the student's probabilistic reasoning over time (Steffe & Thompson, 2000; Cobb et al., 2003). The lessons were taught by an experienced teacher in a 7th-grade classroom of 17 students. Video recordings were made of the entire class from one corner of the room. In addition, sound and screen activities were recorded for three pairs of students. These data materials, together with the students' work on worksheets, were transcribed and analysed. We conducted a thorough analysis of the data collected using interpretive qualitative analysis methods to analyse the fine-grained development of probabilistic reasoning over a short period (Siegler, 2006), considering verbal, gestural, visual, and symbolic actions in the observed contexts.

The lesson

The first part of the lesson is a whole class discussion that begins with the teacher displaying an image of FlexiTree System 2 layout on the whiteboard (Figure 1). She explains that releasing the marble from the top will result in one of three possible outcomes – A, B, or C – and prompts the students to consider these options and determine the probability of each outcome. This is *the main question* for the students to address during the lesson: *What is the probability that the marble will end up in boxes A, B, or C?* From a formal perspective, we might assume that many students will suggest outcome C, providing arguments based on theoretical probability or the visual appearance of the FlexiTree system. Contrary to this expectation, however, the students offered a variety of suggestions and explanations during the whole class discussion. Next, the teacher asks the students to predict the result of dropping a single marble, followed by a discussion after conducting the experiment. This process is repeated three times. Again, from a formal perspective, one might assume that a majority of the students would propose outcome C based on theoretical probability or intuitive beliefs. In the next part of the lesson, students are required to provide a written response to the main question, along with supporting arguments.

The instructional sequence was designed to facilitate students' active engagement with problem contexts, interaction with pedagogical tools, and the development of their understanding of randomness, probabilistic models, and compound stochastic events. The video data were transcribed, revealing several significant episodes that illustrate students' engagement with problem contexts, their interactions with pedagogical tools, and the evolving processes of probabilistic reasoning about various stochastic events.

Results

Through analyses of the data, we identified *how* or *in what way* semiotic tools impact the students' objectification process. First, the computer simulation-based environment played a significant role as students interpret, reflect upon, and use the environment, which affects their reasoning processes. Second, students' active participation in probabilistic thinking evolved with respect to their use of symbolic representations such as fractions and percentages. In so doing, the students utilised semiotic systems/tools to make abstract probabilistic concepts accessible through their words, nonverbal clues, metaphors, signs, symbols, diagrams, and visual aids.

Objectification as experimenting with software

In the lesson, the teacher initiated the exploratory tasks by asking the following question: 'What is the probability that the marble will end up in boxes A, B, or C?' The students exhibited different forms of probabilistic reasoning about the stochastic event (Julien & Iversen, 2021[1]). The initial response to this question was provided by a student who argued that the probabilities of choosing either the left or right path were equal at both crossroads. Another student concurred, stating that the probabilities are indeed equal at the first crossroads, adding, 'I do not understand why, but I believe

[1] In their 2021 analysis, Julien, A. and Iversen, K. utilize a discursive approach to examine student interaction. In this study we included statements by Charlene and Alphonso and employ Radford's theory of knowledge objectification framework. We obtained permission from the concerned author.

it will proceed to B.' Subsequently, a third student, Charlene, contributed to the discussion by offering a physical interpretation of the scenario.

1. Charlene: … it is bent here and then it goes in a straight wall. And if the marble hits the wall, it gets some speed the other way … But … at the same time, the marble has speed … also that way … I don't know.
2. T: If I understand this correct … if it comes … you agree that its fifty-fifty, or is it …?
3. Charlene: Yes.
4. T: So if it comes here [pointing to left side after the first crossroads] then something happens down here?
5. Charlene: Yes, you have this wall. If it hits the wall, it will gain speed in the opposite direction.

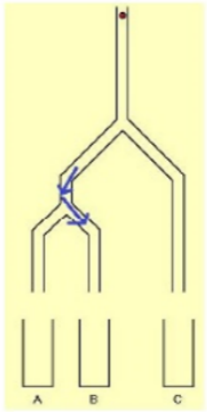

Figure 2: Model of Charlene's physical interpretation of a potential outcome

In the excerpt, Charlene was considering the physical interpretation of the movement of a marble along the slope. She acknowledged the probability of the marble hitting the wall, bouncing in the opposite direction, and thus ending up in box B. We observed a common phenomenon in students' understanding of probability, as they often struggled to separate the physical aspects of the situation from the simulated probabilistic system.

The teacher explained that FlexiTree operates in a computer simulation-based environment without obstructions, unlike in physical space. After this clarification, the students and the teacher agreed to conduct an experiment. Before opening the experiment, the teacher deliberately asked the students to predict the outcome. They were asked to place their foreheads on the desk so that they could not tell what others predicted. The teacher then noted how many students thought the marble would reach boxes A, B, and C. The outcomes predicted by the students' were: [A; 2, B: 9, C: 4]. After that, the teacher ran an experiment, and the marble ended up in box B. This resulted in several students cheering and some shouting, 'I was correct!'

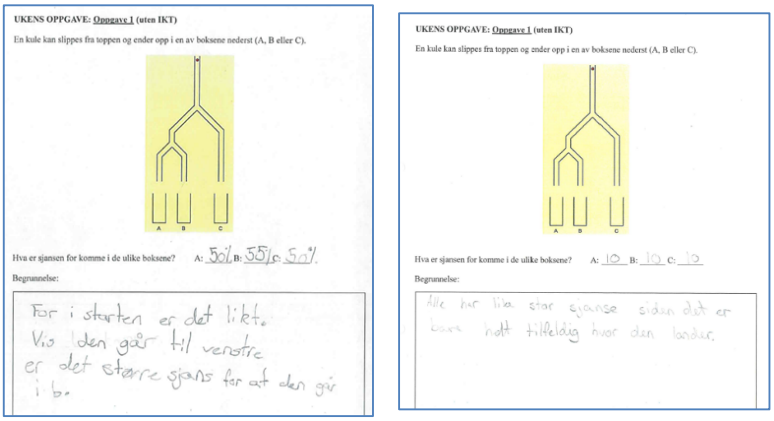
The students showed their eagerness to explore the outcomes of an additional set of experiments. Adhering to previous methods, the teacher noted the potential predicted outcomes. The students predicted the following outcomes: [A:1, B: 5, C: 9]. After conducting an experiment, the marbles ended up in box C. This process was repeated a third time, with the students predicting the outcomes as [A: 4, B: 9, C: 2]. In this round, the result from the experiment was A. To address the main guiding question, the lesson was designed to promote the use of probabilistic thinking, encouraging the

students to analyse the behaviour of probabilistic systems and verbalise the most likely outcome. The students engaged with the interactive FlexiTree software and attempted to analyse the marble's trajectory within the system, thus exploring the interactive visual simulation software. The teacher facilitated by guiding the students to engage in probabilistic thinking processes, pondering and evaluating the variables that influence the probability of each outcome. Many students worked on this task by tracing the path of the marble through the system. However, at the crossroads, which act as a decision point, they found themselves undecided when confronted with an equal chance of the marble going left or right. In these situations, the students felt pressured to pick one of the potential outcomes. After running three experiments, and a subsequent discussion, the students were instructed to submit their written responses along with supporting arguments.

Objectification as symbolising probabilistic reasoning

The overarching objective of the exploratory teaching lesson was to help students objectify their thinking about probability in the context of compound events. The simulation and visualisation in FlexiTree and the teacher's frequent prompts played a crucial role in supporting students in externalising their reasoning about the underlying probability distributions. The teacher slightly modified the main guiding question of the lesson to ask students to calculate the probabilities of the likelihood of a marble ending up in one of three boxes: A, B, or C. The teacher then offered choices to quantify these probabilities as fractions and percentages. Most of the students chose to use percentages, and there were also discussions about dividing the probabilities equally. One student, Alphonso, suggested starting with 100% as the total probability, based on the assumption that the three possible outcomes were equally likely.

6. Alphonso: Since A and B … if you split up … if you split up the chance of one hundred percent, it makes then sixty-six percent for both A and B – chance that (unintelligible) comes to one of them, and thirty-three … thirty-three percent that it comes to C. Because A and B are two.



Charlene joined the discussion, disagreeing with Alphonso and arguing that the marbles must pass through two intersections to reach box A or B. Alphonso then continued his argument.

7. Alphonso: Ok … when I said that I didn't mean … There is fifty-fifty chance, and it goes to either right or left … but it is not about whether it goes right or left, what it is about is that there are three alternatives, and two of them are both to the left. So, it is more likely that … that it comes in two out of three than in one out of three. Do you understand what I mean?

Alphonso outlined his argument using percentages (66% and 33%) and used the phrase 'fifty-fifty' to describe equal probability at the crossroads. In addition, he included fractional interpretations of his reasoning ('2 out of 3' and '1 out of 3'). He was the only student who expressed probabilistic thinking in percentages and fractions. Most students prefer using percentages to quantify abstract thinking in numerical values.

Following the experimentation and whole class discussion, the students were instructed to write down their responses to the main question and provide the reasoning behind their ideas. They all used percentages to express probabilities. Six out of the 17 students wrote 'A = 25, B = 25, C = 50', the expected answer. Eight students proposed that each outcome had an equal probability, while two students said that outcome B was the most likely. It is noticeable how the students expressed their

responses. When modelling random phenomena, teachers often stress that the total of all probabilities must add up to 100%. However, some of the answers submitted in this study did not meet this requirement. Figure 3 presents two written responses in which the percentages did not sum up to 100%, but both elucidated their reasoning about the probabilities.

Tom **Anne**

Figure 3: Students' solutions to the main question: What are the probabilities that the marble will end up in boxes A, B, or C?

In the first solution, Tom wrote 'A = 50%, B = 55%, C = 50%', and the explanation was as follows: 'At the start, it is equal. If it goes to the left, there is a higher chance for it to go to B.' Perhaps he understood that the marble might hit the wall and bounce towards B. Anne, on the other hand, wrote, 'A = 10, B = 10, C = 10', arguing that 'They all have an equal chance since it is completely random'. Although the percentages do not sum up to 100%, this solution closely expresses the relative relationship between the probabilities of various stochastic events.

Conclusion

Teaching probability to middle school students is challenging, but implementing an exploratory teaching approach to engage them in probabilistic thinking is even more complex. By using expert-designed software in classrooms, we aim to deepen our understanding of children's experiences and challenges and enhance the development that they yield. In this study, we investigated how students grasp the abstract concept of probability by offering various learning opportunities to students, such as running experiments in simulation software, participating in games, and reflecting on their thinking in writing. The results illuminate the impact of the FlexiTree computer simulation-based environment, which facilitates engagement in probabilistic thinking and reasoning. However, the students often mixed physical interpretations with their explanations of probabilistic events, revealing a common challenge in distinguishing between real-life random generators and computer-based simulations. We assessed the students' development in understanding probability by analysing their dialogues with teachers and their written responses. In conclusion, the computer simulation-based environment enabled students to experiment, reason, and reflect, and it helped them articulate probability concepts mathematically, fostering a deeper awareness of probabilistic thinking.

Exploring the structure of enumerations in combinatorial problem solving: a case study with Italian secondary school students

Luca Lamanna[1] and Laura Branchetti[1]

[1]University of Milan (Statale), Italy; luca.lamanna@unimi.it

This work proposes a case study aiming at exploring and describing what kind of enumerative processes are developed by a group of Italian secondary school students without previous knowledge in combinatorics. We proposed the students a questionnaire of combinatorial tasks and we focused on the answers in which the numerical answer was computed through an enumeration of the solving configurations, observing the structural elements students introduce in their lists. Our work showed that if, on one side, some of the students develop a structure of enumeration that could be exploited in the development of combinatorial formulas, on the other hand there are some structures that highlight the need of a preliminary work to be done with students before introducing more general solving heuristics.

Keywords: Combinatorics, problem solving, enumeration, secondary school.

Introduction

Combinatorics plays a key role within mathematics and its teaching. On the one hand, it represents a core in discrete mathematics while, on the other hand, in the school curriculum has a role in the development of topics both in mathematics and other disciplines (e.g., computer science or biology – Batanero et al., 1994). Moreover, combinatorics it is a topic that could offer students wide opportunities to develop and train problem solving skills (Kapur, 1970), providing an environment that does not rely on particular mathematical prerequisites and that leaves wide room for the formulation and testing of conjectures (ibid.). As a result, when engaged in the resolution of a combinatorial tasks, students (and people, in general) may develop a multitude of different solving approaches. The literature of research in combinatorics education focused widely and mostly on the study of such approaches – to which we will refer as 'heuristics' following the definition proposed by Schoenfeld (1985) – with an extended description of the possible combinatorial heuristics proposed in Godino et al. (2005) – with university students – and Lamanna et al. (2022) – in the case of secondary school students – or focusing on the difficulties students may encounter while solving a combinatorial task (Hadar & Hadass, 1981) and the variables affecting such difficulties (e.g., Batanero et al., 1997). Another direction of research in combinatorial problem solving is the study of combinatorial thinking and its development, for which a cornerstone research is represented by the model proposed by Lockwood in 2013, where combinatorial thinking is schematized through the interaction of three different dimensions (counting processes, formulas/expressions and set of outcomes), observing that a fully developed combinatorial thinking should take into account all the three dimensions and their interactions. In Lamanna et al. (2022) it was shown that a visible effect of teaching combinatorics is the students' shift from heuristics exploiting many representations of the set of the configurations towards attempts to directly use a single formula or develop arithmetic procedures. This led to the development of a research line focusing on teachers and the ways combinatorics is proposed in Italian schools. As a result, Lamanna & Branchetti (2024) showed that

teachers represent an active variable in students' development of combinatorial thinking and the heuristics they use. In particular it was observed that, in a phenomenon called 'funnel effect', students are encouraged to mostly develop solutions relying only on the use of combinatorial formulas or arithmetical procedures – that are often considered to be more efficient. The effect of such phenomenon is that students' exploration of the dimensions of Lockwood's model is limited – mostly cutting out of the equation the dimension of the set of outcomes. This implies that students are not encouraged to rely on enumerative processes that, according to Lockwood & Gibson (2016), play a key role in the development of a combinatorial formula's understanding. Lamanna & Branchetti (2024) showed that, even recognizing the usefulness of enumerative processes in the resolution of a combinatorial task, teachers mostly consider this heuristic to be 'acceptable' only in early stages of the learning of combinatorics, asking the students to change their approach towards a different choice of heuristics. In this sense, considering the development of a student's combinatorial thinking and the structure of Lockwood's model, it becomes relevant to understand how such change of solving approach is implemented and to what extend it could be anchored on students' developed heuristics, in order not to create a discontinuity in the shift from heuristics relying on the dimension of the set of outcomes to heuristics mostly relying on the dimension of counting processes and formulas. For this reason, it is important to focus on the heuristics students develop before learning combinatorics at school. In the case of Italian students, Lamanna et al. (2022) observed that before learning combinatorics students mostly rely on enumerative processes. In this sense, it is then important to explore how such heuristic is developed and the structures students rely on in order to produce lists of configurations. Therefore, while in the literature of research there are examples of listing techniques developed by students (e.g., English, 1991), fewer attention has been posed on the structure of enumeration that is developed, with almost no focus both on the case of secondary school students' enumerations and the relation between the structure of lists and the passage from an enumeration to a formula. In this paper we will propose a case study conducted on a group of Italian secondary school students, focusing on the enumerations they produce before learning about combinatorics, to explore whether the structures that spontaneously arise could be involved in the process of development of a combinatorial formula.

Theoretical framework

We based our work on the characterisations found in the literature concerning the enumerative processes in combinatorial problem solving. This heuristic consists in the production of the complete list of elements belonging to a certain set of configurations (i.e., the elements to be counted in a combinatorial task). In particular, considering a set C of configurations for a certain task T, an enumeration is a process that produces a complete list of elements of C (Batanero et al., 1994). Enumerative processes could be carried out in different possible ways and described in the works of English (1991), where the heuristics of children and adolescents were studied. We find here a, first, main difference: a-systematic enumeration (or "non-systematic", carried on through a try-and-error procedure) and systematics enumeration (i.e., an enumeration in which it is recognizable a logic in the organisation of the list of configurations). English (1991) also identifies different ways through which children create list of elements, introducing the concept of the "odometer", often identified in literature with different names (e.g., 'pivoting of a variable' or 'fixation of a variable'). The odometer

approach describes a structural use of the variables for systematically creating a list: one of the variables a_i involved in the task is fixed in the configuration to be formed (for instance, in the first position) and the enumeration unfolds by listing all the configurations that have such variable in the position in which is fixed. Once that this process has ended, another variable is fixed in the same position and the respective configurations are listed until all the possible variables become fixed. In 2009, Shin & Steffe, connecting to the description of the odometer approach, conducted a case study in which they described the kind of enumerations produced by two seventh-graders observing how three main enumerative structures were produced: i) multiplicative enumeration, where the list is produced following a multiplicative structure (i.e., the list is organized in a table disposition that would allow the solver to easily count the configurations even not listing them all exhaustively); ii) additive enumeration, when dealing with an exhaustive list that is counted "by-the unit", meaning that each of the elements correspond to a "+1" in the count of configurations and iii) recursive multiplicative, when both an enumeration and a multiplicative structure occur within a same solution.

We can, then, summarize the aim of the work presented in this paper through the following research question: what kind of enumerative processes are developed by a group of Italian secondary school with no previous knowledge in combinatorics?

In particular, we aim at exploring and describing the structures of the enumerative processes that students spontaneously develop in front of a combinatorial task. This is done in order to understand, in a further step of research outside the scope of this work, if and how such structures may facilitate the development and understanding of a combinatorial formula starting from what students actually produced (and therefore, we suppose, interiorized) without inducing discontinuities in their exploration of the model of combinatorial thinking (Lockwood, 2013).

Methodology

To answer our research question we relied on the set of data collected in Lamanna et al. (2022), where a sample of 115 Italian secondary school students was involved, 64 of which did not already learned combinatorics and all belonging to groups of students coming from different schools and backgrounds. In particular, this work will focus on the protocols collected from the 64 students with no previous knowledge on school combinatorics and that consisted in 4 groups of students in grade 10, 11 or 12 (i.e., second, third and fourth year of secondary school with students aged between 15 and 18) with different math teachers. The students were proposed a questionnaire of 13 open-ended tasks (in an Italian translation) adapted from the one used in Batanero et al. (1997) and proposed in two different versions with the same tasks presented in an inverted order, aiming at limiting a possible effect of time on the data collection and to obtain a sufficient amount of data on every item of the questionnaire. Depending on the availability of the school, students had 60 or 90 minutes to complete the questionnaire. We remark, though, that time did not represent an issue, considering that most of the students were able to complete the questionnaire widely before the smaller time limit. In this work we will focus our analysis on one of the tasks proposed in the questionnaire, here presented in an English translation.

> Andrew, Burt, Charles and Dan (A, B, C, D in short) decide to have lunch at the school cafeteria and, after taking the tray, they line up to get the food. Obviously, each of them would like to be the first! We want to write all the possible ways they can get in line. For example, if A is the first, B second, C third, D fourth, we write ABCD. How many ways can the boys be lined up?

We decided to focus on this task because, out of the 13 items in the questionnaire, it represents the task whose solution was attempted the most and that, at the same time, even though with a high percentages of solutions involving enumerative processes, showed a large heterogeneity in students' heuristics when compared to the other items in the questionnaire. The involved task is belonging to the combinatorial model of distribution (Dubois, 1984) of medium dimension (i.e., requiring between 12 and 25 solving configurations), in which students are asked to determine in how many ways 4 people can be distributed in a row and whose solution is $P_4 = 4! = 24$, thus identifying it as a permutation task.

The students' answers were collected in a written form and, out of the 57 answers provided on the selected task, we isolated a total of 45 solutions involving an enumerative process either as a primary or support heuristics (Lamanna et al., 2022). Once that the set of enumerations was selected, we proceeded with a qualitative content analysis (Mayring, 2015) of students' protocols, analysing the nature and structure of the enumeration – that is, systematic enumeration or not (i.e., presence of pattern in the process of enumeration – English, 1991), use of the odometer approach (i.e., fixation of one or more variables – ibid.), structure of the enumeration (i.e., multiplicative, additive and recursive multiplicative – Shin & Steffe, 2009). The occurrences of such elements were recorded and the overall distribution of the codes was analysed.

Results

Out of the 45 protocols collected, we observed that 25 students produced a correct solution by using enumeration either as a primary heuristics or a support heuristics (Lamanna et al., 2023) – meaning that the enumerative process intervene in one of the steps of the resolution, usually to solve a sub-task obtained by fixing one of the variables and analysing the sub-task of reduced dimension. Focusing on such aspect, we can observe in Table 1 the distribution of the use of enumeration either as a primary or support heuristic.

Table 1: Distribution in the use of enumeration

	Primary heuristic	**Supporting heuristic**
Non correct answers ($n = 20$)	0,7 (14)	0,3 (6)
Correct answers ($m = 25$)	0,32 (8)	0,68 (17)
Total ($t = 45$)	0,49 (22)	0,51 (23)

While in the whole sample the use of enumeration is uniformly distributed between the involvement either as a primary heuristic (therefore providing a complete list of all the configurations) or

supporting heuristic (therefore involving enumeration in one of the steps of the resolution), the situation changes introducing a differentiation between correct answers and not. We can, in fact, observe that most of the solutions in which the students attempted a complete enumeration of the configurations produced a non-correct result, with students usually producing an incomplete list of configurations. On the other hand, most of the correct answers involved enumeration as a support heuristic, meaning that students managed to coordinate different heuristics to produce a correct numerical solution (usually involving the arithmetic rule of product – Godino et al., 2005). To delve more in the structures of the enumerations that students produced, we can observe in the following Table 2 a summary of the analysis conducted on the collected protocols.

Table 2: Distribution of structural elements in students' enumerations

			Structure of enumeration		
	Systematic enumeration	**Odometer approach**	***Additive***	***Multiplicative***	***Recursive multiplicative***
Non correct answer ($n = 20$)	0,05 (1)	0,3 (6)	0,7 (14)	0,05 (1)	0,25 (5)
Correct answer ($m = 25$)	0,68 (17)	1 (25)	0,28 (7)	0 (0)	0,72 (18)
Total ($t = 45$)	0,40 (18)	0,69 (31)	0,47 (21)	0,02 (1)	0,51 (23)

We observe that almost all the non-correct answers appeared in correspondence of a non-systematic enumeration. The students approach the solution of the task by a try-and-error procedure that – although relying in some cases on the odometer approach (thus with a hint of systematization of the enumerative process) – does not allow to maintain the control on the configurations that are produced and, therefore, fail in producing a complete list. It is interesting, analysing this sub-case, noting that some odometer approaches occurred in this set of protocols: the students started their enumeration by fixing one (or more) variable and then proceeded in enumerating the relative configurations by try-and-error. For what concerns the structure of the enumeration, we observe that in most of the cases the structure of non-correct answers showed an additive structure, with students aiming at producing lists in order to count configurations by the unit. A smaller fraction of students produced an enumeration with a recursive multiplicative structure but failed in the switch from enumeration to generalisation, thus in the introduction of the multiplicative part of the structure. We finally observe that in this set of answers is included the only one demonstrating a multiplicative structure: the student produced a solution by creating a double entry table with the variables listed on two of the edges and, after listing some random configurations, explained that the total was given by the multiplication of the number of variables listed in the table, thus producing a non-correct calculation.

For what concerns the students that provided a correct answer, we observe that not all the enumerations were systematic, but all the solutions relied on the odometer approach. We suppose that, by fixing one of the variables, the task is reduced to a sub-task whose dimension is low enough to allow students to determine the correct number of configurations – even through non-systematic enumeration. We may argue, considering that there are also non-correct solutions relying on the odometer approach, that the difference here relies on the *a-priori* setting of the solution: on one side, with non-correct answers, the odometer is used to organize the whole listing procedure that, still, needs to produce all the configurations. On the other hand, with correct answers, in most of the cases students introduce the odometer only to reduce the dimension of the task and enumerate a smaller set of configurations. For what concerns the structure of the enumeration, we observe that most of the solutions demonstrated a recursive multiplicative structure that is: the students created a particular partial list (usually by fixing only one of the variables) and then computed the solution of the given task by introducing a multiplicative structure in the list (i.e., once that a variable is fixed, the remaining lists have the same number of configurations and the number of such lists equals the number of possible variables to be fixed).

Overall, we notice that students without previous knowledge in combinatorics tend to widely adopt the odometer approach even though this is not always accompanied by a systematic procedure that, in case the task has a high number of configurations, might induce a loss of control of the process. For what concerns the structure of the produced enumerations, we observe that the students equally rely either on an addictive structure or a recursive multiplication structure with almost no occurrences of multiplication structures. We may argue that this result could be task-dependent, but we find that even the absence of attempts showing a multiplicative structure still provides valuable information regarding the processes of enumeration unfolded by the students. We observe that the use of the odometer approach supported both the process of organising a complete enumeration and setting a resolution computable through product rule, highlighting a multiplicative structure in the process of enumeration. The two approaches, however, when not in correspondence of a try-and-error enumeration, refer to a same organisation of enumeration, with the difference that in one case the enumeration is complete (thus additive) and in the other is partial.

Discussion and conclusion

The analysis conducted on the sample of collected protocols provided an overview of the processes of enumeration that a group of students develop when solving a permutation task. For what concerns our research question, we observed that most of the students spontaneously develop enumeration through the odometer approach, thus fixing one of the variables to simplify the structure of the lists they produce. In spite of this organisation, the use of the odometer approach did not always coincide with a development of a systematic listing procedure. Considering the structure students give to their enumerations, we notice that students mostly rely on additive and recursive multiplicative structures, with different aims. In the former case, the students usually aimed at producing a complete enumeration of the set of configurations (in the sense of Lockwood, 2013) while, in the former case, the overall solving strategy (in the sense of Schoenfeld, 1985) aimed at reducing the dimension of the set of configurations. In this last case, even non-systematic enumerations allowed students to profitably solve the task, in agreement with Lamanna et al. (2022) where it was observed that for

tasks of reduced dimension the non-systematic enumeration did not represent an issue. This aspect, however, would benefit from further analysis, possibly involving students in a think-aloud process of resolution of a combinatorial task to understand which is the reasoning that leads either to an additive or recursive multiplicative structure.

Overall, in spite of the reduced number of students involved and tasks analysed, we observe how our work of research allow us to gain insights on the heuristics that are developed by students with no previous knowledge in combinatorics and, therefore, upon which teachers will build their teaching of the topic. According to Lamanna & Branchetti (2024) teachers accept enumerative processes in the early stages of the teaching of combinatorics but, then, students are asked to drop enumerative processes in favour of more direct approaches. In this sense, also considering the work by Lockwood & Gibson (2016) according to which enumerative processes play a key role in the development of a student's comprehension of a combinatorial formula, it is important – from a teaching perspective – to consider that not all the students develop enumerative processes in the same way. This has an implication on a student's development of combinatorial formulas and, more in general providing a point of interest for educational research on this topic, on the heuristics developed by secondary school students in combinatorial problem solving. In this sense, our work shades light upon the fact that there are some structures that, in spite of being important within combinatorial problem solving, need to be furtherly developed when teaching combinatorics in order to provide a solid base on which students can build formulas and arithmetic rules. In particular, for example, in the shift from an additive structure of enumeration to a recursive multiplicative. In this sense we argue that, exploiting the odometer approach spontaneously introduced by students, it is possible to work on the organisation of students' enumerations and, thus, support the clarification of the numbers that are subsequently involved in combinatorial formulas and arithmetic rules. Such a process would represent a shift in the exploration of dimensions of combinatorial thinking (Lockwood, 2013) passing from the dimension of the set outcomes to the one of counting (and also Formulas/Numerical expressions) without creating a discontinuity in the heuristics that students develop. Similarly, stressing the relevance of the odometer approach, it is possible to provide the students with an approach that would allow them to systematically (and recursively) reason on the configurations to be formed, training a skill that it is not relevant for the sole combinatorics but also for other disciplines (e.g., computer science – Batanero et al., 1994).

This study explores the effect of a growth mindset intervention on pre-service primary teachers' attitudes toward statistics. Of the 315 participants, the 190 experimental group students received a five-week growth mindset intervention. The SATS-36 and the Implicit Theories of Intelligence Scale were administered before and after the intervention to experimental and control groups. An open-response task and focus group interviews were conducted with students from both groups after the intervention. Preliminary qualitative findings suggest that these growth mindset interventions played an important role in improving students' attitudes towards statistics and that students' overall views of growth mindset interventions are positive.

Keywords: Statistics education, growth mindset, teacher education, attitudes towards statistics, SATS

Introduction

Statistical literacy is a critical skill for citizens in making sense of the world. As statistics is often introduced in primary school mathematics, it is essential in initial teacher education (ITE) programmes. Developing positive attitudes toward statistics in ITE is a critical consideration due to the established link between attitudes and subsequent achievement in statistics courses (Chiesi & Primi, 2010). More importantly, negative attitudes may hinder future teachers' ability to teach statistics effectively, perpetuating misunderstandings or leading to its avoidance in their classrooms (Leavy et al., 2021). While research suggests that pre-service teachers (PSTs) generally hold positive attitudes toward statistics, there is concern relating to the widespread perceptions by PSTs of statistics being difficult (Zientek et al., 2011). Evidence suggests, however, that their attitudes towards mathematics and statistics are malleable, with improvements being observed arising from a range of interventions in initial teacher education contexts (Leavy et al., 2021).

Growth mindset (GM) interventions—the belief that abilities can be developed through effort (Dweck, 1999)—have shown promise in improving attitudes towards mathematics. Applying this framework to statistics education could foster positive attitudes in pre-service teachers. Compared to research on K-12 and college students, research on the impact of GM interventions in pre-service teacher education remains underexplored, leaving a gap in understanding how these interventions might benefit future educators. This study aims to fill this gap by investigating the effectiveness of a GM intervention in improving pre-service teachers' attitudes toward statistics.

Review of Literature

Undergraduate students' attitudes towards statistics, especially those of PSTs, are critical, as they can significantly influence their engagement and achievement (Chiesi & Primi, 2010). Not only are such positive attitudes linked to higher motivation, better understanding, and greater persistence in overcoming challenges, but negative attitudes can lead to avoidance behaviours and poor academic outcomes. The Survey of Attitudes Toward Statistics (SATS-36) (Schau et al., 1992, 2003) is the most widely used instrument to measure attitudes. Confirmatory factor analysis has validated its six-factor structure consisting of *Affect* (feelings concerning statistics), *Cognitive Competence* (attitudes about one's intellectual knowledge and skills when applied to statistics), *Value* (attitudes about the usefulness, relevance, and worth of statistics), *Difficulty* (attitudes about the difficulty of statistics as a subject), *Interest* (level of interest in statistics), and *Effort* (amount of work a student expends to learn statistics). Targeted interventions can improve attitudes. Course design and delivery, active learning strategies, such as collaborative projects and real-world data analysis, have proven beneficial. Interest is growing in GM interventions' impact on attitudes. While an initial study by Zonnefeld (2015) found no significant overall effect, positive shifts in how female students value statistics, compared to their male peers, were observed.

The concept of growth mindset, introduced by Dweck (1999), identifies two belief systems that individuals hold regarding their abilities: fixed or growth mindset. A fixed mindset views intelligence and abilities as static traits, leading to challenge avoidance and feeling threatened by others' success. In contrast, a growth mindset believes abilities and intelligence can be developed through effort and feedback. Mindset is measured using the *Implicit Theories of Intelligence Scale* (ITIS, Dweck, 1999). Compared with growth mindset, a fixed mindset predicts lower achievement among students facing academic challenges (Blackwell et al., 2007). Associations between growth mindset and achievement have been found in meta-analyses (Burnette et al., 2013) and studies of 74 developed nations (OECD, 2019, N=555,458).

GM interventions aim to shift beliefs from a fixed to a growth mindset. Interventions vary in duration and intensity, from single-session workshops to online modules and multi-week programs. Studies show even short interventions can impact learning. For example, over 250,000 students on Khan Academy, who received growth mindset affirmations (e.g. "If you make a mistake, it's an opportunity to get smarter!") solved mathematical problems, with effects lasting months (Yeager et al., 2013). Interventions emphasise developing ability over time through effort (Dweck, 1999), the brain's capacity to develop new neural networks when it learns (Yeager et al., 2016) and reflecting on learning processes rather than solely on outcomes and overcoming obstacles (Yeager & Dweck, 2012). Adolescents in GM interventions demonstrated increased willingness to take on challenges in mathematics (Rege et al., 2020, n=21,000) and improved mathematics grades over a two-year period (Blackwell et al., 2007, n=373). A review of 15 studies found that GM positively affected academic achievement for postsecondary students but no discernible effects on college enrollment (IES, 2022). Other studies of postsecondary students reported increased engagement and achievement (Aronson et al., 2002) and improved attitudes toward statistics among female students (Zonnefeld, 2015).

Debate surrounds GM interventions, with some researchers citing weak evidence and low effect sizes (Sisk et al., 2018). In their review, Yaeger and Dweck (2020) stress the importance of well-designed interventions that emphasise developing abilities through concrete actions, convey neuroplasticity with memorable metaphors, present stories of notable figures using growth mindset and encourage active engagement (Yeager & Dweck, 2012; Yeager et al., 2016).

Methods

Sample and course content: Participants were 476 Irish pre-service primary teachers in the first year of a 4-year Bachelor of Education (BEd) programme. They ranked in the top 15% of Irish college entrants as measured by the national standardised college entrance exams and had studied statistics as a compulsory component of both national primary and secondary curriculum. All were registered in a compulsory mathematics education module, provided with study details and signed consent forms during the first lecture. Each student generated a unique project ID to ensure anonymity. The study took place during the first 5 weeks of a 12-week semester, focusing on statistics, with 2 weekly lectures (Table 1). Statistical content covered big statistical ideas: differences between statistics and mathematics, samples predicting populations, data types (categorical or numerical), distributions describing data, statistics summarising distributions, and comparing group distributions.

Randomisation: At college registration, all BEd students were divided into 7 sections alphabetically by last name and randomly assigned to control or experimental group.

Pretest and posttest: A QR code linked to online versions of the SATS-36 (Schau et al., 1992) and Implicit Theories of Intelligence Scale (ITIS, 8 items) (Dweck, 1999) (Table 1). At posttest, they completed the "Esma Scenario": *Imagine Esma, a 10-year-old child in your class, isn't doing well in the data strand of maths. Esma doesn't want to do homework or ask for help because she doesn't think she is smart enough. She doesn't think anything she'll do will help her better understand data. Type what you would say to Esma explaining how her mindset can prevent her from getting smarter. You can use something you have read or use an example from your own life.*

Intervention: The intervention was guided by a review of mindset literature and guidelines from Yaeger and Dweck (2020). Seven *mindset affirmations* were selected and adapted for statistics (e.g. 'The harder I work [at statistics], the better I get!). *Celebrity testimonials* were collected, and a matching exercise paired each testimonial with an affirmation. Table 1 outlines the intervention schedule for control and experimental groups. The lecturer refrained from commenting on any intervention material or slides.

Statistical Analysis: R, Jamovi and SPSS were used to clean and preprocess the dataset for descriptive and inferential analyses. Qualitative data were analysed with QualCoder. Two independent coders initially coded the focus group interviews and Esma task using 47 codes and 18 codes, respectively, ensuring accuracy and consistency. After reaching 95% consistency, discrepancies were resolved, and the second coder completed the remaining data. This dual-coding method enhanced the reliability of the thematic analysis.

Table 1: Study design for control and experimental groups

Lecture 1	ALL received information and consent forms, SATS-36 and Implicit Theories of Intelligence Scale	
	CONTROL GROUP	EXPERIMENTAL GROUP
Lecture 2	Watched a video on the new Irish Primary Maths curriculum and completed a short reflection on the video content	Read "Growing the Brain" describing adult brain elasticity. Three summary points on the reading were provided. They responded to the prompt: *Think about an example from your own life. What is something you weren't good at at first? Then, you practiced it using a good strategy and became really good at it. For the next 2-3 minutes, write about it and explain how you became good at it.*
Lectures 3-9	Statistics content and pedagogy of teaching statistics Generic reflection at the end of the lecture	Mindset affirmation presented on the first slide GM affirmation appeared at the bottom of each slide containing statistics content and pedagogy of teaching statistics Affirmation slide was re-displayed & celebrity testimonial presented The final slide presented the affirmation and testimonial together and asked students to reflect.
Lecture 10	ALL received SATS-36, Implicit Theories of Intelligence Scale and the Esma scenario assignment	
Lecture 24	Focus group interviews with control group and experimental group	

Findings

Of the 476 participants, 351 (278 females, 69 males) had matched pre-test and post-test data. Seven sections were used: 3 control (n=139) and 4 experimental (n=206). The control group showed positive pre- and post-test scores on Affect, Cognitive Competence, Interest and Effort, and neutral scores on Difficulty, with ITIS scores indicating beliefs that intelligence can improve. In the experimental group, pre-test mean scores for Affect and Difficulty were neutral, while Cognitive Competence, Value, Interest, and Effort were positive. Post-test scores for Difficulty remained neutral and Affect, Cognitive Competence, Value, Interest, Effort were positive. ITIS scores in the experimental group indicated views that intelligence can change at both pre-test and post-test (Table 2).

Multiple linear regression examined homogeneity across gender, section, and pre-achievement groups. Pre-ITIS scores were the outcome variable, with gender, class section, and pre-achievement as independent variables. None of the independent variables significantly predicted pre-ITIS scores. The data were examined by instructor type. Some sections were taught exclusively by one instructor (n=215) whereas two instructors shared teaching on the remaining sections (n=121). Hierarchical multiple regression was conducted to examine the effect of the GM intervention on change-SATS component scores and GM change scores. Pre-SATS scores were entered in Step 1, pre-achievement

and gender entered in Step 2, and group (treatment) entered in Step 3. Our results showed that the GM intervention was statistically significant in predicting the change scores of the Affect ($t(210)=2.943$, $p<.05$, uniquely explaining 3.24% of the variance) and Cognitive Competence ($t(210)=2.58$, $p<.05$, uniquely explaining 2.46% of the variance) components for the sections taught by one-instructor only, after controlling for pre-SATS scores, pre-achievement and gender.

Table 2: Descriptive statistics

		Pre-tests							Post-test						
		Aff	CC	Value	Diff	Int	Eff	ITIS	Aff	CC	Value	Diff	Int	Eff	ITIS
M	Control	4.75	5.07	5.15	4.09	4.93	6.22	4.32	4.89	5.20	5.19	4.23	4.77	5.51	4.36
	Exp	4.37	4.67	5.05	3.73	4.62	6.26	4.32	4.90	5.17	5.20	4.14	4.64	5.71	4.49
SD	Control	1.02	.97	1.05	0.75	1.25	1.45	.78	1.24	1.21	1.09	.80	1.24	1.39	.82
	Exp	1.08	1.10	1.04	0.75	1.29	1.34	.80	1.15	1.10	1.04	.81	1.28	1.27	.78

Analysis of focus group interviews revealed that both experimental (EG) and control (CG) groups reported positive improvements in attitudes towards statistics and the teaching of statistics. Neither group reported negative changes. The EG found affirmations helpful at the beginning of the lecture, but not at the end, when students were tired and eager to leave. They found the reading exercise interesting, stating that it helped them to begin thinking of the brain as a muscle. They reported that the Esma scenario was not only helpful for teaching statistics but for being a teacher in any subject; it made them think about how they would act as a teacher as it put them in the context of the classroom. Some of them also thought they were making these suggestions for themselves (Table 3).

Table 3. (Selected) focus group interviews code frequencies from control and experimental groups

	Code Tree	CG	EG	Example quotations
change in attitudes toward statistics	got more positive	8	8	I think it's better now. Because like, understand this greater meaning behind it, rather than just looking at definitions and learning them off, so things have improved for me (E)
	stayed same	1	2	I was fairly confident anyway. It stayed the same for me (C)
change in attitudes toward teaching statistics	positive improvement	5	5	I say I'd be more confident than I would have been. (C)
	stayed same	0	1	… I don't think my interest in it has changed. ..so not more interested but more confident. (E)
	affirmations helpful	NA	5	I thought they were awesome. Honestlytt (E)

interventions	affirmations not helpful in general	NA	4	I kind of just forgot about it and didn't really read anything after (E)
	beginning affirmations helpful	NA	3	…I agree that they were good at the start of the lecture like to kind of let us know what we were going into (E)
	ending affirmations not helpful	NA	3	…but then at the end of the lecture, like everyone's just tired and we want to go home (E)
	reading exercise was helpful	NA	9	…I thought it was interesting like it did strike me the way it is like muscle that you learn. You can grow. You're not just born with a certain IQ or Yeah (E)
	story about Esma was helpful	NA	5	… scenarios like that are good for us to be learning now and coming up with answers for now. So when we got placement, we will have answers. (E)

NA: not applicable; EG: experimental group; CG: control group

When examining the Esma scenario, both experimental and control groups identified similar sources of success: positive effort beliefs, value of asking for help, changing their fixed mindset, improving their resilience and persistence, and changing their study strategies. Both groups had similar response rates to the view that intelligence can be developed. Experimental groups students were more likely to report that failure should be seen as an opportunity to learn. Both groups emphasised that positive attitude change will help students to succeed. The most frequently mentioned SATS attitude component was Cognitive Competence, with students suggesting that if Esma believed she could do statistics, she would do better in statistics. Control group provided more teacher-centred solutions (providing extra lessons, visuals, step-by-step instructions) whereas experimental group had more student-centred solutions such as exploring a different learning strategy (see Table 4).

Table 4: (Selected) Assignment code frequencies from control and experimental group

	Codes	C	E	Example Quotations
Growth Mindset	Positive effort beliefs	63	105	Explain to Esma that she can get better at maths with continued practice (E)
	Value of asking for help	56	84	I would suggest her to tell someone and let them know she is struggling so they can help her out (E)
	Changing mindset	29	41	… Our mindsets play a huge role .. we need to try to keep them positive (C)
	Resilience & persistence	25	31	… when I was young I used to really struggle at statistics but through shear hard work and determination I got better. U can do this never give up (C)

	Strategy change	14	26	… it seems difficult at first but you just have to adapt your way of thinking and look from a different perspective (E)
	Failure as a motivator	9	23	… it's okay if you make mistakes at the start, you can learn from your mistakes. Always remember it's okay to make mistakes (E)
Attitudes	Cognitive Competence	56	34	I would tell Esma to have more confidence ....believe that she can do it, even when it seems challenging. Believing in yourself is half the battle (E)
	Difficulty	10	3	Do easier data tasks until she can feel confident with them and then work on harder data tasks after with Esma (C)

Conclusions

The GM intervention significantly influenced students' intelligence beliefs and attitudes toward statistics. Qualitative data analysis supported the effectiveness of low-intensity growth mindset interventions (Yeager et al., 2013), in this case, requiring less than 30 mins. Findings aligned with Yeager and Dweck's (2020) recommendations, providing evidence for the value of using metaphors to effectively communicate concepts related to neuroplasticity. The Esma scenario problem revealed that the experimental group made more growth mindset trait-related suggestions, whereas the control group made more teacher-centred suggestions unrelated to growth mindset theory. The study provided insights into experiences with the intervention components, for example, focus group interviews revealed that students preferred to see GM affirmations at the beginning rather than at the end of lectures. In addition, they found the Esma scenario useful because it prompted them to think about how they would behave as teachers in the future. While we cannot discount extraneous influences on study results, the study design ensured a balance across instructors, with each teaching both control and experimental groups, thereby minimizing the potential influence of individual teaching styles on the results. Further studies could investigate the timing and delivery of GM affirmations most especially in relation to student engagement. Building on the findings that the Esma scenario encouraged future-oriented thinking, subsequent studies could assess the long-term effects of scenario-based growth mindset interventions on preservice teachers' classroom practices.

Bringing math into politics: the Decision Theatre Lab and the influence of model knowledge on the interpretation of stochastic simulation results

Christoph Lieben[1] and Sinah Gürtler[2]

[1]Humboldt University of Berlin, Germany; c.lieben@hu-berlin.de

[2]Free University of Berlin, Germany

Results of stochastic models in public media are often misunderstood, not least because the uncertainties of stochastic modelling are not sufficiently considered in classical mathematics teaching. This paper first presents a learning environment that confronts students with different forms of mathematical uncertainty: the Decision Theatre Lab. In it, students mathematically explore a professional epidemic model and use its stochastic results for political decision-making. We then present an experimental study that we conducted using this format to investigate how specific model knowledge influences the interpretation of simulation results. The results show that students with specific model knowledge are significantly better at accurately interpreting the stochastic variations in the simulation results than students who had to interpret the results without prior knowledge of the underlying model. The latter, on the other hand, rely more often on contextual knowledge to interpret the model results.

Keywords: Model knowledge, mathematical literacy, stochastic modelling, model uncertainty

Introduction: Mathematics education in the era of vague news

Public media regularly report on the results of scientific modelling, in particular stochastic modelling of climate change. Statements such as "Climate change made US and Mexico heatwave 35 times more likely" (Brosnan, 2024) are prone to misinterpretation, driven by a lack of statistical knowledge and misconceptions about mathematical models. The fact that the underlying models are often inaccessible to readers does not help at all.

Gal and Geiger (2022) have provided a detailed taxonomy of the *Statistical and Mathematical Products* (StaMPs) appearing in public media in the context of the COVID-19 pandemic. They conclude that the interpretation of these StaMPs requires not only an academic understanding of probability but also a literate handling of more subtle and unquantifiable forms of uncertainty that arise, for example, in the case of inadequate data or when making modelling assumptions. They diagnose the need for learning environments that consider these forms of uncertainty.

Against this background, we will first introduce the *Decision Theatre Lab*: a science communication format that enables students to use a scientific epidemic model to make political decisions in a fictitious but reality-based setting. We describe the structure of a Decision Theatre Lab, analyse which forms of uncertainty are inherent in the occurring StaMPs and which aspects of mathematical literacy are important for their interpretation. We then present a case study that used the Decision Theatre Lab framework to investigate how specific knowledge of the model influences students' interpretation of its stochastic results.

Exposing students to uncertainty – a Decision Theatre Lab on infection control

A Decision Theatre Lab – literally and practically – consists of two components: a *Decision Theatre* and a *School Lab*. A Decision Theatre is an IT-supported science communication format in which participants can simulate joint decision-making on various socially relevant topics, guided by the interaction with a scientific model and its simulation results. Decision Theatres have been developed on a variety of topics, from forest planning (Boukherroub et al., 2018) to mobility transition (Wolf et al., 2023) – or infection control (Wiebe et al., 2024), which students attended at Zuse Institute Berlin as seen in Figure 1 and which provides the framework for the study presented here.

In this Decision Theatre, participants take on the role of politicians who must decide on non-pharmaceutical infection control measures at the beginning of a fictitious epidemic. They can draw on the results of GERDA, a GEoReferenced Demographic Agent-based model for the spreading of COVID-19 (Goldenbogen et al., 2022). GERDA simulates the location, the infection probability and the health status of about 12,000 residents of a small town and provides SIRD trajectories for different scenarios. Due to the stochastic modelling, the simulations can differ significantly from each other, even with the same initial conditions. Therefore, the model simulates each scenario almost 100 times and displays the results as a set of curves for the number of susceptible, infected, recovered and deceased. The results should be interpreted as probability distributions that show different degrees of statistical dispersion depending on the scenario. The simulation results depicted in Figure 2, for example, show that dispersion increases the later a potentially imposed lockdown comes into force. This indicates that the prediction accuracy of the model decreases with a later lockdown. Phenomena like these typically emerge in stochastic models (Goldenbogen et al., 2022).

Figure 1: Students in a Decision Theatre

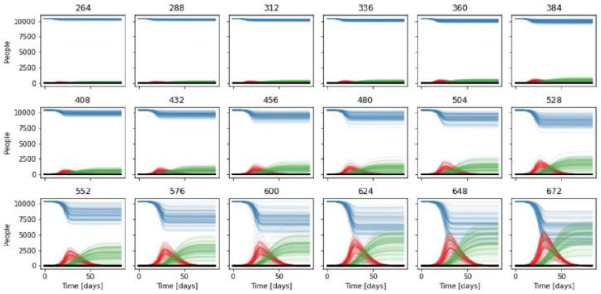

Figure 2: GERDA results for different start times (above graphs in h) of a lockdown

To support their political decision-making, students can simulate three scenarios with different political measures. In the further course of the Decision Theatre, they also reflect on the role of the model for the discussion and evaluate the informative value of the simulation results.

It is important to note that although the participants in a Decision Theatre interact with a mathematical model, this model itself remains a black box for the most part. To put the format in the context of mathematics education, we have therefore developed an optional School Lab that teaches students the mathematical background and the internal structure of GERDA, with a particular focus on the implemented probabilistic concepts: The students derive the probability function for the transmission

of the virus and use it to calculate transmission probabilities in various scenarios. They also use school knowledge of conditional probabilities to determine the probabilities of change in the health status of different people. These calculations, however, are all done once and with pen and paper. It is only after the School Lab in the Decision Theatre that students are confronted with the phenomenon of multimodal distributions resulting from repeated simulations.

The role of model knowledge in the interpretation of stochastic simulation results

The students' use of GERDA exemplifies that the interpretation of Statistical and Mathematical Products (StaMPs) produced by stochastic models is characterised by two types of uncertainty:

- First, uncertainty arises from stochastic modelling itself, particularly from the probability functions and distributions; we refer to this simply as probability. Probability is quantifiable, and its occurrence in the model is intended. It is a basic concept of statistical education, and dealing with it is included in any description of statistical literacy, for example in the influential one by Gal (2002). The correct description and interpretation of GERDAs results, for example, requires basic ideas about the dispersion of probability distributions.
- Secondly, uncertainty is inherent in any form of mathematical modelling. It arises from the fact that models are abstractions, characterised by simplifications and based on certain assumptions. Model uncertainty is a collective term for all reasons that lead to unintended differences between the model and reality and is often difficult to quantify (Thompson & Smith, 2019). An awareness of model uncertainty is therefore an implicit prerequisite for a comprehensive modelling competence, which also includes the evaluation of the validity and scope of given modes, as described by (Niss & Højgaard, 2019), for example. Research conducted during earlier iterations of the Decision Theatre Lab has shown that students tend to explain deviations between model forecasts and actual developments with contextual knowledge rather than with model uncertainty, indicating a low level of awareness of model uncertainty (Lieben, 2023).

Now, one can assume that students depend on appropriate statistical content knowledge and sufficiently developed model competence to accurately interpret such StaMPs – in addition to some general mathematical competencies such as understanding graphs and a positive mathematical identity, as Heyd-Metzuyanim et al. (2021) note. However, the observation of some unsuccessful StaMP interpretations in Decision Theatres without the prior School Lab led us to assume that this framework, as shown in Figure 3, can be extended to include another construct: the specific model knowledge that is acquired in the School Lab.

But since a subject's prerequisites for interpreting (COVID-19-related) StaMPs in the media are usually formulated in terms of statistical literacy and modelling skills – e.g. by Gal and Geiger (2022) or Heyd-Metzuyanim et al. (2021), the influence of specific model knowledge on the interpretation of the model results has so far been underexposed. We, therefore, used the Decision Theatre Lab on infection control to conduct a case study approaching the question: *How does specific knowledge of a model influence the interpretation of its results?*

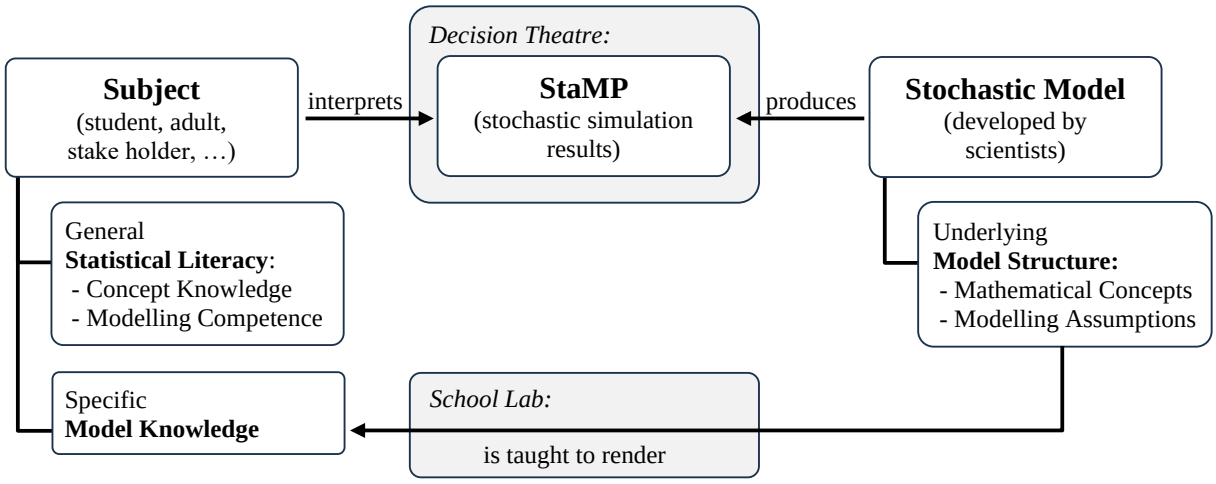

Figure 3: Conceptual framework of a StaMP interpretation in the context of a Decision Theatre Lab

Studying the influence of model knowledge – research design and implementation

To determine the influence of the specific model knowledge acquired in the School Lab on the interpretation of the StaMPs in the Decision Theatre, we conducted an experimental study with the School Lab as an intervention. We defined two groups of students: The experimental group, who first visited the School Lab and then the Decision Theatre, and the control group, who first visited the Decision Theatre and only after that visited the School Lab.

To collect data on how the students processed the stochastic model results in the Decision Theatre, we used the participant observer method according to Weischer and Gehrau (2017) while the students were working on a collaborative group task. For this task, each group received the results shown in Figure 2 from simulation runs with different start times of a lockdown and was asked to interpret the data by completing the sentence “The later the start time of the lockdown, the...”. We recorded the group's communication with microphones and analysed the audio transcripts using quantitative and qualitative methods for comparing the experimental group and control group.

Between June 2023 and April 2024, a total of $N = 89$ students from the 10th grade onwards participated in the study. The students were between 14 and 20 years old, and the average grade was 2.31 (on the German grading scale from 1 to 6, where lower grades are better). Of the students, 70 first attended the School Lab and then the Decision Theatre and were thus assigned to the experimental group. The control group, which first attended the Decision Theatre and then the School Lab, comprised 19 students. We randomly assigned working groups. A total of 24 groups were analysed, with 19 assigned to the experimental group and five to the control group.

The data was analysed using a mixed-methods approach, which enables both explorative and comprehensive as well as multi-layered perspectives on the research topic (Kelle, 2019). The material for the analysis consisted of transcripts of the audio recordings and observation protocols. We processed this data according to Mayring's content analysis (Mayring & Fenzl, 2019).

First, we categorised the material inductively, with a particular focus on statements that allowed conclusions to be drawn about the students' statistical concept knowledge and awareness of model uncertainty. To code the data, we used MAXQDA (VERBI Software, 2023). The obtained codes were quantitatively evaluated to carry out a correlation analysis. We calculated the mean values in each category for the experimental and the control group and tested for significance using Student's *t*-test. In the next step, we evaluated the transcripts qualitatively using the categories specified in Table 1.

Table 1: Coding manual for the audio-transcribed student interactions

	Code	Definition	Example
Statistical Concept Knowledge	Description of dispersion	Statements that verbalise the dispersion of the graphs	*"The more people get infected, the greater the dispersion."*
	Correct interpretation as probability distribution	Statements in which the dispersion of the curves is interpreted as a probability distribution	*"The later the lockdown, the more difficult it is to predict precisely."*
	Deterministic Misconception	Statements that provide incorrect non-stochastic interpretations of the results	*"The later the lockdown starts, the more infections there will be."*
Awareness of Model Uncertainty	Contextual Knowledge	Statements based on contextual knowledge that is related to the model results	*"If no one is sick anymore due to the lockdown, then no one can get infected. So, the earlier the lockdown starts, the better."*

Results

The quantitative analysis revealed two (virtually) significant correlations for the inductively selected categories: In the domain of statistical concept knowledge, 50% of the students in the experimental group correctly described or interpreted the model results. This is significantly more than in the control group, in which only 20% answered correctly ($p = .0358$). In the domain of awareness of model uncertainty, the number of context references per minute and person was lower in the intervention group (0.13) than in the control group (0.24) ($p = .0528$). We then proceeded with a qualitative analysis of the answers. We closely examined how the tasks were solved, what led to correct understanding, and what characterised the misconceptions. To illustrate this analysis, we present two exemplary cases below, which show both a typical path to correct interpretation and a widespread misconception in detail.

The following example from the control group illustrates a common statistical misconception, that is then made plausible by contextual knowledge.

Olivia: The later the lockdown starts, the faster the infection rate increases, perhaps?
[…]
Olivia: Because here it has a higher increase…
[…]
John: Yes, but why? Because it's winter?

At the beginning of the conversation, Olivia constructs a deterministic relationship between the start time of the lockdown and the number of infected people. John then tries to explain the model behaviour with real-world contextual knowledge by asking: “But why, because it is winter?”. This statement illustrates a cognitive escape from the actual mathematical task. The real-world reference not only serves the students to validate the graphs, but the students also consider it necessary to interpret the model results.

In contrast, the example from the experimental group shows a typical dynamic within a conversation in which the students move from the same type of misconception to a correct interpretation.

James: The later the time of the lockdown, the greater the number of infected persons.
Emily: The higher the peak of infected people.
[…]
James: The more infected there are.
[…]
Emily: But look. It's also getting thicker. So, the individual lines here no longer agree about what's happening.
[…]
William: Yes, that's just a probability.
[…]
William: So, the later, um, a lock-. The later-.
Emily: The more difficult it is to predict what will happen.

James initially postulates a causal relationship between the lockdown's start time and the number of infected persons. Emily expands on this assumption by referring to the peak of the infection curve. However, both statements are incorrect as they imply a deterministic relationship and disregard the stochastic nature of the underlying model.

A correction process begins as Emily notices that “the lines are becoming thicker”, indicating the dispersion of the curves. This observation marks the start of questioning the deterministic understanding and leads to a reconsideration of the previously assumed cause-and-effect relationship. As the discussion progresses, the participants become more aware of the probabilistic nature of the model. This awareness is reflected in the statement “that's just a probability”, which explicitly acknowledges the connection between the dispersion of the curves and the induced probability distribution. The introduction of the term “probability” then enables the group to move on from the mere description of the dispersion to its correct interpretation. They discern that stochastic models do not provide fixed predictions but rather depict a range of possible scenarios with different probabilities.

Discussion: How could model knowledge affect StaMP interpretation?

The quantitative observation that students in the experimental group interpreted the StaMPs in the Decision Theatre correctly more often could be related to the fact that model knowledge interferes with both the domain of statistical literacy and the domain of mathematical modelling competence.

On the one hand, the use of stochastic concepts and terms for reproducing the model components in the School Lab seems to motivate some students in the experimental group to use the same concepts and terms to interpret the dispersed graphs in the Decision Theatre – which in this case leads them to correct conclusions. Knowledge of the model thus leads to a better understanding of the model results, since the concepts used to describe the model reappear in the interpretation of its results. On the other hand, as students in the School Lab reproduce the structure of the model, they have to follow some of the underlying modelling assumptions. This may contribute to an increased awareness of model uncertainty. The alternation between reality and the mathematical model during the reconstruction process – which is typical for stochastic modelling (Kelter et al., 2023) – could help students to distinguish more precisely between these two worlds. Thus, they are significantly less tempted to use extra-mathematical contextual knowledge from reality to explain mathematical results.

It is not clearly assessable, however, whether the model knowledge has really improved the interpretation of the simulation results in a direct way or whether the *teaching* of this knowledge in the School Lab has rather led to a promotion of statistical literacy and development of modelling competence, which in turn has led to an improved interpretation. Finally, it should be stated that many modern computer models are obviously mathematically too complex to be reconstructed in a School Lab. The promotion of model-independent statistical literacy and modelling skills therefore remains indispensable.

Problem solving and argumentation in probability context: analysis of some examples of necessary object-level narratives

Francesca Martignone[1], Daniele De Giorgi[1] and Marta Saccoletto[1]

[1]Università del Piemonte Orientale, Italy; francesca.martignone@uniupo.it

The introduction to probabilistic thinking in primary and middle school is one of the goals delineated by the Italian National Curriculum Guidelines and is part of the curricula of other countries. The paper presents activities carried out in Italian classes from grades 3 to 8 in which the introduction to probabilistic thinking is structured through problem solving and argumentation activities. The mathematical claims developed by the students were examined through a qualitative analysis, identifying the necessary object-level narratives and their substantiation. The analysis also considers the role of specific visual mediators in students' justifications when solving probability problems.

Keywords: Probability, primary and middle school, necessary object-level narratives, problem solving, argumentations.

Introduction

In Italy, the National Guidelines, in line with the literature, emphasise the importance in mathematical practice of solving problems, explaining the procedure followed, recognising strategies other than one's own and comparing procedures. This applies to all content areas of mathematics. This paper focus on probability problems. Probabilistic thinking is promoted in the Italian National Guidelines from primary school onwards. Uncertainty permeates many aspects of human life, understanding and managing this uncertainty is hence essential for informed decision-making. It is therefore crucial that students understand probability to make informed decisions when faced with uncertainty (Devlin, 2014; Muñiz-Rodríguez et al., 2020). Research highlights the need to pay more attention to teaching-learning processes related to probability, developing both theoretical and empirical aspects (Batanero, 2020). There are recent studies on the development of argumentative processes and communication in probability contexts in high school (Saccoletto, 2023). Our action-research group, composed of didacticians and teachers, aimed to address this perspective from primary school onwards. Our teaching goals are not only enabling students to acquire knowledge and skills related to specific mathematics contents, but also to promote the development of argumentative processes and communication. To analyse the data collected in our classes, we recognised the need for interpretative lenses to identify and characterize mathematical claims produced by the students. We found that the framework proposed by Valenta et al. (2024) provided tools that met this need. Their study is based on commognition which has close affinities with the approaches adopted by our action-research group. Specifically, we have as common roots the Vygotskian perspective on the social construction of knowledge and the value of communication in mathematics. Our study highlights how the categories identified by Valenta and colleagues can be further characterised by considering the visual mediators proposed by teachers in teaching probability to represent events and evaluate situations of uncertainty. In this paper, we show some tasks developed to introduce probabilistic thinking in the

first cycle of education in Italy. In our work, we will analyse some examples of students' narratives using the interpretative lenses proposed by Valenta et al. (2024) within the field of probability, which we will show as a suitable context for applying these lenses.

Theoretical framework

Research on learning mathematics through communication has been ongoing for several decades. Sfard and colleagues (Sfard et al., 1998) have. addressed this topic since the 1990s. In Sfard's theory of commognition (Sfard, 2008), the study of mathematics learning goes through the exploration and analysis of processes of discourse development. She identifies four aspects of mathematical discourse: word use, visual mediators, routines, and narratives. Of particular interest in this paper are *narratives*, which are utterances (both spoken and written) that describe objects, the relationships between objects, or activities involving or performed by objects. Definitions and theorems are examples of narratives. In the commognitive frame, Jeannotte and Kieran (2017) describe mathematical reasoning (MR) processes as "processes that derive narratives about objects or relations by exploring the relations between objects" (ibidem, p. 9). In this perspective, Valenta and colleagues (Valenta et al., 2024) introduced a framework to analyse opportunities for mathematical reasoning. In their work they investigate the processes of *construction* (which results in new narratives) and *substantiation* (which is related to the endorsement of already constructed narratives) of specific narratives, which they call Necessary Object-Level narratives (NOLs).

> Based on Hewitt, we distinguish between arbitrary object-level narratives (AOLs) and necessary object-level narratives (NOL). AOLs are substantiated by reasonableness (e.g., Kontorovich & Zazkis, 2017), aiming to ease communication or as products of historical development. In contrast, NOLs can be substantiated by proving, following deductive chains of object-level claims. Therefore, NOLs, along with their construction and substantiation, are relevant for investigating opportunities for MR. (Valenta et al., 2024, p. 94)

In their paper Valenta and colleagues analyse discussions among teachers and students in different classroom situations also by talking about written productions. They investigate MR not only in situations in which MR-processes are more easily promoted (such as small-group problem solving), but in all kinds of different situations, such as the introduction of a definition. Table 1 summarises codes and descriptions proposed by Valenta et al. (2024).

Table 1: Classification and description of NOLs construction and substantiation

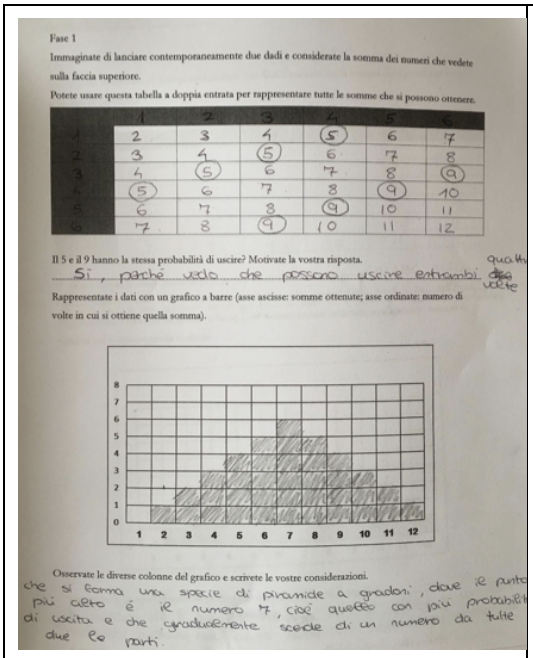
Construction		*Substantiation*	
Code	**Description**	**Code**	**Description**
unclears	The teacher or the students present an NOL, but the construction process is unclear	no protest	NOL is substantiated due to no protest from either the teacher or the students
NOL presented as a rule/fact	NOL is presented as given and true	short confirmation	NOL is substantiated by a short confirmation of validity (given by the teacher or the students)

NOL presented as a claim	NOL is presented as a claim to be further examined or validated	implicit, by construction	Accepting the validity of the NOL through construction (e.g., by using procedures, properties, or a mixture)
using procedure	NOL is constructed by performing some more or less known actions/ procedures	explicit, using procedures	Presenting the procedure as an answer to the question, "Why is this true?"
using a mixture of procedures and properties	NOL is constructed by a mixture of procedures and properties and relations	explicit, mixture of procedures and properties	Using a mixture of procedure and properties to answer the question, "Why is this true?
using properties and relations	NOL is constructed by using properties and relations (e.g., referring to a definition, comparing, classifying, identifying a pattern, generalizing)	explicit, using properties and relations - valid - not valid	Using properties and relations to answer the question, "Why is this true?"

Constructing, substantiating, and recalling narratives are core routines of mathematical discourse. NOLs can be identified in argumentative practice. Argumentations can serve an explanatory function: the aims are to explain to the teacher or to peers and to build knowledge together (Ferrari & Saccoletto, 2023). As the literature highlights, interactive argumentative processes can support collective learning in mathematics, prompting students to participate in students' exchange, to understand and to anticipate others' perspectives, to refine justifications and motivations, and to connect and evaluate different perspectives (e.g. Asterhan & Schwarz, 2016; Cobb et al., 2001; Krummheuer, 2000). In our study we are interested in identifying NOLs and analysing their construction and substantiation in argumentative processes, i.e. when the students have to communicate both writing and orally problem solving strategies and their motivation to their peers. We stress that we consider written productions as part of the argumentative processes, as they are collectively discussed. In addition, it is important to note that narratives developed during argumentative processes are shaped by the topics under discussion. Our research focuses on argumentation in probability problem solving. Students construct and develop narratives and use visual mediators, which we included in the analysis. The study presented in this paper is guided by the following research questions: How can the study of NOLs be used in the analysis of arguments and argumentative processes in the context of probability? What NOLs can we identify in the argumentations of primary and middle school students in the context of probability problem solving?

The study

The educational activities we present in this paper were carried out in the school year 2022/23 in an Italian Institute, which includes primary school, grades 1-5, and middle school, grades 6-8. We work vertically from primary school to middle school, aligning with the Italian National Guidelines. Approximately three hundred students participated in the study. They were involved in our project because the teachers (five primary school teachers and eight middle school teachers) are part of our research group. Teachers and researchers collaborated in designing the educational activities. Our educational goals were: Acquisition of basic knowledge on probability (classical approach - a priori); Enhanced communication and argumentative skills. The focus was on problematising the experience of rolling dice and the production of arguments (oral and written) within a workshop setting, enabling



students the opportunity to engage in reasoning and discussions on probability problems. The problems are usually addressed in the teaching of probability and associated with the birth of classical probability. The history of mathematics can be a useful resource for understanding and providing information on the development of mathematical thinking (Radford et al., 2002), helping to predict students' "misconceptions" (Sfard, 2008). The educational activities, starting from the analysis of the outcomes of the throwing of two dice, lead to the solution of the famous problem proposed to Galileo Galilei by Florentine gamblers related to a game of dice known as *zara*. In his work "Sopra le scoperte de i dadi [On the discoveries related to dice]" (ca. 1620/1898), Galilei lists all possible outcomes of rolling three dice and calculates the probability that the sum of the three outcomes equals 9 or 10. A significant point of discussion is the importance of considering the order of outcomes. Although both sums of 9 and 10 are obtained from the same number of combinations, they have different numbers of partial permutations. Specifically, the sum of 10 can be obtained in 27 partial permutations, while the sum of 9 can be obtained in 25. According to classical probability, therefore, 10 has a higher probability of occurring than 9 (27/216 versus 25/216).

In the first phase of our teaching experiment the students worked individually or in small groups to solve problems, write the solution and justify it. Primary and middle-school students faced similar problems. Teachers provided standard graphical representations, double-entry tables and bar charts, to scaffold students' explorations. The teachers then orchestrated a collective discussion about different answers in which the written argumentations were collectively discussed. The data concern argumentations during a social construction of a classroom mathematical knowledge. We collected students' written answers, and we recorded classroom discussions after problem solving activities. We conducted a qualitative analysis of transcripts of class discussions and students' written work. The data gathered were analysed through a content analysis (Patton, 2002). A top-down coding was performed from model to the data, by using the theoretical lenses provided by Valenta et al. (2024). To enhance the trustworthiness and rigour of our findings we used the classification of NOLs (Table 1) to independently analyse the data. Then we compare our results. Through constant comparison, we decided on the classifications and identified new aspects to be underlined in the students' mathematical reasoning.

Tasks and analysis of NOLs

Figure 1 shows the task given to grade 8 students and an example of answers. We cannot identify NOLs during their first genesis, but when the students communicate their strategies and justify them to peers and teachers. In the example shown in Figure 1 we can analyse written answers made by claims, numbers and signs on the table. Using the classification proposed in Table 1, we label the argumentation produced to answer the first question *Substantiation, explicit by procedures, valid* because the justification for the affirmative answer to the question is made explicit, and the argument is valid. We notice that the argumentation is supported by means of the table of possible outcomes and favourable cases are marked with circles on the table. In this case, the procedure is not fully explained by words, but it is clear from the signs made on the table (the numbers to be considered are circled). In our data we also found incorrect arguments such as "no, since the number 9 is greater than

the number 5 there can be more combinations of numbers". It is a *substantiation explicit, using properties, non-valid* because even if it makes explicit a true property that links the two numbers, that is not the correct argument to support the claim that the two numbers do or do not have the same probability of occurrence. In the second part of the task shown in Figure 1 we can see a construction of NOLs that is generated by the exploration of the diagram. Here, NOLs are *presented as facts*.

Translation of tasks and answers shown in the adjacent picture:

Imagine throwing two dice at the same time and consider the sum of the numbers you see on the upper face. You can use this double-entry table to represent all the sums that can be obtained. [empty table] Do 5 and 9 have the same probability of occurrence? Justify your answer.

"Yes, because I see that they can both come out four times."

[empty grid] Represent the sums obtained with a bar chart. Look at the different columns of the diagram and write down your considerations.

"A kind of step pyramid is formed, where the highest point is the number 7, i.e. the one with the highest probability of exit, and which gradually descends by one number on either side".

Figure 1: Example of tasks and grade 8 student's answers

The next activity dealt with the problem inspired by a question posed to Galileo Galilei. This is the text of the task given to the students: "*In the 17th century, the game of three dice was very popular. The game consisted of betting on a number and rolling three unbiased six-sided dice. The winner was whoever correctly predicted the sum of the numbers rolled on the three dice. Some players were trying to figure out which numbers to bet on to have the best chance of winning. After many observations, they realized that 10 came up more often than 9. Not understanding why, they asked Galileo Galilei for help. What do you think Galileo's answer was?"* Also in this case, the teachers provided a graphic representation to be filled in and explored. We report an extract from a grade 4 classroom discussion. A student completed the diagram shown in Figure 2 and explained to the teacher why 9 may come out less than 10.

Teacher: Explain your thinking better...
Student 1: 9, like the number 3 and the number 18, can be made up of the same numbers, i.e. 3+3+3 so it only has one combination.
Teacher: For the score 9, there is only one combination?
Student 1: No, it's just that it can also be formed with two equal numbers and a different one, i.e. 4+4+1 and you can 'spin' them, but not like when there are 3 different addends.

In the transcript above we can see a development of the arguments. Applying the classifications shown in Table 1, we can identify *substantiations explicit, using a mixture of procedures and properties* because the student explicitly expresses the property used to support the fact that there are fewer combinations in certain cases that she also explains how they are generated. When explaining, the student points to the diagram used as visual mediator (see Figure 2).

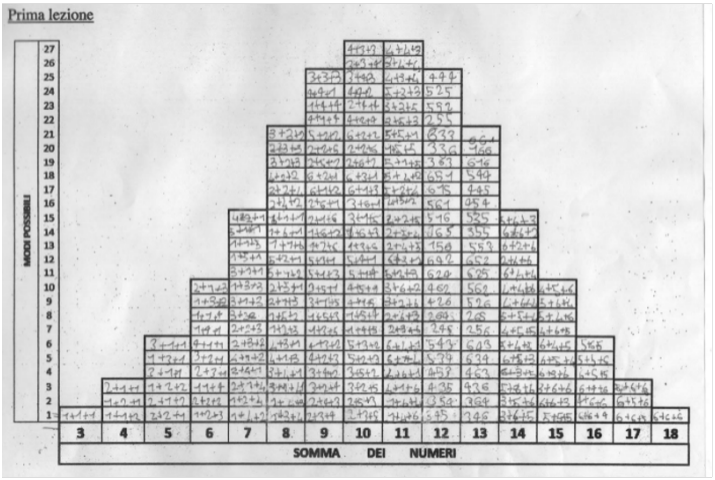


Figure 2: Example of diagram proposed in a grade 4 classroom

The same task was given to middle school students. This is an example of a written answer given by a grade 6 student: "In practice, the number 10 comes out more frequently than the number 9 because even though they have the same number of combinations, it has more variety of possibilities, due to the fact that with the 3,3,3 draw, 9 loses two varieties of possibilities, making 10 slightly more common". Here we can identify NOLs *substantiation explicit, using a mixture of properties and relation, valid* because the arguments generated in support of her statement explicitly mention the properties of the numbers involved and the relationships between their combinations, but the different possibilities are not written down. The specific language on combinations is not precise, but this is due to the knowledge of the students in that school grade. In this case the arguments could be based on the use of the diagram, but we cannot be sure of that.

Discussion and conclusion

This paper shows some tasks for primary and middle school students to introduce them to probabilistic thinking. The goals of these tasks are in tune with Italian National Guidelines. We analyse examples of students' narratives using the interpretative lenses proposed by a framework for necessary object-level narratives (NOLs) proposed by Valenta et al. (2024). We show that NOLs framework provides us with useful tools for identifying and analysing the claims developed by students in order to justify their choices and answers in probability problem solving. In our teaching experiments students are asked to write down the arguments supporting their choices and answers, and then their argumentations are shared and discussed in class. Our data differ from those analysed to exemplify the NOLs framework in the paper by Valenta et al. (2024). Even if we carried out our study in a different country and we analysed problems in different contexts, the NOLs framework

provided adaptable lenses that allowed us to classify not only the narratives developed during oral discussions but also students' written productions to justify their answers developed mainly after probability problem solving activity. By presenting the analysis of our data and the results obtained, we answered the research question: "How can the study of NOLs be used in the analysis of arguments and argumentative processes in the context of probability?". The context is the probability in which the literature tells us that we need to pay more attention to teaching-learning processes (Batanero, 2020). This is only the first attempt to implement the framework for NOLs that we have carried out through the analysis of argumentations in probability context. We show that students in the constructions of NOLs find similarities, differences and identify regularities, and then in the substantiation of NOLs they justify them. The analysis carried out also made it possible to start answering the second question: "What NOLs can we identify in the argumentations of primary and middle school students in the context of probability problem solving?". We have only shown a few examples of argumentations in the area of probability, but the fundamental role of visual mediators already emerges strongly. We show how the categories identified by Valenta and colleagues can be further characterized by considering the visual mediators proposed by teachers in teaching probability to represent events and evaluate situations of uncertainty. We would like to analyse more the genesis and development of NOLs in dialogues during problem solving activities in the context of probability deepening the study of the role of visual mediators. As a matter of fact, Sfard's theory of commognition (Sfard, 2008) identifies visual mediators as crucial aspects of mathematical discourse with word use, routines, and narratives. We hope that our analysis will shed new light on teaching-learning processes of probability by providing refined tools for analysing arguments developed in the classroom, particularly those that rely on visual mediators. However, these aspects require further investigation. This could be the next step in our study which we will develop with our action-research group, to explore how this type of analysis could also be refined as a teaching tool. In particular to develop formative assessment practices and to generate feedback highlighting the characteristics of the NOLs produced and, possibly, the aspects that need to be improved.

Acknowledgment

We wish to thank all the teachers who are part of our action-research group for their fundamental contribution to the design and development of the teaching experiments.

Type of table and reading levels promoted by Spanish textbooks

Jocelyn D. Pallauta[1], María Magdalena Gea[2], Carmen Batanero[2] and Pedro Arteaga[2]

[1]University of Los Lagos, Osorno, Chile

[2]University of Granada, Spain; mmgea@ugr.es

In this paper, we analyze tasks related to the different types of statistical tables included in recent Spanish textbooks and, more specifically, the reading levels required of students to solve these tasks. The sample comprises 10 Spanish secondary-school textbooks (12-15 years-old) from two different publishers. We classified the reading levels proposed by Friel and his collaborators into different types of statistical tables. The results show a predominance of first reading levels, and there is no relationship between the type of table and the reading level required to solve the task.

Keywords: Textbooks, reading levels, secondary education.

Introduction

The COVID-19 crisis highlighted the need for citizens to critically evaluate statistical information and thus make informed decisions in uncertain contexts (Gal, 2024). Statistical tables are widely used in the media and scientific fields because of their cognitive flexibility to summarize and communicate information. Therefore, the ability to read and interpret statistical tables is part of statistical literacy. However, their understanding is a sophisticated skill that requires education.

Curricular changes in several countries have promoted meaningful learning to enhance students' literacy competencies. These curricular changes are required to ensure that future generations develop the knowledge, skills, values, and attitudes necessary to build sustainable societies, thus contributing to the goals of the Education for Sustainable Development (UNESCO, 2017). In this sense, recent Spanish curricular guidelines for secondary education (12-15 years-old), stablish ten specific competences to be developed through numerical, spatial, measurement, algebraic, stochastic, and socio-affective sense (MEFP, 2022). The first cycle of secondary education includes 1st to 3rd grade and the second cycle comprises 4th year, with two strands (A and B) with no differences in the basic knowledge established for each option in a stochastic sense.

We focus on the statistical tables, which have been included in the Spanish curricular guidelines since primary education. In secondary education, different statistical tables (with different types of frequencies, data grouped in intervals, etc.) are incorporated, and their study and understanding involve new cognitive demands. This variety of statistical tables, each of which must be read in a specific manner, is difficult (Pallauta et al., 2023a). However, related research is still scarce.

Because textbooks are a didactic resource for teachers and students that constitute an intermediate stage between the official curricular guidelines and the teaching implemented in the classroom, research analyzing the presentation of different topics in textbooks has increased (Schubring & Fan. 2018). We were therefore interested to know whether the new school textbooks published within the framework of the recent educational legislation in Spain will help develop competence in the interpretation of information represented in statistical tables and graphs (MEFP, 2022) because, for the first time, the stochastic sense is mentioned in the Spanish curricular guidelines. More

specifically, we analyze the tasks related to statistical tables included in recent Spanish textbooks and the reading levels required of students to answer these tasks. In this way, we complete our previous research with Chilean and Spanish textbooks in a previous curricular period (Pallauta et al., 2021a, 2021b, 2023b). This topic is relevant because of the scarcity of secondary education research.

Below, we describe the background and method and present the results. We conclude with some implications for teaching statistical tables.

Background

Classification of statistical tables

We selected the classification of Lahanier-Reuter (2003) to base our research because she considered the specific functions and meanings to differentiate the three types of tables: data tables, distribution tables of variables, and two-way tables. In this study, it is important to differentiate these types of tables because each type involves different levels of complexity and forces to work with distinct mathematical objects. In Pallauta et al. (2023b), we subdivided statistical tables in the classification of Lahanier-Reuter (2003), depending on whether cumulative frequencies are represented in the table and whether the data are grouped into intervals or not. Thus, we considered three types of distribution tables: ordinary frequency tables; cumulative frequency distribution tables; and distribution tables with values grouped in intervals. Likewise, we subdivided two-way tables into two types depending on whether or not the values were grouped in intervals. In the following, we describe this classification of statistical tables.

C1. Data tables contain as many rows as elements in the sample, and the heading indicates the variables collected. The first column contains the list of elements, and each table cell contains data associated with different variables. The concept of a variable and its values are implicit in this table.

C2. One-variable distribution tables display the frequency distribution of a statistical variable and can be of three types: 1) C2.1. Ordinary frequency distribution tables incorporating absolute, relative, or percentage frequencies; 2) C2.3. Frequency distribution tables with cumulative frequencies: in addition to ordinary frequencies, cumulative frequencies are included, requiring work with inequalities; 3) C2.3. Distribution tables with grouped data: this method considers the grouping values of variables in intervals and works with intervals, their extremes, and class marks.

C3. Two-way tables represent the joint distribution of two statistical variables with compound, marginal, and conditional frequencies. We consider two types: C3.1 Two-way table, representing absolute, relative, or percentage frequencies; and C3.2. Two-way table with grouped data, including the classification of values into class intervals for all frequency types.

Reading levels of statistical tables

Starting from a statistical table or graph, we can ask questions involving different difficulty levels because the difficulty of interpreting a statistical graph or table depends on the availability of the required information. Friel et al. (2001) established a hierarchy to consider this complexity when reading statistical graphs, which have also been used to analyze statistical tables (e. g. García-García et al., 2019; Pallauta et al., 2021b). We selected this hierarch because it highlights the different

difficulty levels of questions that can be posed from statistical tables.

L1. Reading the data. This level involves only literal reading of explicit information on the table or graph, for example, finding the frequency of a given value.

L2. Reading between the data. In addition to literal reading, it involves comparing data represented in the table or making calculations. An example is determining the distribution mean.

L3. Reading beyond the data. This level involves finding data that are not immediately accessible in the table, for example, interpolating or extrapolating information displayed.

L4. Reading behind the data. This is the most advanced level. In addition to reading the graphs or tables, this involves a critical appraisal of the content and sources from which the information comes.

Previous research

Most previous studies analyzing the reading level required to solve textbook tasks have focused on statistical tables and primary school education books (e.g., García-García et al., 2019), although a few analyzed isolated secondary education grades (Pallauta et al., 2021a). Regardless of educational level, these studies suggest an excess of procedural tasks focused on the most basic reading levels, such as literal reading (L1) or comparing data and performing calculations (e.g., statistical summaries or probabilities) (L2). For example, Pallauta et al. (2021a) analyzed the different types of statistical tables included in 18 Spanish secondary-school textbooks published on the previous educational system from three different publishers. They observed an increasing variety of types of statistical tables as the school grade progressed. Ordinary frequency distribution tables were the most frequently used, while two-way tables with grouped data were the least used. Moreover, Pallauta et al. (2021b) analyzed six Chilean textbooks and six Spanish textbooks for secondary education 1st and 2nd grade published in the previous period. The textbooks in both countries promoted a stronger L2 reading level (over 75% activities), followed by the L1 reading level (about 20%). More sophisticated reading levels (L3 and L4) were presented at lower percentages and were scarcer in Spanish textbooks.

Method

We present qualitative research based on content analysis (Drisko & Maschi, 2016) of mathematical activities in statistical tables proposed in the statistics and probability chapters of a sample of Spanish secondary-school textbooks. Following an inductive and cyclic procedure: 1) We selected all the activities incorporating statistical tables in each textbook; 2) We coded each activity according to the reading level needed to solve it (Friel et al., 2001) and the type of statistical table involved (Pallauta et al. 2023b), which were described in the background section (Type of tables and Reading levels); 3) The coding was reviewed several times by one author and discussed with other colleagues until agreement was reached, to ensure the reliability of the coding; 4) Results were summarized in tables to facilitate the drawing of conclusions.

The sample included ten Spanish textbooks aimed at grades 1st to 4th (12-15 years-old secondary-school students), used in schools and published by two prestigious editorials (Anaya and Santillana) that were widely distributed in Spain. Thus, we analyzed five textbooks for each publisher because in grades 1 to 3, all students study the same content, but in grade 4, students can choose between

academic (4th B) or applied mathematics (4th A). In total, 1217 activities were analyzed using statistical tables: 633 in Anaya and 584 in Santillana.

The reliability of the coding in the research is guaranteed insofar as successive reviews of the textbooks were carried out by the authors of this study, with subsequent discussions of discordant cases, until agreement on the coding was reached.

Results

Type of statistical tables

The following categories were considered:

C1. Data tables. These tables are mainly devoted to list data. Thus, the values of each variable are represented individually for each element in the dataset. Figure 1 presents an example taken from a 4th A grade book, where two quantitative variables (hours of mobile phone used and hours of sleep) are represented.

10 teenagers were asked about the number of hours they use a mobile phone every day and the number of hours they usually sleep each night. Here are the results:

Hours of use the mobile phone	1	2	5	3	6	5	3	1	2	4
Hours of sleep	10	8	4	7	4	5	6	8	6	7

Estimate the number of hours for a day that a student would use his or her mobile phone if he or she usually sleeps 9 hours a day.

Figure 1: Example of data table and reading level L3 (Colera et al., 2023b, p. 219)

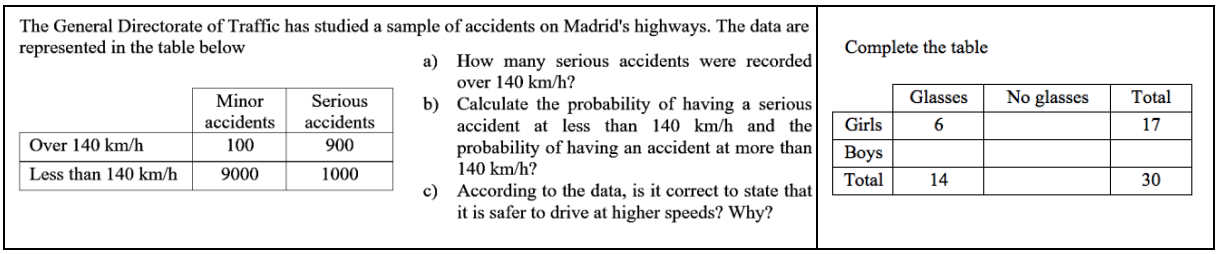
C2. One-variable distribution tables. In these tables, each variable value is linked to one or more types of frequency (absolute, relative or percentage frequency). We distinguish three different types:

- *C2.1. Ordinary frequency distribution tables*. These tables usually have different columns to represent the absolute (f_i), percentage (p_i), or relative (h_i) frequencies of the variable values.
- *C2.2. Cumulative frequency tables*. This type of table represents the cumulative relative frequencies (H_i) or the absolute relative frequency (F_i) of a variable (Figure 2, left-hand side).
- *C2.3. Frequency tables of data grouped in intervals.* The values of a continuous or discrete variable are grouped in intervals (Figure 2, right-hand side), which implies dealing with intervals and their extremes to approximate values and calculating summary statistics.

This is the number of books read by students in a class during the semester. Construct the frequency table:0 2 4 2 0 2 0 1 1 3 2 2 1 0 3 2 4 0 1 1 3 4 1 2 3

x_i	f_i	F_i	h_i	H_i	p_i
0	5	5	0,2	0,2	20
1	6	11	0,24	0,44	24
2	7	18	0,28	0,72	28
3	4	22	0,16	0,88	16
4	3	25	0,12	1	12
	25		1		

The table shows the ages of a group of people. It represents the data in a histogram.



Age	f_i	h_i
[36, 42)	4	0,26
[42, 48)	4	0,26
[48, 54)	5	0,3
[54, 60)	2	0,13

Figure 2: Examples of one-variable distribution tables (Grence, p. 256; p. 258)

C3. Two-way tables. In these tables, it is necessary to identify the values of each variable and the crossing of each category in the table rows and columns. Therefore, three types of distributions

are represented in the same table: joint, marginal, and conditional distributions. We distinguish two different types:

- *C3.1. Two-way tables with ordinary frequencies* represent qualitative or discrete variables. For example, the table in Figure 3 (right-hand side) represents qualitative variables.
- *C3.2. Two-way tables with grouped data* represent continuous variables with data grouped in intervals; for example, in Figure 3 (left-hand side) the intervals are indicated verbally.

The General Directorate of Traffic has studied a sample of accidents on Madrid's highways. The data are represented in the table below

	Minor accidents	Serious accidents
Over 140 km/h	100	900
Less than 140 km/h	9000	1000

a) How many serious accidents were recorded over 140 km/h?
b) Calculate the probability of having a serious accident at less than 140 km/h and the probability of having an accident at more than 140 km/h?
c) According to the data, is it correct to state that it is safer to drive at higher speeds? Why?

Complete the table

	Glasses	No glasses	Total
Girls	6		17
Boys			
Total	14		30

Figure 3: Example of two-way table (Colera et al., 2023a, p. 319; p. 322)

Table 1 presents the percentage of types of statistical tables by school grade and editorial (percentages are computed for each column). Similarly to Pallauta et al. (2021a), we observe the predominance of the distribution table with ordinary frequencies (C2.1), especially for grade 1, although its frequency diminishes after the two first grades because new types of tables are given predominance in the upper grades. For example, distribution tables with grouped data (C2.3) start appearing in grades 3 and 4, although after the percentage diminishes. Two-way tables with ordinary frequencies (C3.1) appear scarcely in Grade 1, but afterwards between 11.6 and 20.9 of the tables are included in this category.

Table 1: Percentage of type of table by school grade and by editorial

Type of table		Grade					Editorial	
		1 N=140	2 N=104	3 N=199	4 A N=344	4 B N=430	Anaya N= 633	Santillana N= 584
C1. Data table		10.0	19.2	11.1	14.2	19.3	22.0	8.4
C2. Distribution table	C2.1. Ordinary	82.9	58.7	35.2	24.7	21.6	30.8	39.4
	C2.2. Cumulative			5.5	20.9	14.4	8.2	15.9
	C2.3. Grouped	2.9		36.7	10.2	24.2	18.8	21.9
C3. Two-way table	C3.1. Ordinary	0.7	20.2	11.6	20.9	20.5	19.9	13.5
	C3.2. Grouped	3.6	1.9				0.3	0.9

Two-way tables with grouped data (C3.2) tasks are very rare and are only included in grades 1 and 2. Similar results were reported by Pallauta et al. (2021a); however, some types of distribution tables were not considered for grades 1 and 2 (C2.2 and C2.3), while two-way tables with grouped data (C3.2) were still more scarce and were not considered for grades 3 and 4.

When analyzing the type of table by publisher, the main differences are that Anaya has almost three

times as many data tables (C1) as Santillana, and Santillana has twice as many distribution tables with cumulative frequency (C2.2) as Anaya. Two-way tables with ordinary frequencies are presented at a slightly higher percentage in Anaya, whereas two-way tables with grouped data are rarely considered by both publishers.

Reading levels

We used the reading levels from the classification by Friel et al. (2001). We describe some examples of activities classified in each of these levels:

L1. Reading the data. At this level, the activity focuses on finding the frequency of a variable value (or the value to which a frequency corresponds). An example is shown in question a of Figure 3 (left-hand side), which asks for the identification of the joint frequency.

L2. Reading between the data. At this level, comparisons or calculations must be performed with the data represented in the table. Question b in Figure 3 (left-hand side) corresponds to this reading level because the probabilities must be calculated. In Figure 3 (right-hand side), this level is also required to complete the table.

L3. Reading beyond the data. This reading level is reached in activities in which the data are not explicitly represented in the table, which includes interpolating or extrapolating data. For example, in Figure 1, students are asked to interpolate the value of one variable according to the data.

L4. Reading behind the data. At this level, the solver critically evaluates the data collection method and its validity or reliability or justifies the obtained conclusions. For example, question c in Figure 3 (right-hand side), the student must assess the veracity of the statement according to the data.

Table 2 presents the reading levels of the activities by grade. Almost all activities required L2 (reading the data) in all school grades like in previous research (García-García et al., 2019; Pallauta et al., 2021b), whereas L1 (reading the data) appeared between 10.6% and 21.4% in different grades.

Table 2: Percentage of reading levels by school grade and by editorial

Reading level	Grade					Editorial	
	1 N=140	2 N=104	3 N=199	4 A N=344	4 B N=430	Anaya N=633	Santillana N=584
L1. Reading the data	11.4	16.3	10.6	15.4	21.4	17.7	14,9
L2. Reading between the data	85.7	82.7	85.4	80.2	74.4	76.0	84.1
L3. Reading beyond the data				4.1	2.6	3.6	0.3
L4. Reading behind the data	2.9	1.0	4.0	0.3	1.6	2.7	0.7

Reading level L3 (reading beyond the data) was very scarce and was present only in grade 4, with no significant difference between the two strands of this grade. The reading level L4 (reading behind the data) was also too rare. Other investigations have also found the scarcity of statistical table tasks that require L3 and L4 skills in both primary education (García-García et al., 2019) and secondary

education (Pallauta et al., 2021b). These results disregard the curricular guidelines and the importance of making inferences and predictions from the data analyzed.

When comparing editorials in terms of reading level, Santillana presents a higher percentage of activities at the L2 reading level (84.1%), which suggests that this publisher places greater emphasis on calculation. Both publishers include a small percentage of L3 and L4 activities; however, they are presented in a slightly higher percentage in Anaya, which promotes statistical reasoning by trying to predict variables that do not appear in the table and reinforces the critical reading of the information.

Conclusions

In this paper we analyze the different types of statistical tables and the reading levels by Friel et al. (2001) required to complete the activities contained in a sample of 10 Spanish secondary-school textbooks published within the framework of the recent educational legislation in Spain (MEFP, 2022). Given the prevalence of statistics tables in secondary schools, our method and variables may serve to analyze other textbooks in that or other countries.

The results, like Pallauta et al. (2021a) demonstrate that the tasks related to different types of statistical tables are focused on distribution tables with ordinary frequencies; however, their frequency decreases as the grade progresses, although no increase was associated with the complexity of the reading levels involved. Moreover, our study revealed a predominance of the first two levels of reading the data, in which only direct reading of the information in the statistical tables (L1) and comparisons or computation with the data (L2) are required, like in García-García et al. (2019) and Pallauta et al. (2021b) and L3 level that promotes the students' ability to interpolate and extrapolate from data which is considered an important part of statistical literacy (Gal, 2024) is almost not-existent in an editorial. These results suggest an excessive emphasis on developing computational abilities rather than focusing on fostering students' statistical literacy or reasoning. We also note the scarcity of L4 level activities, which develop the ability to reason with statistical information, to discuss arguments based on statistical information, and to assess the reliability of such information.

The scarcity of high reading levels activities was also noted in research dealing with statistical graphs (e.g. Friel et al, 2001). Then, it is important to include more L3 and L4 tasks both in graphs and tables, as some research (Sharma, 2013) has shown difficulty with reading at these levels in secondary school students. Furthermore, teachers need to be aware of the variety of the statistical tables, according to the classification described in this paper. The statistical table is not only a powerful tool for statistical literacy but also deepens student's algebraic reasoning (Pallauta et al., 2023b).

Teaching data-driven machine learning in mathematics education

Sarah Schönbrodt[1] and Martin Frank[2]

[1]Paris Lodron University Salzburg, Austria; sarah.schoenbrodt@plus.ac.at

[2]Karlsruhe Institute of Technology, Germany

Technologies based on data-driven machine learning (ML) methods have taken on a central role in our economy, technology and everyday life. The underlying principles of various ML methods are grounded in data and mathematical concepts often embedded in elementary form within high school mathematics curricula, e.g., distances between points and lines or the dot product. In this paper, we propose using classification problems and the Support Vector Machine (SVM), a supervised ML method, to introduce students to data-driven ML techniques. We provide a didactical analysis of the SVM and present intended learning trajectories for both lower and upper secondary education, enabling students to comprehend key mathematical ideas underlying the SVM, which are representative of many ML methods.

Keywords: Machine learning, AI education, Support Vector Machine, mathematics education.

Introduction

Nowadays, AI technologies significantly impact nearly every aspect of society. Consequently, comprehensive AI education is considered an essential component of contemporary general education. The European Commission emphasises in its Digital Competence Framework for Citizens that for citizens to engage "confidently, critically and safely with new and emerging technologies, including systems driven by artificial intelligence (AI), they need to acquire a basic understanding of such tools and technologies" (European Commission, 2022, p. 77). Since data-driven ML methods, which underpin most AI technologies, are fundamentally based on mathematics and data, mathematics education can play a crucial role in fostering a deeper understanding of AI.

An important class of problems that are solved with ML methods are classification problems. These arise in diverse applications, such as the classification of tumors in CT scans, facial recognition for smartphone unlocking, and fraud detection in financial transactions. Various approaches exist to teach data-driven ML methods to high school students using classification problems as an example. Among others, the k-nearest neighbours method (Hazzan & Mike, 2022; Schönbrodt et al., 2023) and decision trees (Biehler & Fleischer, 2021) have been found particularly accessible. This paper focuses on the didactic analysis of a classification model based on the SVM as learning content to introduce key mathematical concepts of data-driven ML. We will particularly focus on applications and classification problems in the context of autonomous driving and medical diagnosis. Building on prior work describing learning arrangements for secondary education (Schönbrodt et al., 2022), this theoretical paper extends previous works by providing a broader subject-matter didactic analysis.

Methodological approach

First, we will highlight key concepts underlying data-driven ML methods in general. Then, following the 4-level approach for structuring and specifying mathematical learning content by Hußmann & Prediger (2016), we focus on key questions that arise at the formal, semantic, and concrete level. The

formal level addresses mathematical content in their logical structure and formal presentation, the *semantic* level focuses on structural relationships, big ideas, and basic mental models and the *concrete* level deals with the implementation of teaching-learning arrangements through core ideas and problems (Hußmann & Prediger, 2016). The empirical level is not included here, although we have already developed and implemented a variety of materials in different learning groups.

At the *formal level*, we address the mathematical concepts underlying the SVM in their symbolic representation. This leads to the logical skeleton of the subsequently described learning trajectories. At the *semantic level,* we discuss key mathematical ideas and representations that are relevant for a basic understanding of the SVM. We discuss how intended learning trajectories for two age groups (ages 13–14 and 16–18) can be sequenced such that they follow the logical structure of the SVM and ensure that students discover key concepts of data-driven ML. At the *concrete level*, we point out contexts and data that facilitate the discovery of the mathematical aspects of the SVM.

Key mathematical concepts of data-driven machine learning workflows

Here, we briefly outline key mathematical concepts (*highlighted in italic font*) involved in developing data-driven ML methods within the domain of supervised learning (see Figure 1).

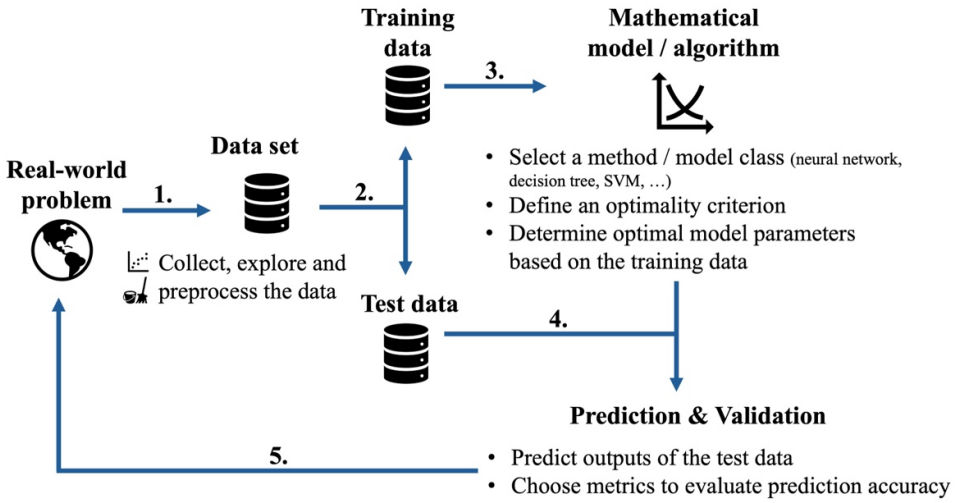

Figure 1: Key concepts when solving problems with data-driven ML (based on Biehler et al., 2024)

Data. The starting point for developing a data-driven ML method to solve a specific real-world problem is a *large amount of data*. This data is typically *explored, analysed* and *pre-processed* (e.g., cleaned by identifying and removing outliers). In supervised learning, the input data $\vec{x}_i \in \mathbb{R}^n$ and the corresponding output data $\vec{y}_i \in \mathbb{R}^m, i = 1, \dots, N$ are known. We restrict the following descriptions to $m = 1$. For classification problems the outputs y_i are categorical (e.g., $y_i = 1$ for class A and $y_i = -1$ for class B). Usually, the available dataset is divided into *training data* and *test data*. The training data is used to develop ('learn') a mathematical model. For most ML methods this means finding a function $f: \mathbb{R}^n \to \mathbb{R}$, with $f(\vec{x}_i) \approx y_i$ that can be used to predict the outputs (here ± 1) of unseen data. The test data is used to subsequently validate the model.

Mathematical model/algorithm and optimisation. In the case of artificial neural networks, SVM, linear regression, and several other ML methods, developing a mathematical model involves choosing a *class of functions* that depend on various parameters. The representative best suited for the given data must be selected from this class. In other words, the function that best describes the unknown relationship between the input data and the output data must be identified. To this end, an *optimality criterion* is determined that defines what is meant by 'best.' An *optimisation problem* is formulated and solved using *numerical optimisation methods*, allowing to determine the optimal parameters of the model. Thus, for most supervised learning methods, the so-called training or learning process boils down to solving a mathematical optimisation problem.

Validation. The mathematical model is used to *predict the outputs of the test data*. The predicted outputs $\hat{y}_i$ and the actual outputs y_i are compared. *Evaluation metrics* are used to quantify the error and thus to evaluate the performance of the model. Using test data to validate a model is a crucial step carried out in mathematical modelling processes beyond ML (Blum & Borromeo Ferri, 2009).

Using the SVM to convey key concepts of data-driven ML

One ML method used to solve classification problems is the SVM (Bishop, 2006). Here, we focus on the linear SVM, which can be applied to (almost) linearly separable data points from two classes (e.g., class A and class B). An example dataset is shown in Figure 2 (left).

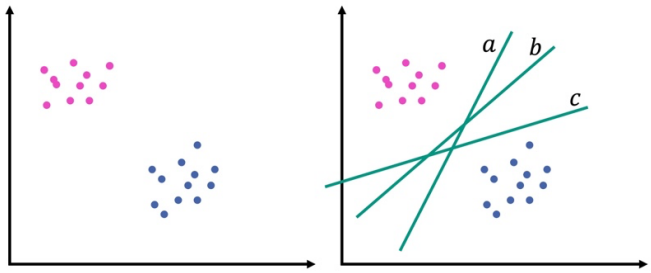

Figure 2: Linearly separable data of two classes (left) and different separating lines (right)

Below, we briefly describe the relevant mathematical foundations of the linear SVM and specify and structure these concepts for both lower and upper secondary education. We discuss to which extend the mathematical aspects of the SVM can be addressed as 'white box' with students of different grades, point out necessary prior mathematical knowledge and highlight links to high school curricula in Austria (Bundesministerium für Unterricht und Kunst [BUK], 2024).

Formal level: key mathematical concepts underlying the linear SVM

The SVM is based on the idea of separating data points of two classes by hyperplanes of the form $\vec{n} \cdot (\vec{x} - \vec{p}) = 0$ (i.e. planes for 3-dimensional and lines for 2-dimensional input data). The maximisation of the data point-free area around the hyperplane, known as the margin, (visualised by dashed lines in Figure 3, left) is used as optimality criterion. This means finding the entries of $\vec{n}$ and $\vec{p}$ such that the distance of the nearest data points of both classes to the hyperplane is maximised, i.e. $\max_{\vec{n},\vec{p}} \min_{i=1,\dots,N} \frac{|\vec{n}\cdot(\vec{x}_i-\vec{p})|}{||\vec{n}||}$. As constraints, the data points of both classes are required to lie on different sides of the separating hyperplane. This is described by linear inequalities. A reformulation leads to

a quadratic optimisation problem under linear constraints that is solved using numerical methods leading to the optimal hyperplane (Bishop, 2006). The class of any data point $\vec{x}_i$ is determined based on the sign of the dot product $\hat{y}_i = \text{sgn}\big(\vec{n} \cdot (\vec{x}_i - \vec{p})\big)$, e.g., class A for $\hat{y}_i > 0$ and class B for $\hat{y}_i < 0$.

Semantic level: intended learning trajectories, key mathematical ideas and representations

We discuss key mathematical ideas of the SVM and representations (verbal, graphical, numerical, and algebraic) that are crucial for developing a basic understanding of SVM-based classification models (Hußmann & Prediger, 2016). We describe the learning trajectory for upper secondary education in detail and discuss how the learning trajectory for lower secondary education differs from it. The intended learning trajectories incorporate the following key mathematical ideas underlying SVM-based classification models, with the corresponding steps of the learning trajectory indicated in parentheses:

Key idea: Using a hyperplane to separate data points of two classes and to classify new data points (steps 1, 2, 6, and 7).

Key idea: Defining an optimality criterion (maximum margin) to find the best separating hyperplane. Based on this criterion, the parameters of the hyperplane are determined optimally (steps 3, 4, and 5).

Key idea: Embedding the SVM into typical data-driven ML workflows (cf. Figure 1), providing a structured approach to classification (steps 1, 8, and 9).

Upper secondary education: When working on a classification problem with 2- or 3-dimensional input data the SVM can be worked out with a direct connection to mathematical concepts from linear algebra and analytical geometry (Schönbrodt et al., 2022). Relevant prior knowledge includes vectors, lines/planes in point normal form, the dot product and distances between points and lines/planes – all embedded in the Austrian upper secondary mathematics curriculum (BUK, 2024). We restrict the following description of the steps that constitute the learning trajectory to lines. However, all mathematisation steps apply to planes (and hyperplanes in general) in the same way.

(1) Exploring input data and separating lines graphically. Based on the graphical representation of the data, the idea of using a line to separate the data points of both classes is derived.

(2) Deriving an algebraic representation of the separating line. Analogously to the formal representation of the SVM the separating line is described algebraically as $\vec{n} \cdot (\vec{x} - \vec{p}) = 0$.

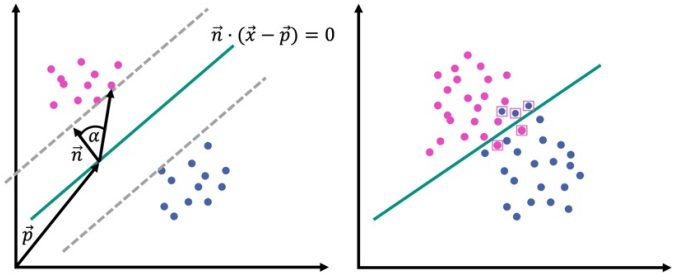

Figure 3: Mathematical description of a separating line (left) and data with overlapping classes (right)

(3) Verbal representation of the optimality criterion. Figure 2 (right) visualises that several lines might be feasible for separating the data. This motivates the definition of an optimality criterion to determine when one line is more suitable than others. If the separating line is very close to the data points of one of the two classes, there is a higher risk of misclassifying new data points belonging to that class. This consideration can be derived based on the graphical representations and leads to a verbal description of the optimality criterion: choosing the separating line with the maximum distance to the closest data points of both classes.

(4) Deriving an algebraic representation of the distance. The distance between any data point $\vec{x}_i$ and the line is described algebraically according to the actual SVM (i.e. $\frac{|\vec{n}\cdot(\vec{x}_i-\vec{p})|}{||\vec{n}||}$) – a mathematical concept embedded in Austrian curricula (BUK, 2024).

(5) Verbalizing the optimisation problem and solving it (black box). The entries of $\vec{n}$ and $\vec{p}$ should then be chosen to maximise the distance between the separating line and the data points closest to the line. Students can conceptually derive the optimisation problem. However, the representation of the optimisation problem does not have to be formalised in detail. Solving the problem can be outsourced to the computer using digital tools (black box approach). Alternatively, the optimal separating line can be approximated through computer-aided variation of the parameters (entries of $\vec{n}$ and $\vec{p}$).

(6) Determining the class of a new data point graphically. Once the optimal line has been found, the next step is to determine how to classify a new data point $\vec{x}_i$. Based on the graphical representation of a new data point and of the optimal line the point is classified by graphically assessing which side of the line it lies on.

(7) Deriving an algebraic term to classify new data. The idea of classifying data points based on

$$\vec{n}\cdot(\vec{x}_i-\vec{p}) = \cos(\alpha)\cdot\|\vec{x}_i-\vec{p}\|\cdot\|\vec{n}\,\| \begin{cases} >0, & \text{for } 0°\le\alpha<90° \\ =0, & \text{for } \alpha=90° \\ <0, & \text{for } 90°<\alpha\le 180° \end{cases} \begin{cases} \text{class A} \\ - \\ \text{class B} \end{cases}$$

is worked out algebraically supported by suitable visualisations (see Figure 3, left) and omitting the symbolic representation of the sign function.

(8) Validating the model statistically. The test data, for which the class labels are known, is used to evaluate the performance of the classification model. The accuracy (the proportion of correctly classified data among all test data) and the confusion matrix are computed as evaluation metrics. Further metrics, such as precision and recall, could be introduced additionally.

(9) Discussing limitations of the model based on graphical representations of data sets. In real-world applications data are often not as neatly linearly separable as previously discussed. During the model development process, it might be necessary to accept data points on the wrong side of the separating function (see Figure 3, right), a fact that should be discussed explicitly to highlight limitations of the model. Furthermore, based on the graphical representation of different data sets, the dependence of the model (the separating line) on the distribution of the training data can be explored.

Lower secondary education. When working with 2-dimensional data and thus using separating lines, the basic building blocks of the SVM for solving classification problems can be introduced in

lower secondary education. Necessary prior knowledge includes handling data (graphically), describing lines as graphs of linear functions, measuring geometrical distances, and, depending on the evaluation metric discussed, understanding absolute or relative frequencies (Schönbrodt, 2024). The learning trajectory follows the same logic as in upper secondary level, albeit with different manifestations in the algebraization steps (2), (4), and (7) as explained in the following.

(2) Developing an algebraic representation of the separating line. Vector calculus and the point normal form of lines are typically not part of lower secondary mathematics curricula. Therefore, we propose describing the separating line using graphs of linear functions f with $f(x) = mx + b$. This is a strong simplification of the original SVM model, which is accompanied by certain restrictions (e.g., no representation of vertical separating lines).

(4) Deriving an algebraic representation of the distance. To find the optimal line, the geometric distance between the data points and the line can be measured manually or by using digital tools – either as black box or as white box by computing the perpendicular base point as the intersection of two lines.

(7) Deriving an algebraic term to classify new data. The location of a data point relative to the separating line and thus the class of any data point (x_1,x_2) can be determined based on the difference $d = x_2 - f(x_1)$, i.e. by comparing the x_2-coordinate of the data point with the function value at x_1. For $d > 0$ the point lies above, for $d < 0$ below and for $d = 0$ on the line (Schönbrodt, 2024).

Concrete level: problems, data and design decisions

At the concrete level, we propose problems, along with data sets, in which students can construct the mathematical concepts in a generic way. We conclude by briefly describing the chosen digital tools of developed learning materials that guide the reinvention of the SVM.

The learning trajectories rely inherently on graphical visualizations of both the data and the separating line/plane. Thus, 2- or 3-dimensional data that can be explored visually is crucial. Publicly available datasets for classification tasks often contain significantly more than two or three features. To address this, larger datasets can be simplified by selecting relevant features or creating synthetic datasets that mimic real-world problems but are simpler to handle.

In *upper secondary education,* we propose using the context of classifying images of traffic lights in the realm of autonomous driving. The input data consists of greyscale images with only two or three pixels. More precisely, from each of the lights (2D: green/red; 3D: green/yellow/red) one pixel is extracted deriving 2- or 3-dimensional input data. The relevant classes are red and green. We chose this context because it allows for systematically increasing the dimensionality of the input data, progressing from 2-pixel images to 3-pixel images to N-pixel images (Schönbrodt et al., 2022) and thus extending the mathematical model from lines to planes to hyperplanes. As digital tools, we chose Jupyter Notebooks that enable various representations of mathematical objects and their interactive exploration. The Notebooks can be accessed in a web browser and are designed such that programming skills are not required.

In *lower secondary education,* we choose the context of medical diagnosis, more precisely classifying patients (classes: sick/healthy) based on two blood values using a synthetic 2-dimensional dataset

(Schönbrodt, 2024). Understanding the data is less complex, than in the case of images represented by the greyscale values of each pixel. For lower secondary education, unplugged materials were developed. Students work with paper-based worksheets. For further exploration, an interactive Gradio app (https://ki-macht-schule.de/ki-und-mathe) is available to investigate the model's performance based on several training and test datasets. The app is operated via sliders.

The SVM in secondary education: practical considerations and educational value

The intended learning trajectories provide a direct link to school mathematics and do not require mathematical knowledge beyond current curricula, theoretically justifying their integration into mathematics education (BUK, 2024). Past implementations with students suggest that these trajectories are also feasible from a practical perspective.

The elementarisation of the SVM for *lower secondary education* significantly differs from the actual mathematical formulation of the SVM due to the use of linear functions. Nonetheless, the key concepts of data-driven ML methods (data, selection of a mathematical model, optimisation, validation) remain conceptually accessible. The formal notation (i.e. symbolic representation) of the optimisation problem is treated as a black box to reduce cognitive load and to focus on conceptual understanding. The elementarisation of the SVM for *upper secondary education* remains close to the original SVM. However, the symbolic representation of the optimisation problem and the numerical optimisation methods are omitted as black box as well.

Value for AI education. Both learning trajectories have educational value in fostering a deeper understanding of key concepts underlying data-driven ML methods, potentially contributing to AI education and demystification. The trajectories reveal the human role in AI system development, which is particularly evident in the model development phase. Using separating lines/planes is an explicit decision made by humans. Similarly, determining the optimality criterion is a deliberate modelling decision. Depending on the context this can lead to fruitful discussions. In the medical diagnosis example, it could be discussed whether it is more problematic to classify sick patients as healthy or healthy patients as sick, and whether the optimal separating line should be shifted closer to the less sensitive group. In this case, a different optimality criterion would be needed.

Value for mathematics education. Incorporating the SVM in mathematics education allows addressing multiple goals simultaneously: (i) It provides an opportunity to connect various mathematical domains, including statistics (data handling and statistical quality measures), analytical geometry (upper secondary level), functions (lower secondary level), and optimisation. (ii) The SVM allows graphically illustrating the interplay and dependence between the ML model ('separating line') and the statistical properties of the given dataset. This demonstrates the crucial role of data in developing ML methods. (iii) It gives students an authentic insight into the role of school mathematics in contemporary, real-world applications while simultaneously highlighting key concepts of data-driven ML (data, mathematical model, optimisation/training, validation/testing).

Outlook

We have seen that for both lower and upper secondary education, intended learning trajectories can be derived that make the key mathematical ideas of SVMs and concepts of data-driven ML methods

tangible. These learning trajectories build upon mathematical concepts embedded in high school curricula for the two age groups considered. Regarding the practical implementation of the learning trajectories in the classroom, we have implemented the described materials in various learning groups – so far without systematically evaluating it at the empirical level. In future research, we are interested in assessing the impact of the teaching-learning arrangements on students' understanding of AI and how they contribute to the promotion of AI literacy.

A local instruction theory to strengthen students' grasp on graphs

Lonneke Boels[1]

[1]HU University of Applied Sciences Utrecht, the Netherlands; lonneke.boels@hu.nl

Keywords: Statistics Education, Dotplot, Histodot and Hatplot, Box-dotplot, Histogram and Boxplot

Theoretical framework

Recent advances in eye-tracking research have provided new insights into how students interpret statistical graphs such as case-value plots and histograms (Bakker, 2004), dotplots (Boels, Lyford et al., 2023; Schreiter & Vogel, 2023) and boxplots (Abt et al., 2024). Building on these studies, this theoretical contribution refines and clarifies a local instructional theory for teaching statistical graphs in grades 4–12. The accompanying poster visually presents this theory with supporting example tasks, contributing to the theme of emerging trends and innovations in teaching statistics.

A key finding from eye-tracking studies is that students and teachers often interpret histograms as case-value plots, despite paying attention to the axis labels (e.g., Boels et al., 2019). Another is that students in Grades 10–12 can easily grasp single dotplots (Boels, 2023). However, both primary and secondary school students struggle more when comparing dotplots (Boels, Lyford et al., 2023; Schreiter & Vogel, 2023). Comparing histograms (Boels, 2023) or boxplots (Abt et al., 2024) turns out to be even more difficult. Both graph types represent aggregated data. The distribution and variability of the same data is represented differently in various graphical representations. Therefore, graphs with different shapes may have the same or similar distributions and variability (Figure 1).

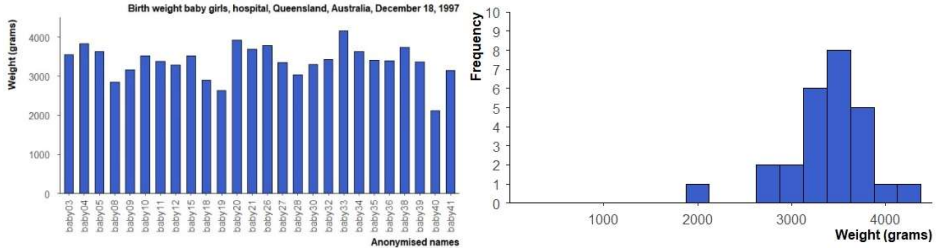

Figure 1 Case-value plot (left) and histogram (right) with the same data and distribution (Boels et al., 2019)

Research on conceptual change provides guidelines for how students can learn key concepts such as distribution and variability. Some important elements are: (1) make students' preconceptions visible [e.g., through eye-tracking], (2) have them predict, (3) create cognitive conflicts, (4) enhance meta-conceptual awareness, (5) increase tolerance of uncertainty and ambiguity (Merenluoto & Lehtinen, 2004). Our poster provides examples of comparison tasks with statistical graphs that illustrate these elements. A task that can prompt cognitive conflict is having students discuss what the data, distribution, and variability are in the graphs shown in Figure 1.

Local instruction theory

Our poster outlines a possible progressive curriculum that exemplifies key elements of a local instruction theory for developing students' understanding of statistical graphs. It shows how dotplots (Frischemeier, 2019) can support a gradual transition from case-value plots (Boels, 2023) via

intermediate graphs such as histodots (Boels, 2023) and hatplots (Fielding-Wells & Hillman, 2018) to histograms and boxplots. The task sequence is based on logical-historical analysis (e.g., Bakker, 2004; Boels, Alberto & Shvarts, 2023) and key findings of eye-tracking research. Researchers can use this overview for further eye-tracking and educational design research studies, and to further investigate how students interpret less-studied graph types, such as frequency polygons, stem-and-leaf plots, and density histograms. For teachers and textbook developers, the overview informs coherent curriculum design for strengthening students' grasp on statistical graphs.

Transferring responsibilities to students in a statistics inquiry through a study and research path

Maria-Josep Freixanet[1], Montserrat Alsina[1] and Marianna Bosch[2]

[1]Universitat Politècnica de Catalunya, Spain; maria.josep.freixanet@upc.edu

[2]Universitat de Barcelona, Spain

Keywords: Investigative questions, Statistics, Study and research paths, Anthropological Theory of the Didactic, Inquiry-based learning.

Introduction and theoretical framework

The choice of a good investigative question that will lead an inquiry or a problem-solving activity in statistics has been proven to be crucial (Arnold et al., 2021; Frischemeier et al.; 2020). This choice usually lies under the teacher's responsibility. We present an activity carried out at the Nelson-Mandela Schule in Berlin with grade 11 students, where the students take an active role finding the investigative questions. The instructional model, study and research paths (SRP), under the theoretical framework of the Anthropological Theory of the Didactic (ATD, Chevallard, 2015) is used for the design and implementation of this instructional proposal. An SRP begins with a generating question Q_0, which guides the investigation. Previous implementations show the students' perspectives when playing an active role in a statistics inquiry (Freixanet et al., 2023).

Research questions and research method

Our research question is: What conditions facilitate the transfer of responsibilities when finding the investigative question in a statistics inquiry and what constraints hinder it? We approach it through an empirical case study based on an inquiry proposal for the teaching of statistics at secondary school level. The research method is an adaptation of the didactic engineering (Barquero & Bosch, 2015). It consists of four phases: the preliminary analysis, which points at a didactic phenomenon to approach (here, the transfer of responsibilities to students), the a priori, in vivo and a posteriori analysis, that is the design, implementation and evaluation of the instructional proposal.

Finding the investigative questions

The main generating question Q_0: "How does our school community contribute to air pollution?" is stated by KlimaLink, a company whose aim is to provide a platform that calculates CO2e emissions from travel components. Grade 11 students are responsible for finding narrower investigative questions and link them to data that can be accessed or collected, and will lead future inquiries. In the a priori analysis, the activity was designed (task responsible in brackets: Y teacher, Z external organisation, x_i students and X_j teams of students) (Figure 1). Google tools were used and shared with the students, and all materials were organised in a common Google Classroom (GC).

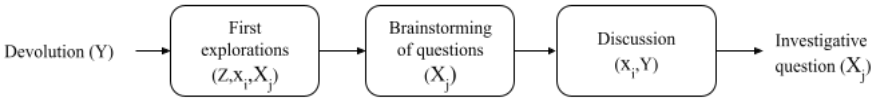

Figure 1. Design of the activity of finding the investigative question

The in vivo analysis showed that two new actions were needed during the implementation, both fell under the teacher's responsibility: (1) the organisation of the questions after the brainstorming, and (2) the creation of an external feedback tool (Google forms) to validate if the questions were good investigative questions, which included videos about "designing a questionnaire" and questions about the availability of data, study purpose, target population, variables of study, etc. (Figure 2):

Figure 2. Final flow chart of implementation of the activity of finding the investigative question

Discussion and conclusions

The a posteriori analysis showed that the prevalence of the traditional didactic contract acted as a main constraint pushing the teacher to assume more responsibilities than planned. The additional didactic tools developed, including Google shared tools and Classroom organisation appear to be useful for the transfer of responsibilities in finding good investigative questions. The evolutions of the didactic contract are weakly described in the literature about the problematisation process in statistics education. Our research aims at contributing to this line of research.

Gaining insight – developing eye-tracking vignettes for teacher training on misinterpretations of statistical graphs

Ayline Heursen[1], Saskia Schreiter[2], Vuslat Seker[3], Anita Alexander[3] Lonneke Boels[3], Frank Reinhold[4], Martin Abt[4], Wim Van Dooren[5] and Markus Vogel[1]

[1]Heidelberg University of Education, Germany; heursen@ph-heidelberg.de

[2]Schwäbisch Gmünd University of Education, Germany; [3] HU University of Applied Sciences Utrecht, The Netherlands; [4]Freiburg University of Education, Germany; [5]KU Leuven, Belgium

Keywords: Statistics Education, Teacher Education, Misinterpretation, Eye-Tracking.

Systematic errors in interpreting statistical graphs are often due to underlying conceptual difficulties (Boels et al., 2024; Lem et al., 2013). These errors can be analyzed and made visible through eye-tracking, which provides insights into participants' thinking processes (Boels et al., 2024). For example, a common systematic error is confusing data values with frequencies, such as calculating the mean frequency instead of the mean of the data values. The gaze data in Figure 1 visualize a thinking process leading to this systematic error.

Despite the growing use of eye-tracking in educational research, its application in teacher training, particularly for addressing misinterpretations of statistical graphs, remains limited. The objective of the Erasmus+ project “Eye-teach-stats” is to develop eye-tracking vignettes for teacher training to address systematic errors in interpreting statistical graphs, including histograms, boxplot, dotplots, and case-value plots. Eye-tracking technology can be used to visualize strategies that lead to systematic errors and provide teachers with further representations of these strategies.

This new and innovative type of vignette uses eye-tracking data to combine visual impressions with verbal statements from students. In teacher training, vignettes consist of teaching situations that are linked to a didactically relevant question and require didactic knowledge and skills to answer (Ollesch et al., 2018). These vignettes are designed using the Four-Component Instructional Design (4C/ID) model by van Merriënboer (2020) with the intention to support teachers in diagnosing and dealing with such systematic errors and their underlying conceptual difficulties.

Construction of eye-tracking vignettes according to the 4C/ID model

The four components of the model, *learning task*, *supportive information*, *procedural information* and *part-task practice* offer an approach to design environments for complex learning. In the 4C/ID model, the individual requirements of complex tasks are not explicitly separated; rather they are combined into one task. Starting point for all the vignettes are real-life situations in the classroom where diagnosing systematic errors and their underlying conceptual difficulties is a common task for teachers.

The learning task are intended to encourage teachers to reflect on the student’s solution process presented in the vignette based on their gaze patterns and thus to deepen their diagnostic skills. Within the vignettes, the learning task are divided into different part-task that are worked on in sequential form along the components of the 4C/ID model. Additional supportive and procedural information offers teachers further help with the exercises. They are always available, but must be accessed by

clicking on the round blue and yellow icons in the bottom right-hand corner in Figure 1. The vignette in Figure 1 offers supportive information on dotplots, as graph type, and procedural information on gaze data plots, as the way in which the eye-tracking data is visualized. At the end of the vignettes, they provide the opportunity to practise subtasks in order to gain routine in the everyday task of diagnosing systematic errors.

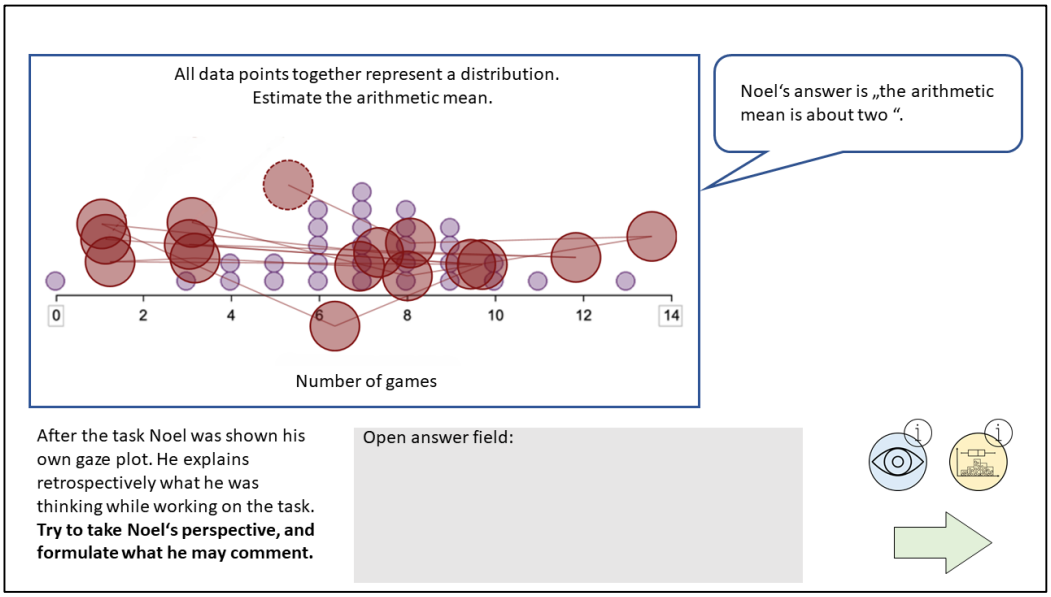

Figure 1: subtask with gaze data in eye-tracking vignette

Following Ollesch et al. (2018), expert surveys will be conducted to review the vignettes and assess their validity. These results will be used for improving and implementing the eye-tracking vignettes in an online learning environment for student teachers from different countries.

Data science modules for preservice teacher education

Susanne Podworny[1], Sibel Kazak[2] and Aisling Leavy[3]

[1]Paderborn University, Germany; podworny@math.uni-paderborn.de

[2]Middle East Technical University, Türkiye

[3]Mary Immaculate College Limerick, Ireland

Keywords: Data science education, STEAM education, preservice teacher education.

Introduction

The project Promoting Data Science Education for Teacher Education at the University level (DataSETUP, https://datasetup.euc.ac.cy), part of the Erasmus+ Cooperation partnership, involves institutions from five countries (Cyprus, Germany, Greece, Ireland, and Türkiye) working together to enhance data science education for preservice teachers. An informal needs analysis regarding the preservice teacher programs at the participating partner universities has revealed that almost no STEAM subject includes elements of data science. The project aims at equipping preservice teachers with data science knowledge to effectively educate future generations of informed citizens, a goal that is widely recognized as important (Biehler & Schulte, 2018; Mike et al., 2023). The poster will show an example module developed within the project for use in a STEAM subject.

A framework for preservice teachers' data science education

At the heart of the project is the development of stand-alone data science modules that can be used in various STEAM subjects in teacher education. These modules are built upon a framework currently being developed as part of the project, carefully informed and guided by existing literature from primary to tertiary education (e.g., Adisa et al., 2023; Lee et al., 2022). An initial version of the framework can be found in Figures 1 & 2; this is a work in progress.

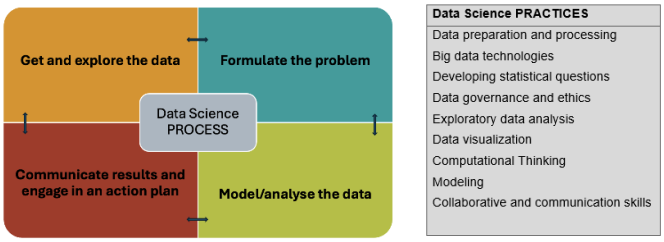

Figure 1: Preliminary DataSETUP conceptual framework for preservice teachers' data science education–Dimension 1: Data science processes and practices

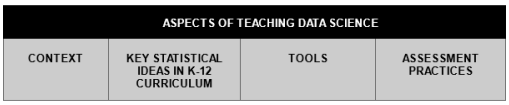

Figure 2: Preliminary DataSETUP framework–Dimension 2: Aspects of teaching data science

The modules center on four interconnected data science processes (Figure 1), each involving practices (right side of Figure 1) that form their core focus. Additionally, the framework incorporates a second dimension focused on teaching data science (Figure 2).

Data Science modules for preservice teachers' data science education

Using a design-based research approach, the objectives are to design independent modules as short courses to enhance preservice teachers' knowledge of data science processes and practices and implement these modules in STEAM teacher education programs. The outcome will be several tested teaching modules. These modules will complement existing teacher education programs and be translated for broader use on the DataSETUP online platform, ensuring a wider impact across European higher education.

The DataSETUP project develops two types of modules. Theoretical modules aim to enhance preservice teachers' essential data science skills and competencies, as outlined in the framework. Application modules will provide participants practical data science skills to tackle real-world problems in various contexts, such as sustainability and civic statistics (Ridgway, 2022).

Sample data science application module on "Gaming habits of young people"

A pilot module was implemented with 19 pre-service primary teacher students in a 90-minute session. Students successfully went through the four-element framework analyzing multivariate data from German young people from the ProDaBi project (www.prodabi.de/en). They explored data, formulated questions, analyzed, and presented their results. Notably, five groups created action recommendations, supporting the development of data-based reasoning.

Investigating students' co-construction of statistical argumentation

Carlotta Vielmo[1]

[1]University of Trento, Italy; carlotta.vielmo@unitn.it

Keywords: Argumentation, statistical reasoning, Toulmin's model, Habermas' rationality.

Introduction and rationale

In the poster, I will discuss a preliminary study of a broader project aimed at investigating the argumentation produced by upper secondary school students when working on statistical tasks that foster data-based decision-making process. Specifically, the poster will inform about the use of the combined lens of Toulmin's model and Habermas' construct of rationality (Boero et al., 2010) to analyse the dynamics of co-producing argumentative steps in such a context.

Supporting the development of data-based decision-making is recognized as central for mathematics and statistics education (OECD, 2023). As reasoning is strictly related to argumentation, studying how argumentative processes evolve allows us to explore also how students develop statistical reasoning and thinking, justify their claims, and interact with the data, while also showing how they connect statistical and contextual knowledge and navigate complex reasoning in collaborative settings. In this context, we intend argumentation as presented by Ben-Zvi (2006).

The project focuses on designing and analysing activities that allow for the activation of argumentative patterns to study their characteristics, understanding their specificities and what can be generalized. This also aims to understand better the contexts in which argumentation emerges and to provide insights into what can trigger it. Particular attention is given to how the choice of data representations affects argument, as several different ones may be used to support the argued claim and give different perspectives. Since transnumeration enables access to the understanding of the phenomena beyond the data (Wild & Pfannkuch, 1999), the choice of appropriate representations may have an impact both in the exploratory phase that involves analysing the data set and in producing the argument to communicate and discuss decisions.

Theoretical framework and research questions

We decided to adopt the combined lens of Toulmin's model and Habermas' construct of rationality, because it may efficiently enhance the ability of Toulmin's model to analyse also statistical argumentation, as being able to consider the communicative and goal-oriented components of rational behaviour, which are pivotal in producing statistical argumentations. The Toulmin model has already shown promising contributions in investigating statistical reasoning. For instance, Gómez-Blancarte and Tobías-Lara (2018) reflect on how to make such a model work with informal inferential reasoning (IIR). We believe its application, combined with Habermas' rationality, may give fruitful contributions also in analysing foundational processes for IIR, that do not go beyond the data yet provide the necessary groundwork to make generalizations (e.g., grouping data). With this view, the study contributes to a better understanding and characterization of these forms of reasoning.

In light of the theoretical framework, the research questions are as follows. When upper secondary school students work on statistical tasks that require data manipulation:

RQ1: What roles do the different components of Habermas' rationality play in the construction of argumentation and argumentative steps, and in particular in the selection and construction of warrants underlying them?

RQ2: How can the choice of data representation be analysed and evaluated in warrant production?

RQ3: What is the relationship between the choice and the construction of data representations in an argumentation, and the production of warrants?

Methods

The project focuses on the design and analysis of a teaching intervention that fosters statistical argumentation in classroom settings. The collected data includes video recordings of students while they work in small groups on the assigned task and during classroom discussion, and recordings of the students' laptop screens, as they use software to manipulate data. The analysis is carried out according to the method proposed by Knipping and Reid (2015).

The poster will present the designed teaching intervention and discuss the results we got from the preliminary study conducted last May. The analysis focuses on the work of a triad of 10th grade students from an Italian secondary school and aims at clarifying how to operationalize the theoretical framework within statistics domain (e.g., how to characterize and identify key terms like claims and warrants in statistical argumentation, how to evaluate students' "strategic" statements about the organization of work).

Case study of a learning environment for collecting and analysing real data in mathematics classrooms with the toolkit senseBox

Anna-Marietha Vogler[1] and Kirstin Erath[1]

[1]Martin Luther University Halle-Wittenberg, Institute of Mathematics, Halle, Germany;
anna-marietha.vogler@mathematik.uni-halle.de

Keywords: Data literacy, particulate matter, secondary school, senseBox, sustainability.

Future-orientated mathematical learning with real data

A central topic of digital future education in mathematics classrooms in Germany is the collection, processing, analysis, and, above all, interpretation of a wide range of environmental (real) data. This is subsumed under the term 'data literacy' (hereafter: DL). Due to the omnipresence of data in the current age and the penetration of data science into almost all areas of life, the development of such DL should therefore be a central aim of future-orientated mathematics education (Biehler et al., 2018). Although DL is included in the German curriculum for mathematics, there is often a lack of ideas for implementing it in everyday mathematics classrooms, especially at the lower secondary level. For closing this gap, we introduce the toolkit senseBox (Bartoschek et al., 2018) as a possible and sophisticated tool for dealing with real data in the mathematics classroom. Furthermore, a learning environment in the context of particulate matter from the UmARsense project (project no. 03 02825, Deutsche Telekom Stiftung) is presented, in which the collection, analysis, and interpretation of real data with the senseBox toolkit is central.

Collecting real data with the senseBox within substantial learning environments

The senseBox is an electronic component experiment set that can be assembled and programmed by the students themselves. Its components can be used to collect a wide range of real environmental data (e.g., temperatures, UV intensity, particulate matter, and noise levels). Programming is carried out via an adaptation of the Blockly programming system. Data output is possible by means of measured values on a display and by reading out data with suitable software (e.g., Excel). However, so far there are no concrete substantial learning environments (hereafter: SLEs) for using the senseBox in the mathematics classroom. In order to realise working with real data in mathematics classrooms in a didactically sophisticated way, several SLEs were developed in the project UmarSense. The SLEs were prepared and standardised in the form of didactical situation patterns following Platz (2019). The developed SLEs include environmental data from different areas and fulfil the requirement of collecting, processing, and critically analysing environmental data in order to promote a multifaceted discussion of the environment and aspects of sustainability. Our poster focuses on one SLE exploring particular matter, as this context is highlighted as an important topic in mathematics education literature (Barwell, 2018). The SLE is developed by Josephine Ebert for sixth-grade students at a secondary school. It is structured into 4 steps: (1) Introduction to the topic of particulate matter and air pollution with presentation of the respective characteristic and limit values; (2) Construction and programming of the senseBox tool and the particulate matter sensor; (3) Carrying out the particulate matter measurement and recording the data; (4) Discussion. The SLE was realised with three groups of three to four children. In step 3, the children worked in teams of

two or three to take measurements of chalk dust emissions caused by wiping the blackboard in the classroom. The children were able to take measurements at different, self-selected locations in the classroom. The measured data was collected using the display, noted, and then prepared in the form of a bar chart. During the subsequent discussion with the whole group (step 4), the children drew first conclusions about valid measuring points for particulate matter based on the data they had collected themselves. They hypothesised about how the measuring point influences the values (proximity or distance to the blackboard). When they were presented with values and comments on real measuring stations, the children made a critical assessment in which they referred to the values they had collected and also included the real limit values. Finally, one girl formulated the need to act with regard to particulate matter pollution in cities. She said, „So that we can say that they have exceeded the specified limit and that we now have to do something about it".

Summary of the empirical findings and concluding remarks

In the trial of the presented SLE within the framework of the project, it became clear that working with the senseBox is suitable for interested learners in grades 5 and 6, particularly for fostering (critical) analysis of (environmental) data, promoting data literacy, and enabling digital environmental exploration. Nevertheless, data from the UmARsense project also shows that one challenge of SLEs involving the senseBox is how to mediate between the collected data and consequences for reality. With regard to its use in regular mathematics classrooms, it can be summarised that the senseBox can be used in lower secondary schools primarily in the context of working groups or project work, as the amount of supervision required, particularly with regard to the construction of the measuring instrument, is high. Future research should start here and develop further learning environments and make them suitable for use in everyday classrooms in order to give digital future education more space in mathematics.

This paper presents and gives an overview of the papers and posters discussed in the Thematic Working Group 6 (TWG6) at the CERME14 conference taking place in Bolzano, February 4–8, 2025.

Keywords: Applications, learning, mathematical modelling, models, teaching

Overview and introduction of the CERME TWG6 on application and modelling

Thematic Working Group 6 (TWG6) focuses on applications and modelling. It highlights the importance of exploring how mathematics is used to understand real-world phenomena in educational contexts. TWG6 investigates the interplay between empirical research and theoretical perspectives on teaching and learning applications and mathematical modelling, both within mathematics and across other disciplines, spanning primary, secondary and tertiary education, as well as teacher education.

Since its establishment at the 4th ERME Congress (CERME 4) in 2005, TWG6 has remained an active and evolving group, contributing to each of the subsequent ten ERME congresses up to and including CERME 14. At CERME 14, TWG6 welcomed contributions addressing a variety of theoretical, methodological and empirical issues. These included the application of mathematics and modelling in interdisciplinary contexts; the role of simulations; sustainability; the integration of technology and resources in modelling; and preparing both pre-service and in-service teachers to teach modelling and applications.

The contributions reflect the diversity of research questions, educational levels, theoretical frameworks, and methodological approaches in mathematical applications and modelling research. This highlights the field's dynamic and multifaceted nature. For CERME 14, TWG6 received 45 submissions, 23 of which were accepted as papers and two as posters. These were presented at the congress. Figure 1 provides an overview of the TWG6 papers and posters presented at various CERME congresses. A total of 33 participants from 13 countries attended TWG6 at CERME 14, compared to 20 different countries at CERME 13. The majority of participants (85%) were from Europe, which is an increase on the 67% from CERME 13. However, in addition to the European participants, TWG6 at CERME 14 also attracted participants from North and South America and Asia.

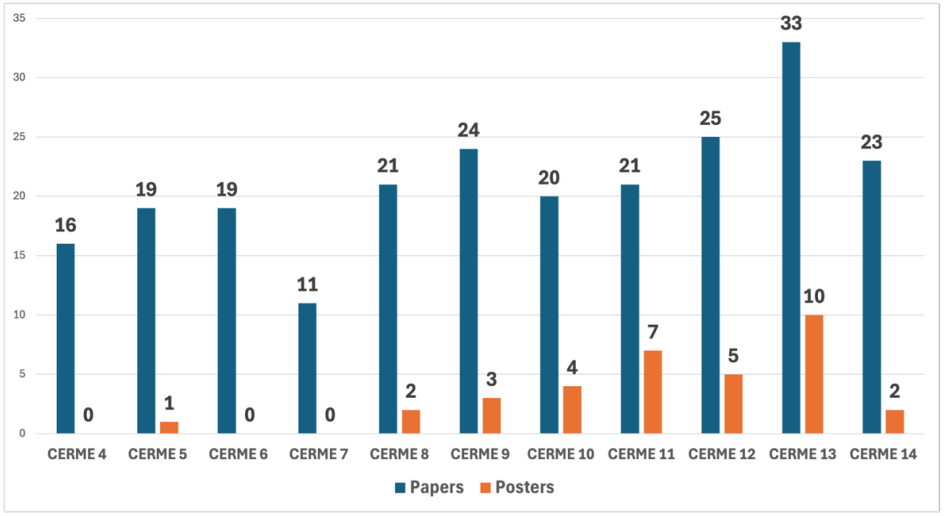

Figure 1: Overview of the presented contributions in TWG6 in CERME 4 – CERME 14

Table 1 outlines the five themes around which discussions and work in TWG6 were structured and organised. The first theme explores ways to support students during Fermi problem solving, including using structuring tools such as Fermi graphs, the importance of estimation and benchmarks, and the potential of AI in modelling processes. The second theme addresses modelling assessment, examining how different tools and theoretical frameworks influence what is assessed and learnt, and how these tools can support research and classroom practice. The third theme focuses on improving mathematical modelling through careful task design, interdisciplinary integration (e.g. with engineering and financial education) and teacher interventions that strike a balance between guidance and student autonomy. The fourth theme considers modelling perspectives within and beyond the classroom, emphasising modelling of societal, educational and research responsibilities and highlighting the role of data science and global challenges. The fifth and final theme investigates the interplay between affect and data in modelling. This includes examining how beliefs, motivation and engagement with diverse data types influence students' modelling experiences and how tools such as ChatGPT may reshape modelling practices and enquiry.

Table 1: Identified themes and number of contributions in the CERME 14 proceedings

Theme	*Papers*	*Posters*
Theme 1: Students' support during Fermi problem solving	4	-
Theme 2: Assessments and models	5	1
Theme 3: Enhancing mathematical modelling – Design, implementation, and interdisciplinary connections	5	
Theme 4: Mathematical modelling perspectives in and beyond the classroom	4	
Theme 5: Mathematical modelling related to affect and data	5	1

Theme 1: Students' support during Fermi problem solving

Fermi problems are a type of reality-based problem that is characterized by a lack of data. This data must be obtained in a meaningful way as part of the processing process. Despite the longstanding focus on Fermi problems within the TWG of Application and Modelling, novel research approaches are continually emerging due to evolving circumstances.

One of the points discussed was the support measures for working on Fermi problems. Fermi graphs are one possible form of support that can be used as a structuring aid during the solution process, as well as to structure the reflection and presentation of the same. In addition to such aids, the role of the teacher is also crucial in facilitating the acquisition of skills in this area. This can include the handling of Fermi problems, as well as the way teachers facilitate class discussions and consolidate results to ensure collective understanding.

Another point that arose in the discussions was the identification of relevant aspects in the processing of Fermi problems. As previously outlined, Fermi problems are distinguished by the necessity of acquiring data to resolve them. One approach to procurement is estimation, which often necessitates the establishment of benchmarks. These benchmarks are not only used for estimation; they are also used to create models and validate results.

A completely different area that has seen significant growth in recent years is the use of AI in the field of Fermi problems. There are various types of interaction with AI during the FP-solving process. In the future, the use of AI in the processing of Fermi problems is seen as having great potential in at least two respects:

- How does the use of AI influence the solution process of Fermi problems?
- (How) Can the use of AI support the evaluation of solution processes of Fermi problems?

A key point of discussion in the TWG's LTs was the contribution to the development of critical citizenship. With regard to Fermi problems, it was highlighted that these problems, although they may appear straightforward, have the potential to contribute significantly to the development of critical citizenship, particularly in the areas of critical thinking and sustainability. In this context, the following questions should be investigated:

- To what extent can the solution processes of students working on Fermi problems be indicative of the development of critical citizenship?
- Which characteristics of Fermi problems are conducive to fostering citizenship awareness?

Theme 2: Assessments and models

Theme 2 is characterized by very diverse explorations of how we can assess students' modelling processes, and what affects the process, but the theme also addresses the question of what is being assessed? Some cases looked at students and others at preservice teachers, none related to exams.

A main issue raised across the discussion of the different papers was the concern that what is assessed may be what students learn. Therefore, we need to discuss further how can portfolio, a priori analyses, criteria, schemes of evaluations scaffold teachers' formative assessment of students modelling processes and therefore their learning? Modelling activities can potentially go in many different

directions and include various mathematical and extra mathematical domains. So a priori map out or consider what knowledge strategies and knowledge expected is valuable. Connected but also different, is the question of how the intertwinement between assessment and theoretical framework (modelling cycle, MEA, Fermi problems, ATD etc.) inform the study, affect the learning potential? Different theoretical frameworks provide specific lenses on modelling and promote or delimits specific features of what can be considered part of modelling processes. Therefore, the frameworks – when guiding the design of assessment activities or explicitly introduced in the teaching – affect what students can learn about modelling and from modelling.

One way to make explicit the consequences of the choice of theoretical framework is the before mentioned a priori analyses or hypotheses about outcomes. Linked to this theme we discussed the importance of the dialectic between designing interventions and analyse hypothetical student strategies when developing assessment tools. This regardless of that being portfolios, tool kits, eye tracking systems etc. Furthermore, for most participants the question of the role of teachers. Are the presented assessment tools suitable for classrooms and everyday teaching? Not all, but some seem to carry the potential of functioning well as tools for students' metacognition regarding modelling processes guided by a modelling cycle, tool kits or explicit encouragement for seeking further resources concerning the extra mathematical domain seem more easily included in classroom practices. Portfolio and eye tracking is deemed more complicated for that.

Thus, more broadly and looking ahead we find it highly relevant to discuss for whom and for what purpose we develop the different tools and methodologies proposed in the papers linked to assessment and models? Which tools are appropriate for teachers and which ones are mainly for research? How can this still inform and improve (someone's) learning?

How to teach teachers to use tools developed for research, which also has potential for practice? Beyond the a priori analysis mentioned, we see research potentials of improving the scaffolding structures for modelling activities. It would be interesting to develop knowledge further on how and why elements like tool kits, empty cycles, eye tracking, potential questioning done during the experiment etc. works? For teachers we see potentials for providing formative assessment, which does not delimit open modelling processes, or which promotes changes of phases in modelling cycles etc. without direct instructions for doing so. Both for research and teaching we see a need for further studies on relevance and linkages between curriculum and assessment, tools, and scaffolding. Also, we see a need to dive further into content related constraints and conditions when designing and implementing assessment tools: What is important to learn and assess? This of course links to the domains of both extra mathematical and intra mathematical modelling, and their intertwinement. When do we expect students to dive into the former or the latter? Or do we wish to see students work in a dialectic between the two, continuously expanding the system and models addressed?

Throughout all initiatives we need to consider time constraints: is there "space" to implement the proposed tools? In research? In teaching and in what form?

During the group sessions we inevitably discussed variations in assessment approaches across different educational systems and how they shape modelling practices. Comparative studies may prove to be productive for further development of this area within mathematical modelling research.

Theme 3: Enhancing mathematical modelling – Design, implementation, and interdisciplinary connections

The discussion on Theme 3 considered different approaches to strengthening mathematical modelling. These relate to the design of modelling courses, their implementation and relationships with other subjects. The discussion focused on the diversity of perspectives in mathematical modelling, the adaptation of contexts in engineering education and the role of modelling in financial education. In addition, the type of implementation and interventions by teachers were discussed in more detail.

Mathematical modelling is approached from *different perspectives*, both theoretical and experimental, depending on the research context. However, a lack of standardised terminology in textbooks and curricula often makes it difficult to understand this complex field. This diversity of perspectives highlights the need to define modelling terminologies more clearly and to clarify their meaning for both teachers and students.

In engineering education, for example, it is crucial to carefully consider and adapt the design principles for modelling problems. This depends very much on the *context* and level of education for which the activities are designed. Especially in higher education, it is important to consider the impact of modelling sequences on the understanding of the intended content. Such considerations are essential to achieve the learning objective effectively.

In addition, mathematical modelling plays a central role in *financial education*. Developing modelling tasks in the context of financial education can improve students' financial literacy. More interdisciplinary research is needed to bridge the gap between mathematical modelling education and financial education.

The *implementation* of modelling tasks by teachers requires a careful characterisation of the conditions that allow a balance between teacher intervention and student autonomy during the modelling process. These conditions must also be transferable to specific contexts, such as lower-achieving groups, and are crucial for the success of the learning process.

Teacher *interventions*, especially scaffolding practices based on the diagnosis of modelling tasks, are essential for effective modelling instruction. Teachers need to integrate diagnostic and instructional skills and design interactive learning environments based on mathematical modelling.

Looking to the future, it is important to adapt perspectives and activities to suit different learning profiles in different contexts. Improving teacher training and professional development in mathematical modelling and strengthening the links between mathematical modelling and current important issues such as financial literacy, sustainable development and social responsibility are crucial.

These broad considerations show the importance of a clear and collaborative approach to mathematical modelling, both in the educational context and in its professional application in different disciplines.

Theme 4: Mathematical modelling perspectives in and beyond the classroom

The theme 4 addresses the discussion of modelling perspectives in and beyond the classroom applications. The researchers highlighted the importance of theoretical approaches that, on the one hand, are drawn from the connotation of its utility in the classroom and, on the other hand, go beyond the classroom applications. Given that mathematical modelling is based on real-world phenomena with uncertainties, challenges, vulnerabilities, harms, and impairments, the modelling perspective has a potential global service to the planet and the society in which we live. In this regard, in CERME14 we articulated three major areas of responsibilities of mathematical modelling: (1) responsibility for society, (2) responsibility for school, and (3) responsibility for research.

First, mathematical modelling provides us a tool to prepare individuals for disruptive times such as pandemic periods or natural disasters due to climate change and global warming. The research investigating how to teach modelling in schools during disruptive times in a data-driven world put forward the opportunities of linking data science and mathematical modelling. In this regard, these societal issues are not merely the real-world contexts to initiate model development, rather they enable problem-solvers to develop solutions for the concerns of the society and promote the awareness and responsibilities of being a world citizen. The data-driven world offers prospects for the integration of data science and modelling activities, which holds the potential for citizenship education.

Second, mathematical modelling puts forward responsibilities for schools. A comprehensive approach for general education along with modelling goes beyond the transmission of specialised knowledge. Considering the development of critical, independent, culturally and environmentally responsible individuals as a part of general education, the researchers called for (re)interpreting mathematical modelling goals, concepts, and tasks. The opportunities given to students in the schools such as teachers' choices of modelling activities or pre-existed activities in the textbooks are needed to be re-evaluated from the modelling perspective. As an attempt of such evaluation, the textbook analysis showed us that modelling processes in French and Norwegian textbooks were often limited with specific cases and types of models, and reversible and recursive work on models were not sufficiently promoted. Yet, our theoretical discussion suggested a need for developing criteria for educational activities, classroom practices, and scaffolding pedagogies, not only for cognitive development but also for identity and personality development in contemporary mathematical modelling.

Third, the TWG in CERME14 discussed the research tools for developing and adapting mathematical modelling for several purposes (e.g., general education, sustainability, etc.). In this regard, the "Wheel of Modelling" introduced in this theme articulated different acts and purposes of mathematical modelling and models, which can be used by both researchers and educators. Similar to the discussion of the TWG in earlier years, the constraints and challenges of researching mathematical modelling (e.g. curricular guidelines, textbooks, lack of measures, etc.) have been on the agenda that we acknowledge as a part of the responsibility for research in mathematical modelling.

The theme on mathematical modelling perspectives in and beyond the classroom also revealed some emerging questions for future developments on this topic:

- How can mathematical modelling be used to address societal and global issues and challenges (e.g., in the context of sustainable development, socio-ecological approaches, or data science)?
- What changes are needed in modelling tasks in a data-driven and technology-driven world for developing critical, independent, culturally and environmentally responsible individuals?
- How do we consider Large Language Models (e.g., ChatGPT) in the emerging modelling-related research issues, trends, and challenges?

Theme 5: Mathematical modelling related to affect and data

Theme 5 addresses two interrelated yet distinct dimensions of contemporary mathematics education: the role of affect in mathematical modelling and the evolving nature of students' engagement with data. On one hand, affective factors such as motivation, interest, and beliefs significantly shape both the teaching and learning of modelling practices, influencing how students approach real-world problems and how teachers design and assess modelling tasks. On the other hand, the growing emphasis on data literacy highlights the need to understand how students perceive, interpret, and work with data in an increasingly digital and information-rich world.

One central issue concerns how teachers' beliefs about mathematics influence the implementation and assessment of mathematical modelling tasks, particularly in relation to assumptions within these tasks. These beliefs shape not only instructional choices but also the ways in which students engage with modelling processes. A noteworthy observation is the positive impact of conducting modelling tasks in outdoor environments, which has been shown to enhance students' motivation and interest. Despite students demonstrating a strong interest in themes such as sustainability, this topic remains insufficiently integrated into mathematics education. The challenge lies in aligning curricular goals with students' affective engagement, thereby fostering a more meaningful connection between mathematical modelling and real-world issues.

In exploring students' knowledge about and with data, several key issues emerge concerning their understanding and use of different data types. Many students appear to hold an implicit belief that only numerical data are valid, often disregarding qualitative information presented through text or other non-numerical formats as irrelevant or less valuable. This tendency affects how they manage data in modelling tasks, potentially leading to the neglect of meaningful contextual information. Moreover, students' perceptions of data are shaped by the nature of the tasks and classroom activities they engage with; when thoughtfully designed, such experiences can help students recognize data sets as powerful tools for interpreting and making sense of the world. Importantly, the incorporation of big data and tools like ChatGPT into mathematics education offers new opportunities to enrich the exploratory modelling process. These digital resources support more dynamic and interactive engagements with data, allowing students to apply statistical methods in ways that are more aligned with contemporary practices than traditional classroom settings typically allow.

In moving forward with Theme 5, several research directions emerge. First, there is a call for deeper exploration of how affect—both students' and teachers'—influences mathematical modelling. This includes examining how modelling settings, task characteristics, and contexts such as sustainability shape engagement, as well as how teachers' concerns may reflect a fear of departing from mathematical traditions. Second, with regard to knowledge about and with data, it is essential to

pursue a more refined understanding of the role data plays in the modelling process. This includes analysing how the presence, absence, quality, and quantity of data influence key phases such as mathematization and validation. Further attention must also be paid to how knowledge about data is constructed and utilized by students, teachers, and textbooks within the modelling process. Finally, the integration of generative AI tools like ChatGPT opens new possibilities for modelling, raising questions about the types of knowledge students seek. Research is needed to explore what kinds of knowledge students seek when interacting with AI, how these tools influence modelling activities—including the validation of models—and in what ways they may encourage or inhibit deeper inquiry.

Discussion/conclusions/outlook

The five themes that emerged from the contributions to TWG6 at CERME 14 reflect both a continuity of interest and a dynamic evolution in the field of applications and mathematical modelling in education. Compared to previous congresses, the discussions at CERME 14 revealed a deepening engagement with established topics—such as Fermi problems, assessment, and interdisciplinary modelling—while also embracing new directions, including the integration of AI tools, the role of affect and data, and the broader societal responsibilities of modelling education.

The thematic strands illustrate a rich diversity of theoretical perspectives, methodological approaches, and educational contexts. They also highlight a growing concern with how modelling can contribute to critical citizenship, sustainability, and data literacy in a rapidly changing world. The discussions underscored the importance of supporting both students and teachers in navigating complex modelling processes, and of designing tasks and tools that are both pedagogically meaningful and practically feasible.

While these developments are encouraging, they also invite us to reflect on how the TWG can continue to evolve. The introduction of new topics such as generative AI, sustainability, and data-driven modelling signals a need to revisit and renew our shared research agenda. Drawing on the collective experience and insights developed over the years; we are now well-positioned to explore how our work can remain relevant and impactful in an increasingly complex educational and societal landscape. This renewal is not a departure from our foundations, but an opportunity to build on them—strengthening our contributions to both research and practice in mathematics education.

Looking back at the trajectory of TWG6 since its inception at CERME 4, and building on the developments seen at CERME 13, the work presented at CERME 14 demonstrates a healthy balance between consolidation and innovation. It is encouraging to see how the group continues to foster a collaborative and reflective research community, committed to advancing the theory and practice of mathematical modelling in education.

Acknowledgment

We extend our gratitude to all attendees of TWG6 at CERME 14 for presenting their work, engaging in the discussions, and constructively collaborating during the intensive working sessions.

The wheel of mathematical modelling: Seeking a new perspective

Jonas Bergman Ärlebäck[1], Serife Sevinc[2] and Lluís Albarracín[3]

[1]Linköping University, Department of Mathematics, Sweden; jonas.bergman.arleback@liu.se

[2]Middle East Technical University, Turkiye & TUD Dresden University of Technology, Germany

[3]Universitat Autònoma de Barcelona, Spain

In this theoretical paper we present an initial conceptualisation of a new perspective on mathematical modelling. Drawing on seven phases of a creative problem-solving process and making parallels to the purposeful and creative writing process, we first elaborate on the similarities between the modelling process and the writing process. We then reconceptualise the so-called 'Wheel of Writing' in the context of mathematical modelling as a 'Wheel of Modelling' and articulate the acts and purposes of mathematical models and modelling within this perspective.

Keywords: Mathematical modelling, models, theories, wheel of modelling, wheel of writing.

Introduction

In mathematics education research, theories play many important roles such as *defining overarching frameworks* providing views of teaching, learning and mathematics; supporting the *organising of sets of specific observations and interpretations; providing concepts and terminology; and offering methodological approaches* (Niss, 2007). Overall, there are numerous theoretical perspectives within the field of mathematics education reflecting various aims and different social and cultural contexts of the research (Sriraman and English, 2010) – the research field of mathematical modelling is no exception. While a multitude of perspectives enrich the understanding of mathematical models and modelling, they also pose a risk of misunderstandings if researchers are not clear about their theoretical foundations and intentions. This is especially the case, when the theories adapted are taken for granted and are highly specific and specialised with respect to the modelling process or modelling competencies. In this paper, we seek a perspective that is more generic and inclusive when thinking about mathematical modelling, by reflecting on similarities between an inclusive conceptualisation of the mathematical modelling processes along with its purposes and the processes of purposeful writing various types of texts.

Our rationale departs from acknowledging that (i) mathematical modelling is a creative process (Cevikbas et al., 2022) in which modellers are offered opportunities to use, adapt and learn mathematics in different contexts for various purposes; and similarly (ii) that engaging in the process of writing, here generally understood as the process of producing any written text (like a novel, essay, report, biography etc.), is also a creative process (Piirto, 2018). From these premises we draw on selected literature to first express and elaborate on the similarities between the modelling and the writing process, and then to reconceptualise the so-called Wheel of Writing with its *purposes* and *acts of writing* (Berge et al., 2016) in the context of mathematical modelling. In this theoretical inquisition, we asked ourselves the following questions: 1) *What similarities between mathematical modelling and the writing process can be identified when compared from the viewpoint of creative problem-solving components?* and *2) What could a Wheel-of-Writing-inspired conceptualisation of*

mathematical modelling look like and entail? and *What would be the corresponding purposes and acts of modelling be given the similarities in the creative problem-solving process components?*

Before reporting our initial exploration of these questions, we briefly present the main premises of mathematical models and modelling and the wheel of writing.

Mathematical models and modelling

There are numerous approaches and frameworks for mathematical modelling in educational research (cf. Kaiser and Sriraman, 2006). In this paper, we follow Lesh and Doerr (2003) in understanding models as "conceptual systems (consisting of elements, relations, operations, and rules governing interactions) that are expressed using external notation systems, and that are used to construct, describe, or explain the behaviors of other system(s)" (p. 10). In this perspective, mathematical models are "purposeful mathematical descriptions of situations, embedded within particular systems of practice that feature an epistemology of model fit and revision" (Lesh and Lehrer, 2003). That is, we adopt a broad perspective on mathematical modelling in which mathematical modelling is viewed as a general problem-solving process that involves the mathematization of real-world problems, situations, or phenomena, resulting in a model that helps to make sense of the task or situation at hand (Niss and Blum, 2020). All notions and concepts used in research are to varying degrees theory laden (Niss, 2007), and we acknowledge that the above notions of models and modelling are also theory laden. However, we argue that these are generally accepted definitions in our field of research when taken literally without considering deeper underlying theoretical and philosophical considerations. Hence, in this paper, we elaborate aspects of models and modelling with a broader outlook through contemplating about the parallelism of the modelling process and the purposeful writing process.

The Wheel of Writing (WoW)

In context of a curriculum reform on writing competence in Norway, Berge et al. (2016) developed the so-called Wheel of Writing (WoW), which is "a tool for conceptualising the complexity of writing in different cultural and situational contexts that constitute the arenas for writing in a society, including writing in different school subjects" (p. 172). The WoW conceptualises writing as a creative process in which writing is an activity that individuals (or groups) express themselves through different *acts of writing (to reflect, to explore, to describe, to interact, to convince, and to imagine) based on their purpose of writing (identity formation, knowledge development, knowledge organization and storage, exchange of information, persuasion and creation of textual worlds)*; see Figure 1. The blue double arrows in Figure 1 below indicate that the WoW is fundamentally dynamic in the sense that the two concentric circles that make up the model can be freely rotated. This means that different acts of writing can be combined with multiple purposes, and also that a text can be the result of more than one act of writing. It is worth noting that writing as understood in the WoW always takes place in a cultural and situational context.

Similarities between mathematical modelling and writing from the lens of creative problem-solving

As the first step into our theoretical query, we identified the similarities between mathematical modelling and the writing process, using Treffinger's (1995) *Creative Problem Solving* (CPS)

framework. Treffinger (1995) described the CPS process as a mutual interaction between three major components, *Understanding the Problem, Generating Ideas*, and *Planning for Action*, and described six more specific stages of the CSP process along these components. Specifically, Treffinger divided the first component, *Understanding the Problem*, into the stages of *mess-finding, data-finding*, and *problem-finding*; associated the second component, *Generating Ideas*, with the stage of *idea-finding*; and considered the last component, *Planning for Action*, to involve *solution-finding*, and *acceptance-finding*. Neither the CPS components nor the stages are linear in nature in the CPS process, rather they could be engaged in the process as many times as needed. Furthermore, although not listed explicitly as components or stages, Treffinger (1995) discussed that *revisions and refinements*, and *presentation and communication* were implicitly intertwined in the *Generating Ideas* and *Planning for Action* components.

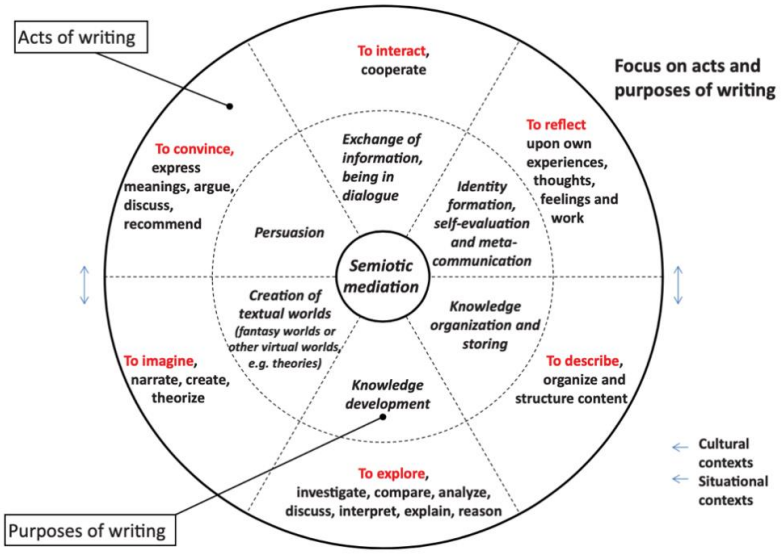

Figure 1: The Wheel of Writing (Berget et al. 2016, p. 180)

Considering the stages in the CPS process, our generally adapted notions of models (cf. Lesh and Doerr, 2003) and mathematical modelling (cf. Niss and Blum, 2020), and the view of the writing process as discussed in Berge et al. (2016), we identified the *categories of similarities* between the modelling process and the writing process, presented in Table 1. We note that since neither the CPS process nor the modelling and writing processes are linear in nature, Table 1 does not present steps of the modelling cycles (c.f. Niss and Blum, 2020) or steps taken in the writing process. Rather, the table structures the similarities between modelling and writing processes from the CPS perspective. To facilitate connections to the existing theoretical discussions on modelling, we briefly use of the notions of *situation-*, *real-* and *mathematical models* (cf. Borromeo Ferri, 2006) to communicate about different phases of the modelling process.

As seen in Table 1 below, we aligned the CPS stages with the modelling and writing processes. To provide a more complete picture of the processes, we additionally considered *revisions and refinements* and *presentation and communication* noted by Treffinger (1995) and named new stages for CPS needed to revise, refine, and present a model and a text. Intrigued by these similarities between modelling and writing that we identified and outlined in Table 1, we asked ourselves the

questions *What could a WoW-inspired perspective for mathematical modelling look like and entail?* and *What would the corresponding purposes and acts of modelling be given the similarities in the creative problem-solving process components?* Hence, the below mentioned identification step served as a methodological organization for us to explore these questions, which report on in what follows.

Table 1: Comparing and outlining similarities between the modelling and the writing processes

Stages in the creative process	Mathematical modelling	Writing	Categories of similarities**
Mess-Finding *Problem-Finding*	Defining and understanding the problem; identifying potential domains, disciplines, potential general ways of working; making assumptions (this akin to creating a situation model	Creating outline or a plan; organizing once's thoughts and ideas into a coherent structure; creating a vision of the text.	**Planning and Structuring**
Data-Finding	Collecting information and (if needed) data to inform the model to be developed. This facilitates the modeller to transitioning toward a real model.	Gathering information, facts, and references to support arguments or narrative in the written text.	**Background research and data collection**
Problem-Finding *Idea-Finding*	Formulating the initial models using prior mathematical knowledge; transforming the real model into a mathematical model.	Creating a first draft; tentatively writing the main ideas (knowing it will need refinement).	**Drafting and initial formulation**
Idea-Finding *Solution-Finding*	Working mathematically with the mathematical model to find mathematical answers.	Working on developing and realising the plan and composing a coherent text or narrative.	**Implementing solution strategies and doing the work**
Acceptance-Finding	Evaluating and validating the mathematical outcome with respect to both the calculations done and their interpretation in relation to the context of the original situation and problem. This can be done by for example collaborating with colleagues, consulting experts, or collecting more data.	Revising the first draft to improve clarity, coherence, and style, often through multiple iterations. This can involve seeking feedback from peers, editors, or reviewers to improve the text.	**Evaluation and Validation**
*(Re)Problem-Finding** *Extension-Finding**	Incorporating the evaluation results and determine the possible revisions and refinements to improve the mathematical model.	In-cooperating comments and feedback from the evaluation and validation to improve the text.	**Revisions and Refinements**
*Communicate-Finding**	Communicating the results and implications of the model and the modelling process in a suitable format (report, presentation, or publication).	Presenting the final written text in a clear and engaging manner (regardless of type of text).	**Presentation and Communication**

**New stages named by the researchers for the CPS process; **Identified categories of similarities*

The Wheel of Modelling - A *WoW-inspired perspective for mathematical modelling*

Drawing on the connections presented above in Table 1, we elaborated on purposes and acts of modelling, in order to construct a Wheel of Modelling (WoM) with the hope to provide a productive perspective to think about models and modelling. Similar to the writing acts and purposes in the WoW, we consider that purposes of modelling aim to describe and capture key aspects of modelling carried out given specific rationales and purposes. Acts of modelling on the other hand aim to describe and capture key aspects of the activities involved in the modelling process. Table 2 below provides an overview and summary of the discussion and elaboration of the parallelism between the purposes

and acts of modelling and writing processes. Figure 2 then pulls all the modelling purposes and acts together, presenting the Wheel of Modelling (WoM). Mathematical models are placed in the centre of the WoM since we argue that it is a mathematical model that constitutes the mediating artifact enabling the realisation of modelling purposes through modelling acts.

Table 2: Comparing and summarising WoW- and WoM purposes and acts

WoW purposes	WoM purposes	WoM acts	WoW acts
Exchanging information and being in dialogue	Using in the context of collaborative interdisciplinary settings	Collaboration and communication across disciplines	Interact, cooperate
Persuasion	Prescriptive modelling	Use the models to convince the clients about their viability; express, argue and discuss the reasonability of the made underlying assumptions and methods used; and additionally, that the recommendations based on the models are ethical and fair	Convince, express meanings, argue, discuss, recommend
Organising, systematising and storing knowledge	Descriptive modelling	Capture, represent and/or describe the situation or phenomenon being modelled	Organise, systematise and store
Knowledge development	Generating understanding, explanations and knowledge	Explore, investigate, compare, analyse, discuss, interpret, explain and reason	Explore, investigate, compare, analyse, discuss, interpret, explain and reason
Identity formation, self-evaluation and meta-communication	Self-conception as a modeller and a more nuanced view of mathematics	Reflect on both the model and the modelling process, self-evaluation, and develop awareness about one's own modelling competencies as well as one's attitudes towards and comprehension of mathematics	Reflect on own work, experiences, thoughts and feelings
Creation of textual worlds	Underpinning/facilitating simulations	Adapt and implement a mathematical modelling so that it can be used as part of a simulation, connect to suitable technology, programming, and use visualization aids	Imagine, narrate, create and theorize

It is important to stress the dynamical relation between the two concentric circles that make up our constructed WoM model in Figure 2. This means that although one specified modelling act looks radially aligned with one specified modelling purpose, this relationship is nor static or one-to-one. The elaboration below is structured based around the six modelling purposes which together constitute our first iteration of the WoM model. In an attempt to be as clear and transparent as possible about the parallelisms identified between modelling and writing, all WoW purposes and acts in what follows are written in *italics*, whereas WoM purposes and acts are underlined.

Collaborative interdisciplinary modelling: The WoW act *to interact* is foremost put forward "with the purpose of establishing and/or strengthening contacts with other people" (Berge et al., 2016, p. 181), but also with the WoW purpose of *exchanging information and being in dialogue* across disciplinary subjects and topics. This latter aspect of the WoW resonates with the modelling purpose of using modelling in the context of collaborative interdisciplinary settings such as STEM projects, cross-curricular collaborations, and STEM education in general. In line with this type of WoM purpose are modelling acts that emphasise collaboration and communication across disciplines. The former WoW act on the other hand aligns with the act of modelling that is reflected in the

collaborative work of groups of students in co-constructing of models in a classroom setting as well as in interdisciplinary teams.

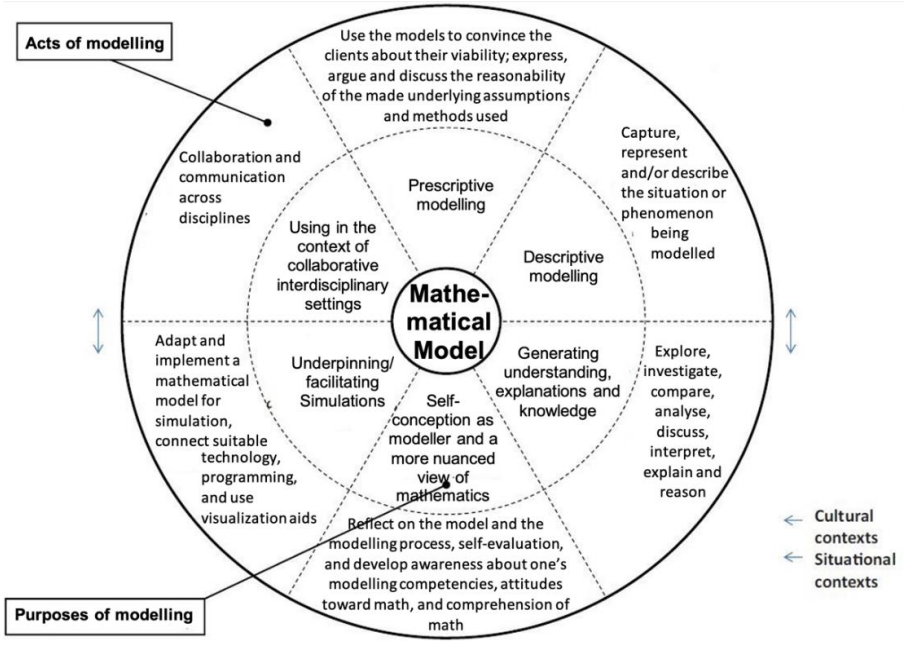

Figure 2: The Wheel of Modelling (WoM)

Prescriptive modelling: The WoW act *to convince* is centred around expressing a position or recommendation about how (some aspect of) the world should be given the WoW purpose "*to persuade* a reader to share our position" (Berge et al., 2016, p. 181, emphasis added). In our conception of the WoM, this is akin to the modelling purpose of prescriptive modelling which aims to design, organise or structure a certain aspect of the real world, often to achieve a specific goal (Niss, 2015). The modelling acts especially coming to the fore in prescriptive modelling are similar to the corresponding acts of WoW, namely, to use the models to convince the clients about their viability; express, argue and discuss the reasonability of the made underlying assumptions and methods used; and additionally, that the recommendations based on the models are ethical and fair.

Descriptive modelling: The WoW purpose *to organise, systematise and store knowledge*, is achieved by engaging in these very acts: *organising, systematising and storing* (Berge et al., 2016). Broadly speaking, these WoW purposes and acts have natural parallels in the WoM. The corresponding modelling purpose is descriptive modelling (Niss, 2015), which focuses on describing events, phenomena or situations given existing conditions. The key modelling acts to achieve descriptive models are to capture, represent and/or describe the situation or phenomenon being modelled.

Generate understanding, explanations and knowledge: In the WoW, the purpose of *knowledge development* is achieved by acts like *exploring, investigating, comparing, analysing, discussing, interpreting, explaining and reasoning*. Berge et al. (2016) describe that the purpose of knowledge development for example involves finding "the most valid interpretation of a phenomena" (p. 182) by acts aiming at critically examine evidence and assumptions. This type of knowledge development in the context of the WoM has the analogue modelling purpose of generating understanding,

explanations and knowledge, and the analogue modelling acts of exploring, investigating, comparing, analysing, discussing, interpreting, explaining and reasoning.

Self-conception as modeller and a more nuanced view of mathematics: The WoW act *to reflect focused on own work, experiences, thoughts and feelings* align with the WoW purpose of *developing self-insight, identity and own understanding* (Berge et al., 2016). This WoW act strives to achieve WoW purposes related to *identity formation, self-evaluation and meta-communication*. In a modelling context, this is similar to the modelling purpose of building one's self-image, confidence and attitudes as a modeller, as well as using models and modelling for students to form a more nuanced view of what mathematics is and its application and role in science, work- and everyday life. The modelling acts through which this is accomplished involve reflecting on both the model and the modelling process, self-evaluation, and developing awareness about one's own modelling competencies as well as one's attitudes towards and comprehension of mathematics.

Underpinning/facilitating simulations: When the WoW purpose is the *creation of textual worlds* the aim is to engage in acts resulting in a described "reality [that] is constituted by the text. That is, a reality that does not exist in other places than the fiction construed and expressed in the text." (Berge et al., 2016, p. 182). The WoW acts connected to those WoW purpose are *to imagine, to narrate, to create* and *to theorize* (the latter in the sense of speculating). The corresponding WoM purpose is to use models in (doing) simulations, based on the fact that simulations for the most part are run based on mathematical models. This exhibits the fictive dimensions mirrored in the WoW purpose *creation of textual worlds*; simulations are not real, and their existence depend on the models and the actual simulations being executed. In the WoM therefore the corresponding modelling acts heavily rely on aspects of adapting and implementing a mathematical model as a basis or part of a simulation: connecting to suitable technology, programming, and using (technological) visualization aids.

Discussion and outlook

In this theoretical paper, we introduced a perspective on mathematical modelling by exploring the similarities between the modelling and the writing processes, and aligning these with components of the creative problem solving process. By reconceptualising the 'Wheel of Writing' as a 'Wheel of Modelling', we articulated different acts and purposes of mathematical modelling mediated by mathematical models. Using theoretical frameworks from other fields, such as the didactics of language, forces us to clarify our own conceptual notions and their meanings. While different fields may use similar terminology with different meanings, these external frameworks can offer new perspectives and enrich mathematics education. Although this is our first attempt to conceptualise the 'Wheel of Modelling', this perspective and approach opens up several avenues for discussion, future research and development: (i) future work should focus on refining and elaborating the WoM model. This includes introducing additional modelling purposes and connected modelling acts. For instance, 'using modelling to build and develop theory' could be explored whether it fits within the use in/for simulation purpose, the purpose of generating understanding, explanations, and knowledge, or if a new purpose in the WoM is needed; (ii) new ways of thinking about modelling like the one presented in this paper could significantly impact the integration of mathematical modelling into the classroom. By dynamically connecting different acts and purposes of mathematical modelling, researchers and

educators alike can focus on areas that potentially lead to innovative teaching methods and improved student engagement. By addressing and exploring issues raised by these points, we are hopeful that we can continue to develop and refine the WoM model and use it in systematic reviews in the area of mathematical modelling, as well as stimulate further theoretical discussions.

Modelling indoors and outdoors: A comparison of the student's interest and competence development in two task settings

Simon Barlovits[1], Anton Kunz[1] and Matthias Ludwig[1]

[1]Goethe University Frankfurt, Institute of Mathematics and Computer Science Education, Frankfurt, Germany; barlovits@math.uni-frankfurt.de

Mathematical modelling aims at transferring mathematical knowledge to real-life phenomena. This competence can be promoted in different school settings, e.g. when working with text and pictures related to the task situation in the classroom or when exploring a real object outdoors. While recent research has qualitatively compared the work processes in different task settings, this study aims to address the lack of quantitative results. The study firstly investigates the student's interest in outdoor and indoor task settings. Secondly, it focuses on the development of modelling (sub-)competences. To this end, a quasi-experimental study design was conducted with 10th graders of a German grammar school (15–16 years old; N = 80). The results show that the students have a significantly higher interest in modelling outdoors than in working on similar tasks in the classroom. However, no differences were found between the two settings in terms of the student's competence development.

Keywords: Competence, interests, mathematical modelling, outdoor education.

Introduction

Mathematical modelling aims to investigate real-world phenomena by transferring a given situation into mathematics and vice versa (Blum. 2015). In classroom practice, mathematical modelling activities are usually initiated by a task description, supplemented by a picture of the real-world situation (e.g., Blum, 2015). This approach is referred to below as the *indoor setting*. Also, a modelling process can also take place in an *outdoor setting*, where the real object is investigated on site (Buchholtz, 2021; Hartmann & Schukajlow, 2021; Jablonski, 2023a, 2023b). The present study focuses on a comparison of the indoor and outdoor settings. Within a quasi-experimental study, we investigate (1) the student's interest and (2) their ability to develop modelling (sub-)competences.

Theoretical Background

According to the modelling cycle by Blum and Leiss (2007), mathematical modelling can ideally be depicted as a process of seven modelling steps (also: modelling sub-competences; Hankeln, 2019). A real situation is *understood*, *simplified/structured* as well as *mathematicised* with regard to a given task. The resulting mathematical model is *worked on mathematically* before the mathematical result is *interpreted, validated,* and *exposed* in relation to the real situation (Blum & Leiss, 2007). However, as Buchholtz (2021) points out, the nature of modelling activities still depends on the setting.

> In contrast to the photo [indoors], the visual-haptic presence of the [outdoor] object and its actual size would allow for a broader range of approaches […] and an easier interpretation of the mathematical solution […] in relation to the student's data collection (Buchholtz, 2021, p. 144).

Due to the high degree of contextualisation, modelling in the outdoor setting enables students to relate directly to the real object during the modelling steps of *simplification/structuring, mathematisation,*

interpretation and *validation* (Buchholtz, 2021). Recent research finding on the nature of modelling processes in the indoor and the outdoor settings are summarised below.

State of the Art

Affective attitudes: Regarding the outdoor task setting, several studies emphasise the high interest of students to perform modelling activities directly at the object's location (e.g., Barlovits & Ludwig, 2023; Cahyono, 2018). On the other hand, by comparing the student's interest in indoor and outdoor settings, Hartmann and Schukajlow (2021) find no statistically significant differences between both settings in an experimental study with $N = 43$ lower secondary students. Also, Jablonski (2023a) reports non-significant differences in the student's interest based on a study with $N = 29$ lower secondary students who worked in both settings. Jablonski (2023a) explains this as follows: Firstly, the study was conducted as part of an enrichment programme for gifted students, which limits its transferability to classroom practice. Secondly, the study shows a ceiling effect, as the students are highly interested in both indoor and outdoor settings. Given the promising results of outdoor mathematics in terms of the student's interest, and the relatively small sample sizes of the studies by Hartmann and Schukajlow (2021) as well as Jablonski (2023a), we see a need for further research on the affective attitudes of learners when modelling in indoor and outdoor settings.

Modelling sub-competences: In a qualitative study, Jablonski (2023b) highlights that working indoors and outdoors is associated with different foci in the modelling competences of *simplification/structuring* and *mathematisation*. In terms of *simplification/structuring*, students are aware of the limitations of using photos to analyse a real situation when working indoors. They accept assumptions and estimates – and the resulting inaccuracies – as an inherent aspect of the indoor setting. In contrast, when working outdoors, students intensively discuss their real-world model, the availability of data and ways to minimise inaccuracies. Consequently, students in the outdoor setting focus primarily on the process of data collection in terms of *mathematisation* (Jablonski, 2023b). In contrast, students in the indoor setting discuss intensively the extent to which the perspectives of the two-dimensional photos might influence their mathematical assumptions about the three-dimensional real-world object (Jablonski, 2023b). These observations are supported by a survey of lower secondary students, who perceive *simplification/structuring* and *mathematisation* as significantly different indoors and outdoors (Jablonski, 2023a). In terms of *mathematising*, significant differences in the use of strategies can also be found for pre-service teachers in the indoor and outdoor settings (Segura et al., 2023).

These findings support the meaning of contextualisation in the outdoor setting described by Buchholtz (2021). So far, however, it remains unclear to what extent the different modelling processes indoors and outdoors lead to a comparable or different competence development.

Research Questions

The present study aims to address the two identified research gaps. Firstly, we investigate how the two task settings affect the student's interest, i.e., whether the work on tasks indoors or outdoors leads to greater interest in the modelling process. Secondly, we investigate to what extent the task settings impact the development of modelling competences. Here, the modelling sub-competences of

simplification/structuring, *mathematisation* and *interpretation* as well as *validation* are focused, as they may differ between the outdoor and indoor settings due to their high degree of contextualisation (cf. Buchholtz, 2021). These considerations lead to the following two research questions.

[RQ 1] To which extent does the student's interest in modelling tasks depend on the setting?

[RQ 2] To which extent does the student's development of modelling competences depend on the setting?

Methods

To answer the research questions, a quasi-experimental study using a pre-post-test design was conducted in Spring 2024. A total of $N = 80$ students from four classes took part in the study, processing up to four modelling tasks in 90 minutes. They attended the 10th grade of a German grammar school (15–16 years old) and collaborated in teams of three students.

Two classes were assigned to the experimental condition, i.e., the *outdoor group* ($N_1 = 43$). The students were equipped with folding rulers and calculators so that they could take measurements and perform calculations directly on the object's side. As a control group, two classes worked on comparable modelling tasks in the classroom (*indoor group*; $N_0 = 37$), equipped with rulers and calculators. The students were supported by pictures of the task situation including a reference object. Both the indoor and outdoor groups worked with identical task formulations on the same objects.

All tasks of the study dealt with the surface area or volume of composite solids. An exemplary task, called "the bench", is formulated as follows. *"The bench around the tree is to be coated with a protective varnish (without the legs). How many square metres of wood need to be coated with varnish?"*. The task is illustrated in Figure 1 for both the indoor and outdoor settings.

Figure 1: The task "The bench" in the outdoor setting (left) and its graphical representation in the indoor setting (all pictures from left to right)

Test instruments

In view of the first research question, the student's interest in mathematics as well as their interest in the task setting was surveyed. In a pre-test, the student's interest in mathematics was assessed using four items on a four-point Likert scale. The items were selected from Rakoczy et al. (2005), such as

"I like mathematics" (from 0 = "I totally disagree" to 3 = "I totally agree"). For the post-test, the items were adapted to assess the student's perception of the setting, e.g. *"I like these kinds of tasks [worked on during the intervention]"*.

With regard to the second research question, two performance tests on modelling competences were completed by the students, namely a pre-test before and a post-test after the intervention. For each modelling sub-competence, four items were selected from Hankeln (2019) that showed high discriminative power for the related construct. From these items, two different performance test versions A and B were created, where both tests contained two items each on the modelling sub-competences *simplification/structuring*, *mathematisation*, *interpretation* and *validation*.

In a rotation design, one class of the indoor group worked on test version A as a pre-test and test version B as a post-test. The other class of the indoor group worked on the test versions in reverse order. This test rotation was also used for the outdoor group. Thus, all participating students completed all selected items exactly once, i.e., half in the pre-test and half in the post-test.

Data processing

The data processing and analysis was carried out in *RStudio*. Due to the rotation design, only half of the test items in both the pre-test and post-test could be processed by the students, i.e. the other items were *missing by design*. In addition, some items that were presented to the students were not answered due to time constraints. To maximise the power of the statistical test for data analysis, all missing values were imported using the *missForest* algorithm (Stekhoven et al., 2012). The *Proportion of False Classifications (PFC)*, estimated by *missForest*, was around 21 %. This value is substantially lower than the expected value of misclassification (60 %). Further, the PFC was at a similar or lower level to the results found by Stekhoven et al. (2012), indicating a successful imputation.

For both the student's interest in mathematics and in the setting, the four items showed a satisfactory internal consistency (Cronbach's α_{math} = .88 and α_{sett} = .89). Therefore, a sum scale (ranging from 0 to 12) was computed for both scales. On the other hand, the four items per modelling sub-competence test did not show satisfactory internal consistency.[1] This issue was addressed by selecting subsets of two to three items per modelling sub-competence. Thus, out of a total of 16 items, seven poorly fitting items were excluded from the data analysis. This resulted in four subsets that achieved at least an acceptable level of reliability of Cronbach's $\alpha \geq .7$ for each, pre- and post-test. Only the mathematisation competence at the pre-test is below this threshold value (α = .61). On this basis, sum scales were computed for all subsets of the four modelling sub-competences (ranging from 0 to 3 for *mathematisation* and 0 to 2 for the other sub-competences).

In addition, all pre-test items analysed were summed to form a scale representing an overall *modelling competence* in relation to the test instrument used (scale from 0 to 15; Cronbach's α = .72). Given the relatively small sample size, which limits the number of predictors for the linear regression, this scale is used as a proxy for all four sub-competences in the data analysis. This is justified because all four

[1] The items were rated according to Hankeln (2019) by 0 and 1 points (dichotomous) or 0, 1 and 2 points (polytomous). In contrast to Hankeln (2019), classic test theory instead of item-response theory was applied for data processing.

sub-competences show a strong correlation with the *modelling competence* scale (*simplification/ structuring*: r = .55; *mathematisation*: r = .81; *interpretation*: r = .54; *validation*: r = .55).

For analysing the data, *robust t-tests* via the *R* package *WRS2* (Mair & Wilcox, 2020) as well as *robust multiple linear regression* via the *R* package *robustbase* (Todorov & Filzmoser, 2009) were used. Robust approaches were chosen because the scales of the modelling (sub-)competences partially violate the test assumptions of normal distribution and homoscedasticity.

Results

Preconditions

In order to check for comparable preconditions between the two groups (indoor and outdoor setting), we compare the mathematical interest, as well as the modelling (sub-)competences via *robust t-tests* (10 % trimmed means; 2,000 bootstraps). No significant differences are found between the two groups, neither for the mathematical interest, $t(64.00) = -0.30$, $p = .765$, nor for their modelling competence in the pre-test, $t(63.68) < 0.01$, $p = .996$. This is also valid for the sub-competences of *mathematisation*, *interpretation* and *validation*. Only for *simplification/structuring*, the assumption of equal preconditions cannot be hold. Here, the *robust t-test* shows a significant difference in favour of the outdoor group, $t(63.91) = -2.23$, $p = .029$, $\xi = .35$ (small to medium effect). Nevertheless, it can be assumed that the two groups are comparable, despite small deviations.

RQ1: Interest in modelling settings

To investigate the student's interest in indoor and outdoor modelling settings, three predictors are considered: the group, the student's interest in mathematics as well as their score in the pre-test of modelling competences. The latter two predictors are centred. The three models are shown in Table 1.

The first model ($R^2 = .09$) shows that the average interest in working on the modelling tasks in the indoor group is 6.11 points (scale from 0 to 12), while the interest of the students in the outdoor group is on average 1.60 points higher than the interest of the indoor group, $p = .009$.

Table 1: Robust multiple linear regression on the student's interest in modelling settings

Predictors	**First model**	**Second model**	**Third model**
Intercept	6.11 ***	6.19 ***	6.22 ***
Group *(indoor setting = 0)*	1.60 **	1.62 **	1.56 **
Interest in mathematics		0.31 **	0.41 *
Modelling competence *(pre-test)*		0.13	0.26 °
Group * Interest in mathematics			-0.23
Group * Modelling competence			-0.22

In the second model (R^2 = .22), the student's interest in mathematics and the modelling competences assessed in the pre-test are added. This leads to a significantly higher variance explanation compared to the first model, $F(2) = 15.14$, $p < .001$. While the intercept and the influence of the group are comparable to the first model, the second model confirms that the student's interest in mathematical modelling depends on their general interest in mathematics. It shows that a student with a one-point higher interest in mathematics (scale from 0 to 12) tends to have a 0.31-point higher interest in the intervention, $p = .004$. Remarkably, but possibly due to the relatively small sample size of $N = 80$, the modelling competence is not significant, $p = .124$. The predictor shows that a student with a one-point higher pre-test competence in mathematical modelling (scale from 0 to 15) tends to have a 0.13-point higher interest in the intervention. The standardised regression coefficients indicate that the student's interest in mathematics ($\beta = .32$) is two times as influential as their modelling competence ($\beta = .16$) in predicting the student's interest in the setting.

The third model (R^2 = .28) includes the interaction effect of the group and the other two predictors in the analysis. It does not provide a significantly better description of the data than the second model, $F(2) = 4.23$, $p = .120$. Being aware that this might be caused due to a lack of power caused by the relatively small sample size, the third model is briefly analysed: The intercept as well as the influence of the group remain stable, while for the indoor group a stronger influence of the interest in mathematics ($b = .41$), and of the modelling competence ($b = .26$) on the interest in the setting can be found. The model does not show significant interaction effects between the group and the interest in mathematics, $p = .271$, or the modelling competence, $p = .200$. Nevertheless, it can be hypothesised that an interaction effect is likely to be found when a larger sample size is investigated: The student's interest in the setting seems to be about twice as strongly influenced by the interest in mathematics of the indoor group ($b = .41$, $\beta = .43$) compared to the outdoor group ($b = .18$, $\beta = .18$). Similarly, it can be hypothesised that the interest in the setting is more strongly influenced by the modelling competence in the indoor group ($b = .26$, $\beta = .33$) compared to the outdoor group ($b = .04$, $\beta = .05$).

RQ2: Development of modelling competences

To investigate the impact of the setting on the development of modelling (sub-)competences, *robust linear regression models* are used to predict the modelling (sub-)competence at the post-test by the group, the modelling (sub-)competence at the pre-test and the interaction effect of the two predictors.

For the *modelling competence*, the indoor group achieved a mean pre-test score of 7.91 points (SD = 3.18). In the post-test, the score remained almost unchanged (mean = 7.81), while wider range of scores was observed (SD = 4.03). These observations are similar for the outdoor group (pre-test: mean = 7.98, SD = 3.59; post-test: mean = 7.95; SD = 3.73). Consequently, neither a significant group effect, $p = .591$, nor an interaction effect of the group and the pre-test score, $p = .736$, can be found in the regression model. Only the pre-test score for the *modelling competence* is highly significant, $p < .001$. The regression model (R^2 = 38 %) predicts that per each added point on the pre-test score a 0.74-point higher result in the post-test score (scale from 0 to 16 each) can be expected.

These results can be maintained for the modelling sub-competences of *simplification/structuring*, *mathematisation*, *interpretation* and *validation*. The regression models each show a significant relationship between the pre- and the post-test, while no group or interaction effect can be found.

Discussion and Outlook

Mathematical modelling aims to investigate real-life situations through the application of mathematical knowledge (Blum, 2015). As mathematical modelling processes can be initiated inside and outside the classroom (Buchholtz, 2021; Hartmann & Schukajlow, 2021; Jablonski, 2023a, 2023b), this study investigated the role of the modelling task setting. It compared the processing of modelling tasks based on photos (indoor setting) with the work on analogous tasks at the location of the real object (outdoor setting). In particular, it examined the impact of the setting on the student's interest (RQ1) as well as on the development of student's modelling (sub-)competences (RQ2).

With regard to RQ1, the outdoor group self-reported a 1.60-points higher interest in the setting compared to the indoor group (scale from 0 to 12), resulting in a significantly higher interest in working in the outdoor setting, $p = .009$. This finding supports the high student's interest in outdoor modelling reported by Barlovits and Ludwig (2023) as well as Cahyono (2018). On the other hand, it contrasts with the findings of Hartmann and Schukajlow (2021) as well as Jablonski (2023a).

This paper went beyond the latter two studies by considering further predictors of the student's interest, namely the interest in mathematics as well as the modelling competence. The results show for both settings that the interest in the modelling setting is more strongly influenced by the student's interest in mathematics than by the student's modelling competence. Moreover, this study can be seen as a first indication that the student's interest in the outdoor setting might be less dependent on their mathematical interest and modelling competence than in the indoor setting. This hypothesis might be supported by the findings of Buchholtz (2021) and Jablonski (2023a), who emphasised that modelling processes outdoors are different from modelling processes indoors. Nevertheless, further studies with larger samples are needed to validate the aforementioned hypothesis. These future studies might also consider additional predictors, such as the student's intra-mathematical competence (as precondition) as well as their performance during the intervention (as process data).

With regard to RQ2, the pre-scores of the modelling (sub-)competences were significant predictors of the corresponding post-scores. However, no learning gain was observed for any of the modelling (sub-)competences. Moreover, no significant group or interaction effects were found. These findings may be due to two limitations of the present study. Firstly, although well-tested items were selected from Hankeln (2019), seven out of 16 items showed a significant misfit with the other items of the related construct and thus had to be excluded from the study. This may limit the variation of the data, which in turn affects the results in relation to RQ2. Secondly, given the design of the study, (i) a relatively small sample size of $N = 80$ students participated (ii) in a short-term intervention of only 90 minutes. These limitations open the field for further research on the development of modelling (sub-)competences in different settings, with a particular focus on the long-term perspective.

Students managing of modelling problems with superfluous data

Caterina Bassi[1] and Rosa Iaderosa[1]

[1]Politecnico di Milano, Department of Mathematics, Milan, Italy; caterina.bassi@polimi.it

Research has shown that students often encounter difficulties in processing modelling problems with missing data. Modelling problems often also contain superfluous data and differentiating between these data and relevant ones is a key competency for carrying out the modelling process. We thus investigate students' processing of data in a modelling task, wondering to what extent they differentiate between relevant and superfluous data, and how can the anomalous use of relevant and superfluous data be characterized. We perform a qualitative content analysis of the protocols produced by 102 secondary school students, while working in groups. The analysis shows that, for most data, students successfully distinguished relevant and superfluous data. It also provides a first characterization of students' anomalous use of data, which confirms the students' tendency of focusing on numerical data and not considering reality in modelling problems.

Keywords: mathematical modelling, superfluous data, data representation.

Introduction and theoretical background

Problem solving activities in schools often involve the use of word problems. which verbally present problem situations with questions emerging in them. The answer to these questions can be obtained working mathematically with the numerical data available in the problem statement (Verschaffel et al., 2020). Word problems in school settings are mostly well-defined, in the sense that all relevant data are present in the problem statement and no superfluous data is included (Kanefke & Schukajlow, 2022). Authentic problems encountered in the real-world do not often share these features: some real-world problems can be solved with the help of mathematics, but questions are less explicit, and it is often not clear which numerical data and mathematical tools have to be employed for their resolution (Verschaffel et al., 2020). In fact, solving such problems requires performing a complex process of translating between the real-world and mathematics, namely a Mathematical modelling (MM) process (Blum, 2015). Such a process can be represented by the Blum and Leiss (2007)'s modelling cycle, which is composed of seven steps. The first two steps occur within the real-world and enable the transition from the real situation to a situation model (understanding) and then to a real model (simplifying/structuring). The third step (mathematizing) leads to the mathematical model within the domain of mathematics, where it is possible to work mathematically (step 4) to achieve a mathematical result. The next two steps allow for returning to real-world, by interpreting (step 5) and validating (step 6) the results. Finally, in step 7, the results are presented in the real situation. Due to the complexity of the modelling process, MM is highly demanding. Literature (e.g., Galbraith and Stillman, 2006) has shown that each step can be a cognitive barrier for students, even the first steps, namely understanding the task and simplifying/structuring the model situation. Furthermore, many empirical studies (e.g., Verschaffel et al., 2000) have shown that students often treat modelling problems as if they were well-defined word problems, by putting into play superficial solution strategies, for example executing mathematical operations with the numbers presented in the problem, without considering reality in their solution process. For example, in Kanefke and Schukajlow (2022),

this tendency is identified as one of the possible causes for students' difficulties in processing modelling problems with missing data, with students encountering difficulties in identifying that data are missing. Other studies (e.g., Fung Lin, 1990) highlight that the lack of consideration of reality can be the cause of students' difficulties in distinguishing relevant and superfluous information when processing word-problems with irrelevant data.

As highlighted in Maas (2010), the presence of superfluous data is, together with relevant and missing data, one of the features that could distinguish modelling problems from well-defined word-problems. In fact, "to look for available information and to differentiate between relevant and irrelevant information" is, according to Maas (2006), a sub-competency crucial to the initial steps of the mathematical modelling cycle. However, while students' processing of modelling problems with missing data has been the object of research in the past (Kravitz et al., 2018; Kanefke & Schukajlow, 2022), to the best of our knowledge, no study has focused specifically on how students process superfluous data while solving a MM problem. Thus, our aim is to contribute to identifying the reasons for possible students' difficulties in dealing with this particular feature of MM problems. Thus, a MM task, which will be described in detail in the next section, was delivered to students and students' protocols were collected as data. The paper is structured as follows: we first present the research context, the data gathering and the method of analysis. Afterwards, we report the results and, finally, we discuss the findings according to the research questions.

Research context

The modelling task was co-designed by two researchers (one of whom is the author) and 4 teachers participating in a community of practice (Wenger, 1998) on MM. The task was then proposed by the teachers to their students, who worked in groups. Both teachers and students had little experience in MM. The task, translated in English, was as follows:

A new link for the Rimini airport

The city of Rimini is planning to develop a new link to allow passengers to comfortably move from the Fellini airport to the "Metromare" stop (CRT Coastal Rapid Transport). Two alternatives have been identified: (1) Elevated mechanized pedestrian walkway. (2) Shuttle. There is the necessity of estimating the travel time for the two alternatives, to understand which one is the most advantageous in terms of time. Attached are the two projects' sheets. Which one of the two alternatives is most advantageous in terms of travel time? Explain the reasoning you carried out to answer the question through a brief report, to be delivered to the project managers.

- **Sheet 1: Elevated mechanized pedestrian walkway.** The first alternative consists of an elevated mechanized pedestrian walkway (see Figure 1). The key features are the following: it is sheltered and protected (from sun and bad weather); it is elevated; it is mechanized with a moving walkway along 70% of the total path, to reduce the time and inconvenience of pedestrian movement. We report the moving walkway datasheet: energy efficiency class: A+++; connectivity: ok; operating environment: indoor/semi-outdoor; speed: 2m/s; slope: 0°-6°, maximum length: 900m.

Figure 1: blueprint of the project. The path of the pedestrian walkway is highlighted in black

- **Sheet 2: shuttle.** To avoid a pedestrian zone, the shuttle would cover 1.5km. We report the shuttle datasheet: battery capacity: 300kWh; maximum capacity (seated-standing): 40-20 people; average waiting time: 5 minutes; speed:15 km/h.

For the sake of clarity, we now present an a-priori analysis of the task. To this end, we resort to the classification of modelling tasks proposed in Maas (2010), focusing on the categories "Data" and "Type of representation". The category "data" classifies modelling tasks based on the type of data, like, for example, missing data or superfluous data. The category "type or representation" specifies how a task is presented, for example using text or materials.

Concerning the category "Data", the task contained both superfluous and missing data, as well as the relevant data. We distinguish between relevant and superfluous data on the basis of the problem's request, which is identifying the best alternative in terms of travel time. We highlight that, if the problem's request was more open — for example, identifying the best alternative by considering multiple factors such as energy consumption or cost — the distinction between relevant and superfluous data might change accordingly. The relevant data for computing the travel time for the pedestrian walkway are: (1) the total length of the path, which had to be estimated from the blueprint in Figure 1, (2) the fact that the moving walkway covers 70% of the total path, contained in the text, (3) the moving walkway speed contained in the moving walkway datasheet, (4) the walking speed (missing data) and (5) the information about whether passengers walk or not on the moving walkway (missing data). All the data in the moving walkway datasheet, except for speed (4), are superfluous data. The relevant data for computing the travel time of the shuttle are: (6) the distance covered by the shuttle reported in the text, (7) the average waiting time and (8) the shuttle speed in the shuttle datasheet and (9) the getting on/off the shuttle time (missing data). The pedestrian walkway is the more advantageous solution in terms of time. Concerning the category "type of representation", some data were presented as numbers in the text, while other data were presented through materials (blueprint and datasheets). The choice of representing some data using materials was made to increase the authenticity of the task. We highlight that, once the relevant data are identified and proposals for the missing data are made, mathematization and mathematical work are straightforward. This choice was made to make students work mostly on the first steps of the modelling cycle and to ensure that all students held the prior knowledge necessary for solving the problem. Finally, the request to write a short report for the project manager was made to monitor students' resolution processes.

Methods

Participants were 102 students (6 students of grade 10, 82 students of grade 11 and 14 students of grade 12) from 5 classes, belonging to different secondary school tracks (humanistic, scientific and technical), in Italy. Students worked in random groups of 3 to 4 students each. The data of the present study are the 26 groups' protocols, namely the report they produced. The first research question we aim to answer is: to what extent do students differentiate between relevant and superfluous data? Groups' protocols were analysed using a deductive qualitative content analysis (Mayring, 2014). For each relevant and superfluous data, we coded whether students used that data, specifying whether they used the data for computing the travel times or after having computed the travel times. Indeed, we hypothesized that students could correctly distinguish relevant and superfluous data for finding the solution of the problem in terms of travel times and that, afterwards, they could use superfluous data in an attempt of refining the model. Each author interpreted the data independently, and then, we discussed the analyses until consensus was reached. As an example, in the protocol N2 in Table 1, the maximum length of 900m for the moving walkway (a superfluous data) was employed by the group for computing the travel time for the pedestrian walkway. In the protocol M3 in Table 1, the maximum capacity of the shuttle (60 people), an irrelevant data, was considered after having computed the travel times, as a further factor in favour of the pedestrian walkway.

Table 1: examples for the coding procedure for answering RQ1 and RQ2

Prot.		RQ1	RQ2
N2	Through a proportion, we compute the total distance of the path, considering that 70% is moving walkway. $900m : 70\% = x : 100\%; \quad x = \frac{900m \cdot 100\%}{70\%};$ $x = 1285{,}714286$ We compute the time spent on the moving walkway, staying still: $t = \frac{s}{v}$ t=time s=space v=average velocity $t_1 = \frac{900m}{2m/s} = 450s$	Superfluous data for computing travel times	Ignoring
M3	For the same time, we must consider other factors: 1) The time we computed for the first option (moving walkway) considers the case in which one stays still on the moving walkway. However, to reduce the time, it could be possible to walk on the parts covered by the moving walkway, reducing time. 2) The shuttle is subject to traffic and bad weather and the maximum capacity is 60 people.	Superfluous data used after computing travel times	

S5	Moving walkway 70% of 900m (total distance) v=2m/s |---| = 42m → 1cm We did the computations both using the 42m unit and not using it. We present in the following the two different solutions. 1) With the ruler the length of the moving walkway path measures 11.5cm, thus multiplying by 42m we would have 483m, which does not correspond to 70% of the total (900m) $11{,}5 \cdot 42m = 483$ →We do a proportion to show that it isn't the 70%. $483 : 900 = x : 100$; x=53,06% Using the data and not considering the 42m unit, using the proportions: $x : 900 = 70 : 100 \quad x = 630m.$ The time required for the moving walkway to lead a person to his destination $t = s/v \rightarrow x = \frac{630m}{2m/s}$ $x = 315s$ → then, 5,25 minutes However, 270m must be walked. On average, a person walks 270m in 3 minutes, thus it would take 7.25 minutes to get to the metro.	Superfluous data for computing travel times	Misinterpreting Discarding

We then focused on the data that were used by students in an anomalous way, namely superfluous data that were used and relevant data that were not used for the computation of travel times. More precisely we ask: how can the anomalous use of superfluous and relevant data by students be characterized? To answer this second research question, we resorted an inductive qualitative content analysis (Mayring, 2014), identifying in the whole material three categories: misinterpreting, ignoring and discarding. Protocol N2 in Table 1 belongs to the category "ignoring": the way students set up the proportion highlights that the word "maximum", which belong to the data "maximum length: 900m" contained in the moving walkway datasheet, is ignored, thus leading to the interpretation of this data as the length of the moving walkway. Moreover, the blueprint, from which the total length of the path had to be computed, is also ignored, since it is not mentioned in the protocol. Protocol S5 in Table 1 belongs to both categories "misinterpreting" and "discarding". On the one hand, the fact that the group writes "900m (total distance)" highlights that the word "maximum" is misinterpreted as "total", thus leading to the interpretation of this data as the total length of the path. On the other hand, the blueprint is correctly considered by the students, who, however, discard this data due to the supposed inconsistency with the previous one. The students highlight their intentional choice with the sentence: "using the data and not considering the 42m unit".

Data analysis

In the following, we report, for each relevant and superfluous data, two percentages that refer to the groups that used that data for the computation of travel times and after having computed the travel times, respectively. We first present the results for relevant data: total length of the path (60% - 0%); moving walkway on 70% of the path (92% - 0%); moving walkway speed (100% - 0%); shuttle distance (100% - 0%); average shuttle waiting time (92% - 0%); shuttle speed (100% - 0%). We now report the results for superfluous data: energy efficiency class for the moving walkway (0% - 8%); connectivity (0% - 0%); operating environment (0% - 0%); moving walkway maximum length (54% - 0%); moving walkway slope (8% - 0%); shuttle battery capacity (8% - 3%); Shuttle maximum capacity – seated (8% - 23%); shuttle maximum capacity – standing (8% - 19%).

These result show that almost all superfluous data were either not used or seldom used by the groups for the computation of the travel times. An exception is the maximum length of the moving walkway which was used by half of the groups (54%). Some superfluous data (energy efficiency class for the moving walkway (8%), shuttle battery capacity (3%), and shuttle maximum capacities (23% and 19%)) were employed by some groups after having computed the travel times. For example, In the following excerpt from protocol P1, the shuttle limited capacity is considered, after the computation of the travel times, as a further factor in favor of the mechanized pedestrian walkway: “Considering the daily turnout, no queue forms on the walkway, differently from the shuttle for which, every 60 people, the waiting time increases by 5 minutes”. Concerning the use of relevant data, all groups employed the moving walkway speed, the distance covered by the shuttle and the shuttle speed. Almost all groups noticed that the moving walkway covered 70% of the total path and that there was an average waiting time for the shuttle. On the contrary, only 60% of the groups considered the total length of the path, which had to be computed from the blueprint, as a relevant data for computing the travel times.

Concerning the second research question, 5 groups belong to the category “misinterpreting”. In fact, they misinterpreted the word *maximum* in the irrelevant data “maximum length: 900m”, as *total*, thus interpreting 900m as the total length of the path. An example is protocol S1, where the students wrote: “The moving walkway extends for 70% of the path, which measures a total of 900m”. 12 groups can be classified according to the category “ignoring”. In fact, they ignored either the word *maximum* in the irrelevant data “maximum length: 900m” or the blueprint, from which the total length of the path had to be computed. An example of the former case is protocol N4, in which students wrote “s=900m (70% of the total path)”, thus meaning that 900m was considered as the length of the moving walkway and not as the maximum length of the moving walkway. An example of the latter case is protocol N2 in Table 1, in which the blueprint is not mentioned. Finally, one group (S5) belong to the category “discarding”. In protocol S5 in Table 1, the students, along with misinterpreting the maximum length of the moving walkway as the total length of the path, used the blueprint and the scale for computing the total length of the path and pointed out the inconsistency between the two values. For the computation of the travel times students decided to discard the relevant data, underlining their choice with the sentence “Using the data, without the 42m unit [...]”.

Discussion and conclusions

We recall that the present paper addresses the following research questions: (1) To what extent do students differentiate between relevant and superfluous data? (2) How can the anomalous use of relevant and superfluous data by students be characterized? Concerning the first research question, for most data, students successfully distinguished between relevant and superfluous data. In fact, students showed difficulties only in classifying the maximum length of the moving walkway, provided as a numerical data in the datasheet, as superfluous data and in identifying the total length of the path, which had to be measured from the blueprint, as a relevant data.

Regarding the second research question, our analysis provides a first characterization of the anomalous use of relevant and superfluous data by students, that is, when relevant data are not used and/or superfluous data are used. In most cases, the anomalous use of data by students is characterized by the fact that they ignored data or part of the information contained within data. In our study, in particular, the ignored data were either represented as materials or text. In a substantial number of cases, students also misinterpreted certain data or part of the information contained in the data. Again, we emphasize that the misinterpreted information was represented as text. Finally, in one case, students deliberately discarded a relevant piece of data, pointing out its inconsistency. It appears that all three of these student behaviors — where data presented as text and materials are misinterpreted, ignored, or discarded — indicate that these types of data are perceived by students as less significant. In contrast, students seem to prioritize numerical data, as further evidenced by the following statement included in the protocol categorized as "discarding": "using the data, without the 42m unit […]". This statement seems to highlight that the blueprint was not understood as a piece of data and that the only part of the blueprint which was considered as data by students is the scale (i.e., a number). This tendency of prioritizing numerical data, and even not understanding non-numerical data as proper data, aligns with patterns previously identified in the literature, where students employ superficial solution strategies in which they combine numerical data, treating mathematical modelling problems as if they were well-defined word-problems, without considering the real-world context (Kanefke & Schukajlow, 2022; Vershaffel et al., 2000). However, our analysis seems also to be partially in contrast with the just mentioned literature. In fact, some groups, after having computed the travel times, tried to employ superfluous data (e.g., the maximum capacity of the shuttle) as a further input for building a model closer to reality, thus showing to consider the real-world situation.

In Maass (2006), distinguishing relevant and superfluous information is considered as a key competency for successfully carrying out the mathematical modelling process. Our study provides a first indication of students' difficulties in managing relevant and superfluous data, especially when data are non-numeric and are provided through textual information or materials. Despite the limited sample size and the fact that only one modelling task has been analyzed, we believe our study suggests that students must practice processing modelling problems with superfluous data characterized by different representations. As a future work, we aim at testing the same mathematical modelling task presented in this work by providing the relevant data of the total length of the path as a numerical value, to more specifically investigate the impact of the type of data representation on the students' processing of relevant and superfluous data. Furthermore, since Kanefke and Schukajlow (2022) showed the influence of task on how students manage missing data, we aim at extending this study

by considering different modelling tasks which contain non-numerical superfluous data to verify whether our findings can be generalized.

Portfolio as a form of assessment for mathematical modelling with digital tools – Advantages and challenges from students' perspective

Catharina Beckschulte[1], Jascha Quarder[1], Stanislaw Schukajlow[1] and Samuel Blankenstein[1]

[1]University of Münster, Germany; beckschulte@uni-muenster.de

The assessment of mathematical modelling competencies poses significant challenges, particularly when authentic tasks and digital tools are integrated into the learning process. This study explores the potential of portfolios as an alternative assessment format, focusing on students' perspectives. Using qualitative interviews with eight ninth-grade students, we examined the perceived advantages and challenges of portfolio work in the context of digital-based modelling tasks. The results show that the portfolio offers many advantages such as cooperative working with reduced pressure to perform, combined with the possible integration of real modelling processes and the use of digital tools in mathematics lessons. However, there are also some challenges to consider, firstly in connection with the portfolio as an unfamiliar form of assessment and secondly with the challenges related to modelling tasks and digital tools.

Keywords: portfolio, assessment, mathematical modelling, digital tools, interview study

Introduction

The assessment of modelling competencies is the subject of ongoing intensive debate within the international modelling discourse, as it is very demanding, especially in written performance assessment (Frejd & Vos, 2021). In a study of assessment forms for mathematical modelling, Frejd (2013) concludes that the portfolio has the potential to develop into a valid and reliable assessment method. But what does this potential look like? To find out more about this potential in school practice, the project **AlPMo** (Alternative forms of assessment in mathematical modelling, in German: **Al**ternative **P**rüfungsformen beim mathematischen **Mo**dellieren) was launched in 2024. The aim of the project is to investigate the portfolio as an alternative form of assessment in mathematical modelling. As digital tools can be helpful at different points in mathematics lessons (Geiger, 2011; Greefrath, 2011), it can be promising to combine the portfolio with the processing of digital-based modelling tasks. However, we do not know much about students' perception of using portfolio in the classroom. The aim of the presented study is to determine the advantages and challenges of portfolios in modelling with digital tools from students' perspective.

Theoretical Background

Mathematical Modelling with Digital Tools

Mathematical modelling as well as the use of digital tools are an integral part of national mathematics curricula in many different countries. We understand mathematical modelling as a process of solving a real, non-mathematical task with the help of mathematics (Niss et al., 2007). Modelling tasks are characterized by their authenticity, reference to reality, openness and complexity (Maaß, 2010). Solving modelling tasks is a challenge for students in different phases of mathematical modelling processes (Schukajlow et al., 2023). Digital tools can be beneficial at various stages of solving mathematical tasks or modelling tasks in particular, such as during experimentation, visualization,

calculation, or control (Cevikbas et al., 2023; Geiger, 2011). One example of a digital-based modelling task is the task ‘Flat search’ (Quarder & Greefrath, 2024, p. 119):

Flat search

Anna and Ben are a couple. Anna works in Aachen and Ben works in Brühl (both in Germany). They want to move into a flat together and are therefore looking for a suitable place to live.

What place would you recommend to Anna and Ben?

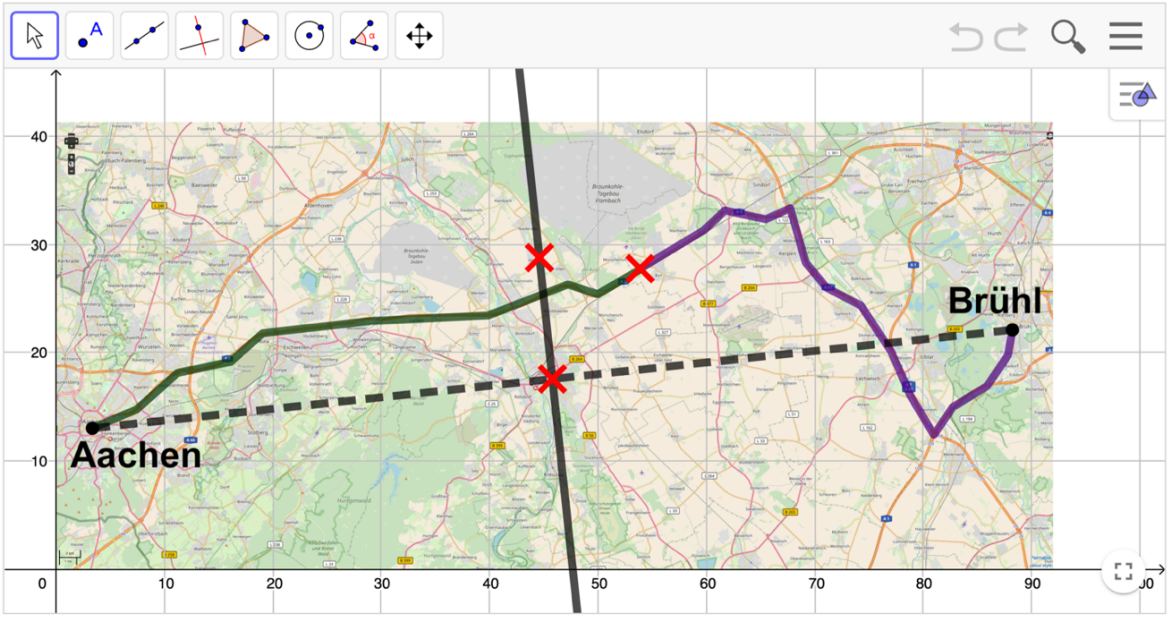

Figure 1: Task ‘Flat search’ with three possible solutions (Quarder & Greefrath, 2024, p. 119)

(Screenshot: © GeoGebra.org; Map: © OpenStreetMap, www.openstreetmap.org/copyright)

The aim of this task is to determine a common and ‘fair’ place of residence for a couple who commute between two workplaces. For this purpose, the centre point of the direct connecting line can be formed as one possibility. Alternatively, students can select a point on a previously constructed centre line so that a more rural region can be considered for the housing search. A third option, creating a point between two polygons of equal length that consider the motorway network and not the straight line, is shown in Figure 1. While digital tools offer potential for teaching mathematical modelling, they also present certain challenges such as the necessary translation processes into and out of the digital tool or programme-specific challenges (e.g., technical aspects or the basic ability to operate the digital tool) (Cevikbas et al., 2023).

Assessment of Modelling Competencies by using Portfolio

Mathematical modelling with digital tools is part of curricular standards and should be integrated into assessment of modelling performance. The most used method to assess modelling competencies is the written test (Frejd, 2013). There are mainly conceptual differences in the design of written modelling test items. On the one hand, so-called holistic tasks are used in which the entire modelling cycle must be completed. On the other hand, so-called atomistic tasks are used, in which only one or a few sub-competencies of modelling are activated (Hankeln et al., 2019). However, written tests have their limits when it comes to validity of assessing modelling competences. For example, Frejd

and Ärlebäck (2011) found in a study that collaboration is limited in a class test and that written tests often only consider an atomic view of modelling. In addition, Haines and Crouch (2007) note that written tests do not cover the full range of modelling tasks, such as simplifying a model.

To create alternatives to written tests which may include authentic mathematical modelling tasks, other forms of performance assessment than tests are being discussed in the modelling debate, such as projects, contests and portfolios (Frejd, 2013; Dunne & Galbraith, 2003). Portfolios can be understood as a collection of students' work completed in the classroom or at home and other material that exhibit the student's progress, efforts and performances (Frejd, 2013). As Dunne & Galbraith (2003) point out, portfolios could not only include modelling tasks but also diary notes or written data of achievements. As there is little empirical research on portfolios in connection with digital-based mathematical modelling, it is worth looking beyond modelling to identify the potentials and challenges of portfolios. Portfolios combine possibilities of formative feedback, by collecting it and giving comments during the course, and summative, by assessing it at the end of the course (Francis & Hobbs, 1991). In mathematics education, portfolios foster a more comprehensive evaluation of students' mathematical and "extra-mathematical" competencies (e.g., problem-solving) compared to traditional tests, as discussed by Krall (2023). They present opportunities for improved pedagogical practices, such as reduced test anxiety and enhanced student engagement through metacognition, but also come with challenges related to increased preparation time, questions of reliability, and difficulties in fostering teacher assessment literacy (Krall, 2023; Mak, 2021). In the debate on school digitalisation, digital portfolios are gaining importance as they integrate digital media and technologies into teaching and assessment. One of the challenges posed by digital portfolios is the high level of media literacy on the part of students and teachers (Rachbauer et al., 2023). In this study, we understand digital portfolios as collections of solutions to specific assignments related to the completion of two selected modelling tasks implemented in GeoGebra, conducted within a teaching unit aimed at developing modelling competencies.

Research question

The consideration of the portfolio as an alternative form of assessment is of great relevance, as Frejd (2013) already emphasised, seeing in the portfolio the potential to develop it as a reliable assessment method of modelling processes. To date, there are not yet many studies on the portfolio as a form of assessment in mathematical modelling. The following research question arises from the motivation to look at the student's perspective to work out the conditions for the successful use of a portfolio for assessment in mathematical modelling with digital tools:

What are the advantages and disadvantages of the portfolio as a form of assessment for mathematical modelling with digital tools from a students' perspective?

Methods

To answer the research question, we carried out a teaching unit on mathematical modelling with digital tools at a German grammar school. The sample consists of eight grade 9 students (five females, average age 15.38 years).

Firstly, there was an introductory lesson on the use of GeoGebra because the students had not yet had any experience with this software. During the teaching unit, consisting of five 45-minute lessons, the students created their own individual portfolio on the iPad. The main components of the portfolio were the solution processes of two digital-based modelling tasks, which have been selected from four available tasks. One of these is the task 'Flat search' shown above. In addition to the portfolio, the students worked on an analogue folder with worksheets for a step-by-step introduction to mathematical modelling. These three worksheets were organized in a three-step structure, introducing the steps of (1) simplifying a model, (2) mathematising into a mathematical model and (3) interpreting and validating the solution.

To collect empirical data, we conducted guided interviews at the end of the teaching unit with the aim of capturing the subjective opinions of students. We designed the interviews as one-to-one conversations, as otherwise the students could influence each other. The interviewer followed an interview guideline. The main part of the interview guideline is divided into three sections: general experiences, questions about the portfolio work and questions about the portfolio for assessment in mathematical modelling. The respective workbook and portfolio were used as a stimulus for the students. Transcripts were created based on the audio recordings. These transcripts were coded using Mayring's (2014) qualitative content analysis to inductively uncover advantages and disadvantages concerning portfolios. Categories were developed through four steps: (1) initial transcript review to define coding units, (2) creating a framework with deductive themes from the research question, (3) refining inductive subcategories based on recurring patterns, and (4) validating and adjusting categories. This combined deductive and inductive methods to analyze students' views on portfolio work, assessment, and digital-based modelling tasks. A trained bachelor student and the second author coded the interviews with a high level of intercoder agreement (Cohen's Kappa $\kappa = .84$).

Findings

The results of the qualitative content analysis are shown in Table 1. The categories are structured deductively in perceived advantages and challenges, which in turn are split into the three aspects of portfolio work, assessment and task format. Further, the sub-categories of portfolio work are documentation and working phase.

Portfolio work

Students perceived the documentation in a portfolio as an advantage because it served as a *memory aid*. Ben described the creation of his portfolio as follows:

> Ben: So from my point of view, it was a bit like a kind of college notebook, only digital [...] so that you could read through it again and then not have to look again, ah, how did I do that again? As a kind of memory aid."

Other advantages of the portfolio work are the following: It allows better *traceability for teachers*, especially for modelling tasks; a portfolio can have a *learning effect* due to a better understanding by writing things down and it offers *creative freedom*. However, some students reported disadvantages related to the documentation in the portfolio. On the one hand, students perceived the additional *effort* as a disadvantage of portfolio work. On the other hand, students reported their *lack of experience* with portfolios as a hindering factor. Regarding the working phase for creating the portfolio, students

perceived an advantage in the fact that there was more *autonomy* when working. The *structure* offered via the introductory task as a three-step-sequence for working on a modelling task was evaluated by some students as a strength and by other students as a hindering aspect of the portfolio work. Some students expressed their confusion in the *structure*, as something can get mixed up when creating the portfolio using the three-step sequence. The category of *cooperation* also appears also among advantages and disadvantages. Four students liked cooperation, whereas one student mentioned the difficulties of partner work, as it strongly depends on which partner you get for cooperation.

Assessment

Assessment includes the comparison between the portfolio and a written class test. All students interviewed perceived *reduced performance pressure* as a decisive advantage because of the emotions associated with the assessment. Students reported lower stress associated with this form of assessment and relief due to a smaller amount of preparation. In addition, *time* was another advantage of portfolios in assessment, as Emma described in her interview:

> Emma: Well, I think above all class work you write for 90 minutes, then you hand it in and if you don't have such a good day or somehow, you're not doing so well, then you don't get such a good grade. HERE you don't just work on it for an hour, but a bit longer. That means that if you don't have such a good day, you can make up for it with other lessons.

However, some students experienced *time* also as a disadvantage, as portfolio requires much more time than a test. Further, one student reported that she perceived more time stress in creating the portfolio compared to test. The possibility of *cheating* with the help of the internet was also suggested to be a disadvantage of portfolios.

Task format

Regarding the task format, students positively emphasise aspects that are associated with the characteristics of modelling tasks. This is therefore summarised in a common inductive category of *real modelling processes*. In portfolio work, students positively emphasized ‘more openness in the tasks’ and ‘more reference to reality’ compared to tasks in a class test. Furthermore, students attribute greater relevance and excitement to modelling tasks, as pointed out by Laura:

> Laura: "There wasn’t a single moment where I could say, yes, I didn’t know what to do […]. When I finished the task, I could think of a second solution because it was just fun.”

The *challenges in modelling processes* are summarised as a challenge of portfolios in relation to the task format. The biggest challenge mentioned was understanding the task. Students reported that the modelling tasks led to more frustration as they were perceived as more tedious. Another disadvantage described is that more non-mathematical knowledge was required to solve the tasks, which is also included in the category of challenges in modelling. One student highlights that she prefers written tests over creating a portfolio on mathematical modelling because the test focuses solely on applying class-taught knowledge, while the latter requires integrating basic knowledge from various topics.

Digital working appeared as another advantage as well as another disadvantage of the task format. This category summarises two facets that have emerged inductively in relation to digital tools: On

the one hand, students perceived GeoGebra as making their work easier, especially in terms of working mathematically during the modelling process. On the other hand, students expressed their enjoyment of digital work in general. In contrast, students mentioned technical difficulties with GeoGebra as well as difficulties in using GeoGebra.

Table 1: Perceived advantages and challenges

		Perceived advantages	Perceived challenges
Portfolio work	Documentation	Memory aid Traceability for teachers Learning effect Creative freedom	Effort Lack of experience
	Working Phase	Cooperation Structure Autonomy	Cooperation Structure
Assessment		Time Reduced performance pressure	Time Cheating
Task format		Real modelling processes Digital working Interest	Challenges in modelling processes Digital Working

Discussion and Outlook

This study aimed at the uncovering advantages and disadvantages of the portfolio as a form of assessment for mathematical modelling with digital tools from students' perspective. The analysis indicates that there are many advantages such as the integration of real modelling processes or the use of digital tools in mathematics assessment. Students have a positive attitude towards portfolio work, for example because it enables more independent and cooperative work. The results of our study thus empirically validate the assumptions regarding the benefits of portfolios in mathematics education, particularly with respect to their advantages in mathematical modelling (Krall, 2023; Mak, 2021; Dunne & Galbraith, 2003). The novel contribution of our study is the uncovering of the perceived disadvantages of modelling with digital tools, as the portfolio work shows that modelling is a major challenge for students (cf. Blum, 2011). Furthermore, portfolio work poses a few challenges, such as the potential lack of experience with this form of work. If it were to replace a class test as an alternative form of assessment, the main thing to consider from the student's perspective would be the time and the opportunities for cheating. This is probably related to the fact

that portfolio work allows more collaboration, which fits in with Frejd and Ärlebäck (2011) findings on less collaboration in written tests.

The study has some limitations and strengths, e.g. it has a qualitative methodology that initially reveals findings using a small sample of eight subjects. However, through this study, we have gained deep insights in the success for portfolio work as an alternative form of assessment in modelling. In addition to the student's perspective, the teacher's perspective is particularly interesting and relevant when using a portfolio as a form of assessment, as they are responsible for evaluating student performance. A planned future study will involve conducting a survey of practicing teachers to gather valuable insights. Another forthcoming study will investigate how students' performance in a portfolio is related to their performance in a written modelling test and their overall grade. Students' perspective of the study suggests that mathematical modelling and portfolio work require real-world knowledge and competencies. In future studies, the relationship between performance in creating a portfolio and performance in other subjects should be analyzed. Overall, this study indicates that portfolios are an interesting assessment method in mathematics lessons and that it is worthwhile taking a closer empirical look at them in the context of mathematical modelling.

Teacher's actions in class discussions after solving a Fermi problem

Mireia Brunet-Biarnes[1] and Lluís Albarracín[1]

Universitat Autònoma de Barcelona; lluis.albarracin@uab.cat

This study examines the teacher's role during a whole-class discussion following group work on a Fermi problem, a clear example of a modelling activity that connects mathematics with the real world (Albarracín and Gorgorió, 2014). The problem tasked fifth grade students with estimating how many people could fit in the schoolyard. After working individually and in groups, they presented their solutions and reasoning. Using Drageset's (2014) framework, the teacher's actions were categorized as redirecting, progressing and focusing actions. Results show that the teacher primarily used focusing and progressing actions to guide students through the discussion. While this approach encourages student participation, interactions mainly followed the IRE (initiation-response-evaluation) pattern (Cazden, 2001). The study highlights the importance of teacher's role during class discussions, though further research is needed to explore student contributions in such settings.

Keywords: Mathematical modelling, Fermi problems, classroom discussion, teacher interventions, primary education.

Introduction and research questions

In recent years, there has been a growing interest in introducing mathematical modelling activities at various educational levels to show students the connection between mathematics and their environment (Vorhölter et al., 2014). An example of problems that require a model-based approach and can be explored in primary school classrooms are Fermi problems (Albarracín & Gorgorió, 2014). These are characterized as open-ended questions that offer little or no specific information to guide the problem-solving process (Ärlebäck, 2009; Efthimou & Llewellyn, 2007).

Primary school students can solve Fermi problems by generating mathematical models (Albarracín & Gorgorió, 2019) but it is necessary to explore ways to support them in connecting the main concepts of the different models they can generate. In this study, we analyse the work of 24 fifth-grade students solving the following Fermi problem: How many people can fit in the schoolyard? (Albarracín & Gorgorió, 2014). To encourage student participation, the activity is structured in several phases: beginning with individual work, moving to small group work (with groups of four students), and concluding with a whole-class discussion. In a previous study, we have identified the potential of small group work to generate models to solve the problem and the role of each of the students (Brunet-Brianes & Albarracín, 2024). This study focuses on the final whole-class discussion, in which students present the methods used to solve the problem, discuss the results and justify their answers. This process facilitates the development of their mathematical understanding (Franke, Kazemi, & Battey, 2007). In this class discussion, the teacher plays a crucial role in managing the discussion, including facilitating turn-taking, posing questions, and providing feedback (Smith and Stein, 2016).

The objective of the study is to describe the teacher's role during the class discussion following the resolution of a Fermi problem in groups. The research questions are as follows: (RQ1) What types of

actions does the teacher do during the class discussion? and; (RQ2) How do these actions impact student participation and engagement?

Mathematical modelling and Fermi problems

In the context of mathematical modelling, we adopt Lesh and Harel's (2003) definition of a mathematical model. We understand a model to be a construct comprising a variety of elements, both conceptual and procedural, and that it encompasses different representations of reality, including words, drawings and diagrams. The function of models is to explain a system, which is often complex, that the student seeks to understand. In the primary school context, students do not have the mathematical language tools, such as algebra, to express their models. Nervertheless, they can use natural written language, drawings, diagrams, and corresponding calculations to illustrate their ideas (Albarracín & Gorgorió, 2019). In the context of problem-solving, the model serves to represent the situation presented in the problem and, through the application of mathematical processes, to arrive at a solution.

A category of problems that can be effectively addressed through the introduction of a mathematical model in a primary school classroom setting are those known as Fermi problems. As stated by Ärlebäck (2009), these are "open, non-standard problems that require students to make assumptions about the problem situation and estimate relevant quantities before carrying out often simple calculations" (p. 331). The introduction of Fermi problems in a mathematics classroom is based on the assumption that students can relate to the real-world context presented to them. Efthimou and Llewellyn (2007) defined Fermi problems by the way they are formulated, as they are always posed as open-ended questions that offer little to no information to those attempting to solve them. From the perspective of mathematical modelling, one of the most significant aspects of Fermi problems is the necessity for a comprehensive analysis of the situation presented. The procedure proposed by Fermi was to decompose the original problem into simpler subproblems, and to reach a solution to the original question by making reasonable estimations or educated guesses after first considering the individual subproblems (Carlson, 1997).

In their research, Albarracín and Gorgorió (2019) investigated the models constructed by primary school students to solve Fermi problems. Their findings revealed that there are multiple methods for developing these models, with the most prevalent approaches involving reduction and use of proportion, concentration of measures, reference point, grid distribution, and others.

Class discussion: teacher's role

Class discussions facilitate mathematical reasoning and meaningful learning by enabling students to actively engage in the exchange of ideas and the justification of their perspectives (Drageset, 2014). The development of mathematical understanding requires that students present problem solutions, propose conjectures, discuss a range of mathematical representations, elucidate their solution processes, demonstrate the rationale behind their solutions, and formulate generalisations (Franke, Kazemi, & Battey, 2007, p. 230). Furthermore, it is also crucial to engage in discourse on diverse solution methodologies and to evaluate outcomes (Kooloos et al., 2020).

A substantial body of research has been conducted on the various patterns observed in classroom discussions within the field of mathematics education, with a particular emphasis on the interaction between students and teachers. In many instances, the discourse is dominated by the teacher, following the pattern described as IRE (initiation-response-evaluation) where the teacher asks the questions, the students answer, and the teacher evaluates the response (Cazden, 2001). Although IRE can limit student engagement and focus on procedural tasks (Franke, Kazemi, & Battey, 2007), some researchers highlight its variability (Wells, 1993). More interactive classroom cultures, such as inquiry-based and strategy-reporting, promote student reasoning and justification Wood, Williams, & McNeal, 2006). However, merely increasing student talk is insufficient; teachers must scaffold discussions to make mathematical thinking explicit (Franke, Kazemi, & Battey, 2007). Stein et al. (2008) state that early efforts in mathematical discussions often lacked teacher guidance, leading to superficial exchanges. Brendefur and Frykholm (2000) describe reflective communication, where discussions aim to deepen mathematical understanding by building on students' ideas. Instructive communication further involves teachers guiding and deepening in students' mathematical thinking.

There is a growing consensus that students' contributions should be a significant aspect of classroom communication. However, there is a need to understand how this can be achieved. For students to have this opportunity the class discourse should be dominated by pupils, giving them space to share their ideas and explain their reasoning (Drageset, 2014). Smith and Stein (2016) present five key practices that can assist teachers have control over a class discussion. Smith and Stein (2016) present five key practices that can assist teachers in maintaining control over a class discussion. Their objective is to anticipate potential developments during the activity and thereby afford teachers more time to make decisions. These five key practices are:

- **Anticipate** the possible student responses to challenging mathematical tasks.
- **Monitor** the actual responses of students to tasks (when solved in pairs or small groups).
- **Select** specific students to present their mathematical work during group discussion.
- **Sequence** the student responses to be displayed in a specific order.
- **Connect** the different student responses and link them to key mathematical ideas.

As Smith and Stein (2016) claim, asking the right questions is crucial to promote deeper understanding on cognitively challenging tasks. Effective questions can guide students' attention to previously overlooked aspects of a problem or encourage the discovery of new perspectives. Additionally, such questions facilitate students' ability to articulate their thought processes in a clear and coherent manner, thereby enhancing the comprehensibility of their reasoning to others. This model focuses on students' thinking and how they understand the mathematical content. Teachers have direct and regular access to students' ideas and the details that support them, which is essential information for effective teaching and learning of mathematics (Drageset, 2014; Frank et al., 2007). As Kooloos et al. (2020) emphasise, teachers must strike a balance between student-led contributions and teacher-led guidance in order to ensure meaningful mathematical learning and understanding. While several studies have explored how teachers actively use students' ideas to promote accurate and deeper mathematical understanding, there is a paucity of research on this practice within class discussions where students present their solution strategies for Fermi problems.

Methods

The problem used during the data collection was: how many people can fit in the school yard? In this case, students were required to estimate the number of people that can be arranged across the school yard. The decision to utilise this problem was informed by its previous deployment in the study conducted by Albarracín and Gorgorió (2019). Consequently, the potential strategies that students may employ in response to this problem are already known. The activity presented to the students was set in different stages:

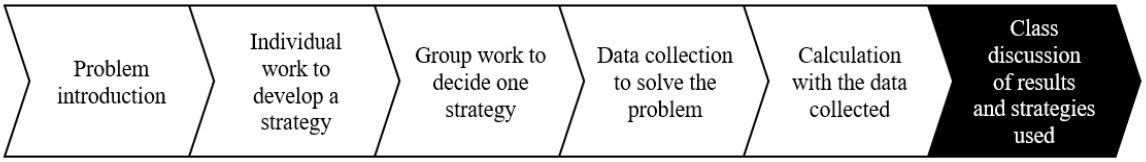

Figure 1: Stages followed during the data collection process

The class discussion was orchestrated following the guidelines of Smith and Stein (2016). The sample was of 24 students in the fifth grade of primary education and their teacher. The activity was developed in two sessions of one and a half hours each. The class discussion was conducted in the second session, with one teacher guiding the conversation. This was recorded in video and audio for subsequent analysis. Two researchers observed and participated in the sessions. Due to space constraints, this paper will focus on the role of the teacher during the class discussion, their interventions, and how they used students' comments.

Analysis

Following the collection of data, the recording of the class discussion was transcribed and structured to facilitate the categorization of the teacher's comments. To ensure the reliability of the data analysis, the audio recordings were reviewed by two researchers to confirm the categorisation of teacher actions. The pre-defined coding categories detailed by Drageset (2014) in the redirecting, progressing and focusing framework were applied. These categories, with minor changes, have been used in other studies, including Kooloos, Oolbekkink-Marchand, Kaenders and Heckman's (2020) work.

- Redirecting actions represent teacher interventions that are designed to guide students towards an alternative approach or strategy. The teacher may acknowledge a student's response but then redirect it, either through corrections, suggestions, or questions that encourage the student to rethink their approach. This category includes putting aside students' comments, explicitly advising students to use an alternative strategy, and correcting questions. An example of this category is when the teacher corrects a student's approach by saying: "Okay, but this part still needs to be filled in, right?"
- Progressing actions are those taken by the teacher to guarantee that the class continues to make progress towards the resolution of the problem. This may entail demonstrating solutions, simplifying tasks, or dividing the problem into discrete, manageable steps to facilitate the ongoing progression of the process. This category includes demonstration of steps or the entire solution, simplifications of the task providing hints, closed progress details by guiding students step-by-step through a process, and open progress initiatives in which the teacher

asks open-ended questions. An example of this category is when the teacher asks students to present their solving process: “Group four, can you tell us how you solved the problem?”

- Focusing actions involve the utilisation of teacher comments or questions that direct attention towards specific elements of the problem-solving or solution process. The objective is to facilitate deeper comprehension by prompting students to elucidate their rationale, substantiate their responses, or emphasise pivotal details. This approach is categorised into two distinct sections:
    - Requests for student input: the teacher asks students to explain details, justify their answers, apply knowledge to similar problems, or seek validation from peers. This category includes enlightening details of the solution process, justifying the reasoning behind the methods used, or applying it to similar problems, and requesting peer-assessment. An example of this category is when the teacher asks students to justify their answer by saying: “How did you arrive at this result?”
    - Pointing out: the teacher highlights or recaps key information. This category includes recap of the solutions or clarification of key points and noticing important details. An example of this category is when the teacher points out one possible strategy for solving problems: “Look, sometimes we have a big problem, one good strategy is to break it into smaller problems. It is easier to find a solution to small problems.”

Results

A key characteristic of the data in this study is that the majority of instances align with the IRE pattern (Cazden, 2001), characterised by the teacher's consistent intervention and response to students' comments. This also indicates that the teacher exercises control over the order of turns, speaking only after the students. Consequently, it was evident that the teacher played a pivotal role in guiding and advancing the class discussion. Considering the categories described previously, the following table presents the results obtained after analysing the data:

Table 1: Teacher actions according to the categories detailed by Drageset (2014) in the redirecting, progressing and focusing framework

Category	Subcategories		Teacher actions
Redirecting	Put aside		2
	Advising new strategy		2
	Correcting questions		3
Progressing	Demonstration		5
	Simplification		2
	Closed progress details		16
	Open progress initiatives		11
Focusing	Request students’ input	Enlighten details	3
		Justification	8
		Apply to similar problems	3
		Request peer-assessment	4
	Pointing out	Recap	19
		Notice	7
Actions of classroom management			9

A new category has been incorporated to the initial list: actions of classroom management. This category refers to the strategies and interventions employed by the teacher to maintain order,

structure, and an effective learning environment during the class discussion. It is important to note that the most prevalent teacher actions are recap (focusing), closed progress details (progressing) and open progress initiatives (progressing). Considering the nature of the activity, the open progress initiatives are often used to give students the opportunity to explain the process they followed to solve the problem. Closed progress details are used by the teacher to follow step-by-step solution plans, with the help of the students he advances to the solution of the problem. Finally, the most frequently used action is recap, in which the teacher often summarizes and rephrases the explanations provided by students. This is a key action as it gives the opportunity to make sense of what students explain and making it available for all the class. Two further significant actions are ask for justification (progressing) and notice (focusing). This first action is used primarily to ask students to explain some parts of the strategy used to solve the problem. Moreover, the action notice is used by the teacher to drive attention to certain details of the different strategies used to solve the problem. Another key action is demonstration (progressing), in which the teacher uses drawings, exemplifies the situation in the classroom, makes references of other areas, etc. This action encourages students to actively participate in the discourse, responding and demonstrating their comprehension of the situation.

In general, the most frequently employed actions in the classroom are focusing actions (52%). These are defined as teacher interventions, either in the form of comments or questions, that direct students' attention to key elements of the problem or solution process Drageset (2014). Given the complexity of the task, the teacher often requested students to provide more comprehensive explanations and justifications. This approach enabled the identification and clarification of their underlying strategies and reasoning processes. Additionally, the teacher regularly summarizes the discussion and emphasizes important aspects to ensure that all students can follow and engage with the discussion. This ongoing process of clarification, recapping, and highlighting key points not only ensured students remained on track but also cultivated a deeper understanding of the mathematical concepts being discussed. Through focusing actions, the teacher guides students in reflecting on their work while ensuring that the entire class remains involved and comprehends the ongoing discussion.

Discussion of the results and conclusions

In regard to the actions of teachers during a class discussion (RQ1), the study highlights that recap (focusing), closed progress details, and open progress initiatives (progressing) are the most frequently employed teacher actions. The frequent utilisation of recap actions indicates a focus on summarizing and clarifying student contributions to ensure collective understanding, consistent with Franke et al.'s (2007) emphasis on making mathematical thinking explicit. Additionally, this can also be connected to one of the key practices suggested by Smith and Stein (2016), connecting students' ideas and linking them between the different approaches. Other pivotal actions observed include justification and notice, whereby the teacher requests students to explain their reasoning and highlights critical aspects of the problem-solving process. Additionally, the utilization of demonstrations by the teacher, such as drawings and references to familiar topics, encourages all students to follow the class discussion and provides them with aspects to reconsider their strategies.

The teacher exerted a considerable influence on student participation and engagement (RQ2). The classroom interactions predominantly followed the IRE (initiation–response–evaluation) pattern

(Cazden, 2001), which is consistent with the findings of Drageset (2014). By balancing IRE sequences with open progress initiatives, the teacher created opportunities for more profound student reasoning and participation, a point also emphasised by Wells (1993) in his work on interactive classroom cultures. Nevertheless, the use of closed questions requiring brief responses resulted in greater student involvement, with a notable number of students offering their responses aloud. However, this type of engagement was less reflective. Therefore, it is essential to find a balance between open progress initiatives and closed progress details to ensure broad student engagement while still encouraging deeper reasoning and self-assessment.

This research offers insights into the dynamics of class discussions and the teacher's role after solving a Fermi problem in groups in the upper cycle of primary education. In the context of class discussions, it is essential that primary school students are provided with clear guidance and structure by their teachers, while also being afforded opportunities to elucidate their reasoning. Teachers may also facilitate comprehension by providing examples and connecting students' ideas to foster collective understanding. These teacher actions are crucial for fostering student engagement, promoting deeper reasoning, and ensuring effective participation in mathematical discussions. The findings of the study are based on a relatively small sample size, which may limit the extent to which they can be generalised. Furthermore, the analysis predominantly concentrates on teacher actions, with comparatively less attention devoted to student comments and interactions. Future research should consider a larger and more diverse sample and include a more comprehensive analysis of student contributions to gain a fuller understanding of the dynamics in classroom discussions. Exploring how students' comments and responses influence and interact with the teacher's actions could provide deeper insights into effective teaching strategies and student engagement in mathematical discourse.

University students learning to model through large amounts of data, simulations and ChatGPT

Louise Meier Carlsen[1] and Britta Eyrich Jessen[2]

[1]IT University, Department of Computer Science, Copenhagen, Denmark; loca@itu.dk

[2]University of Copenhagen, Department of Science Education, Denmark

Digital technologies have been studied in the context of modelling for a couple of decades, with recent discussions focusing on the potentials and pitfalls of AI tools such as ChatGPT. In this paper, we present a preliminary analysis of university students' engagement with a modelling activity that encourages them to utilise various digital technologies to develop autonomy in applied statistics, a core field within data science, and a modelling field in itself. The activity is designed to initially draw on students' prior knowledge before requiring the acquisition of new knowledge. We observe varied approaches among students and point to further research needed regarding how to teach students to integrate AI tools in their modelling practices.

Keywords: Study and research paths, digital technologies, simulations, statistical modelling, tertiary education

Introduction

The impact of digital technologies on modelling education has been a recent focus (Siller, Geiger & Greefrath, 2023; Cevikbas, Greefrath & Siller, 2023). Siller et al. (2023) list the roles of digital technologies such as calculators, visualisation tools, dynamic representation tools, simulations, communication, data handling (collection or selection), learning materials developed for specific purposes including full learning environments e.g., virtual reality hardware and software. They identify four distinct ways of drawing on digital resources:

> extending mathematical capability: digital resources specific to mathematics […] digital resources not specific to mathematics […] accessing extra-mathematical knowledge: digital resources for communication and information gathering […] digital resources for simulated, virtual and augmented worlds. (Siller et al., 2023, p. 9).

Despite detailed research and discussions in each category, neither Siller et al. (2023) nor Cevikbas et al. (2023) address studies related to ChatGPT or other AI tools. This paper presents a study examining students' unrestricted use of digital tools to solve an open-ended modelling problem in a first-year applied statistics course for data science. This context is particularly suited to explore students' autonomous tool use, including AI, as it does not face the constraints of limited experience or reluctance to engage in digital inquiries (Cevikbas et al., 2023). The activity integrates statistical knowledge and techniques with extra-mathematical knowledge from a large data set. Students use digital resources beyond those specific to mathematics as well as testing their hypotheses and addressing the modelling tasks through simulations and digital resources specific to mathematics and data science.

Some domains of mathematical modelling are more strongly influenced by digital technologies than others. According to Greefrath and Siller (2017), simulation "serves to investigate an operation, a process or an experiment with the help of mathematical models […] usually in conjunction with a digital tool." (p. 530). When randomness is a factor in the experiment, they refer to these as stochastic simulations. The modelling activity in this paper aligns with this definition. Our aim is for students to employ digital tools and stochastic simulations, leveraging the potential that "statistical modelling can be comprehended holistically as a vehicle and platform for developing statistical competencies, statistical content, and social and societal decision-making" (Kawakami & Ärlebäck, 2023, p. 39). That being a more recent aim in statistics education as well (Pfannkuch et al, 2018) where:

> "The advent of data science has provided new challenges and opportunities for statistics education researchers to re-think what it means to model. […] How can new simulations and visualizations using technological tools increase students' access and agency for telling data stories, and enrich understanding in modeling processes?" (Noll et al., 2022, p. 331).

This aligns with the aims of the bachelor program in data science (IT University of Copenhagen, 2017). To address the holistic nature of modelling in relation to content knowledge, we analyse the activities from the perspective of the Anthropological Theory of the Didactic (ATD) (Chevallard, 2019; Barquero & Jessen, 2020). The notion of Study and Research Paths (SRP) provides a lens to examine the dialectic between study and research processes, showing how digital technologies support modelling from pragmatic and epistemic viewpoints. This approach facilitates students' learning of content knowledge across tertiary and secondary levels (Jessen & Kjeldsen, 2023), encouraging autonomous model construction and refinement through continued questioning and exploration (Jessen, 2017). While we have previously presented the a priori analysis of the task (Carlsen & Jessen, 2024), this paper focuses on two cases from its implementation, preceded by an elaboration on the theoretical framework.

Theoretical background

SRP is an ATD approach to modelling, and is initiated by a generating question, Q_0, which is an open question understandable to students, but it requires the students to engage in a learning process in order to be answered (Jessen, 2017). Learning in ATD is considered the process, where students pursue a question and recall prior or existing knowledge, A_i°, and seek to combine this knowledge in new ways to develop some new answers. However, questions may require the acquisition of new knowledge, meaning students will have to study works, W_j, decompose the knowledge they contain, and put it together with students' prior knowledge, $\sum A_i^\circ$, and reconstruct it when developing a personal answer to the generating question. We denote the final answer, $A^\heartsuit$. The collection of prior knowledge, works to be studied, data, D_n to be produced and analysed, together with questions driving the inquiry process, is called the milieu. Thus, according to Chevallard (2019) and Jessen (2017), we can analyse the learning process by identifying the didactic system (which consists of a group of learners, X_k, guided by one, y, or more teachers, Y, and the generating question at stake, Q_0) and its interaction with the milieu. In short, we describe the elements of the didactic system and milieu using the Herbartian schema: $[S(X_k; Y; Q_o) \rightarrow M] \rightarrow A^\heartsuit$ The milieu can then be written as the set:

$$M = \{A_1^\circ, A_2^\circ, \dots, W_1, W_2, \dots, D_1, D_2, \dots\}$$

As described by Jessen (2022), both data and digital technologies can play the role of a media to be studied and the milieu in which answers are being developed through the reconstruction process of research (in the ATD meaning). Thus media, being elements of the milieu, can be web searches, videos, textbook materials, answers provided by other students and even newspaper articles. It can also be an existing model students seek to make sense of or a model they have produced in their modelling process, being evaluated, and improved through further study processes. Similarly, data can be both qualitative and quantitative, according to Chevallard (2019), and be something students produce or gain from other sources. As demonstrated by Jessen (2022), this allows students to engage in a dialectic between empirical and theoretical modelling and continued questioning and development of students' answers to the generating question. In particular, the continuously changing roles of digital technologies in a SRP seem to enable students' autonomous modelling processes.

This leads us to the research question of this paper: Using the Herbartian schema, how can we map the modelling process of the stochastic simulations? And how is technology and AI as ChatGPT furthering students' modelling processes?

Context of study

This study was conducted at the IT University of Copenhagen as part of a 15 ECTS Applied Statistics course, involving approximately 80 students in the second week of their second semester. The program aims to provide students with the skills to perform "data-centred, empirical analysis of real-world problems" (IT University of Copenhagen, 2017, p. 2) and develop expertise in statistical analysis, methodologies, and data-driven reflection. The curriculum emphasises cleaning, transforming, querying organizing, visualising data, and interpreting inferential processes. Admission is competitive, requiring a strong background in mathematics and English. The diverse cohort, with about 50% international students, mainly from Europe, reflects varying pre-university experiences. While some students may have prior exposure to stochastic or mathematical modelling, this cannot be assumed for all. At this stage of the course, students have learned basic R for simple data visualization and have used ChatGPT generating code and conceptual assistance but have not yet been introduced to statistical models or model testing.

Data was collected from recordings of plenum discussions, students' logbooks documenting their questions and investigated sources, observation notes, and reports submitted after both rounds of the tasks. This qualitative study uses discourse analysis to identify what questions students raise and how they develop answers, with or without digital technologies (cf. Jessen, 2017, 2022). The implemented activity is presented below.

Presentation of task design

The modelling activity reported here, is an SRP initiated by the generating question, Q_0: Are boys better at math than girls? We previously analysed its relevance for Danish upper secondary students, highlighting how it productively integrates digital technologies and links to a public debate showing the relevance of mathematics and stochastic modelling (Carlsen & Jessen, submitted). In a tertiary education context, this activity bridges applied statistics in secondary and tertiary education. More concretely, it supports teaching phases of statistical analysis and modelling, including exploratory

data analysis, descriptive and graphical examination, and selecting appropriate statistical models based on the data and research question (Ramsey & Schafer, 2012). These phases involve verifying model assumptions, fitting models using software to estimate parameters, performing hypothesis tests, interpreting statistical outputs in context, and assessing both the statistical and practical significance of the findings.

When engaging students with the modelling activity and Q_0, we have altered the design a bit compared to the previous proposal (Carlsen & Jessen, submitted). For the first part of the activity, students are required to design a study to determine if boys are better than girls, but they will not need to carry out the study. In the second part of the activity, students are provided with a data set, D_1, and asked to perform a statistical analysis. D_1 includes all final written exam grades in mathematics A-level from upper secondary school in Denmark, 2019, and the students' sex. Students were strongly encouraged to seek knowledge and inspiration from sources beyond their textbook and use of ChatGPT. When analysing the data set, students will find an average grade difference of 0.2 between boys and girls. The a priori analysis indicates that this will lead to questions about the significance of such a difference (Carlsen & Jessen, submitted). To address this, students must perform statistical analysis, including determining a suitable model that fits the context and data distribution and conducting a hypothesis test. Our a priori analysis anticipated that students would spontaneously utilize ChatGPT, as has been observed with SRPs in upper secondary school (Milthers & Wedderkopp, 2024). ChatGPT will propose various statistical models needing to be studied, emphasising the importance of meeting model assumptions and considering the study's context when selecting the appropriate model.

Results of analysis

Although the first part of the project includes valuable student reflections, our analysis will focus on the second part, where students conduct a statistical analysis. In this part, all groups have performed data visualisation and descriptive statistics. Some groups have explored various partitions of the data such as passed/fail, top-grade/non-top-grade, and more. For selecting a statistical model, many student groups have considered one-way ANOVA, while others have used statistical tests such as the Welch t-test and bootstrapping. In our study, we will analyse two cases: one demonstrating how students utilize their existing knowledge, and the other, where students use ChatGPT and other technology to study new knowledge.

Case 1 – use of existing knowledge

One group of students, X_1, begins by considering the number of data points in each group, male and female. After noting that the groups have different numbers of data points, they proceed by distinguishing between count and proportion respectively, which is existing knowledge $A_1^{\Diamond}$ and $A_2^{\Diamond}$. They first present a histogram, and a segmented bar chart based on count, utilizing previous knowledge, $A_3^{\Diamond}$ and $A_4^{\Diamond}$. The group concludes that, although there are more female students than male students in the data set, the charts show more male students receiving the lowest grade, and more female students receiving grades above. These charts provide insight into the distribution of the grades between the genders. We see that the previous knowledge $A_3^{\Diamond}$ and $A_4^{\Diamond}$ enriches the milieu by providing new insight into the data, D_1. Following, the students observe that the data approximates a

skewed normal distribution, with the second and third-highest grades being the most frequent. Though, the second lowest grade has a significantly higher count than expected in a skewed normal distribution. Based on their prior knowledge, $A_5^{\Diamond}$, regarding visualizations of the normal distribution. This further contributes to the milieu, leading to the conclusion that the data does not follow a normal distribution. Then the students standardise the data, i.e., considering the proportional distribution, transforming the data: $tr(D_1) = D_{2,X_1}$ based on $A_2^{\Diamond}$. Based on D_{2,X_1} they conclude that

> the plot shows that females outperform males in grades 3-5, while males take the lead in the two lowest and highest grades. So, the females' grades are more towards the centre while males are more spread out. (X_1 report).

This observation is confirmed by calculating the standard deviation for the two genders, another piece of prior knowledge, $A_6^{\Diamond}$.

> The standard deviation for males is 1.47 while the standard deviation for females is 1.39. This observation aligns with the pattern observed in our chart depicting the distribution of grades across both sexes. (X_1 report).

The students then describe the average grades for each gender, utilizing yet another element of prior knowledge, $A_7^{\Diamond}$. They conclude that, $A^{\blacktriangledown}$:

> Although the mean grade for males may be higher on average, the higher standard deviation suggests that there is more variability in the performance of the male students, with some excelling and others struggling. In contrast, females may have more consistent performance, with a larger share of grades clustered around the middle range, leading to a lower standard deviation despite a slightly lower mean grade. (X_1 report)

We can depict the study and research process of the student group, X_1, using the Herbartian schema to list how they draw on prior knowledge:

$$[S(X_1; y; Q_o) \rightarrow \mathrm{M}] \rightarrow A^{\blacktriangledown}$$

The milieu engaged with can be described as the set: $\{A_1^{\diamond}, A_2^{\diamond}, \dots A_7^{\diamond}, D_1, D_{2,X_1}\}$

We see that students study their own preliminary model of the data, D_1, the skewed normal distribution, to analyse the data, the uneven number of girls and boys, leading to the need for the transformation of data into visualisations allowing them to complete the analyses based on deviations and nuance preliminary answers, only based on average grades. Thus, the genuine open modelling task in terms of Q_0 and the proposed data, D_1, seemed to be sufficient in nudging the engaged students in the study-research dialectic building arguments for transforming data, and revising models, to better reach conclusions. Still, they did not engage in studying new works, nor explore proposals from ChatGPT.

Case 2 – exploration of technology and simulations

In our second case, we will focus on the use of technology such as ChatGPT, internet pages with distinctive authorship, and simulations, analysing their role in enriching the milieu by recalling existing knowledge. Our analysis focuses on group, X_2, consisting of five other members. According to the self-reported logbook attached to the project, the group used ChatGPT, YouTube videos and

various internet pages. There is a clear distinction between the type of knowledge learned from ChatGPT, a dynamic media, and from webpages and YouTube videos, a (relative) static media.

Initially, students asked ChatGPT broader questions, such as, Q_1"what kind of approaches are there to conduct a statistical analysis on a data set about grades". Based on this prompt, ChatGPT provided a list of ten different approaches: descriptive statistics, data visualisation, inferential statistics, regression analysis, multivariate analysis, longitudinal analysis, cluster analysis, machine learning, survival analysis and text analysis. Each approach and concept were briefly described by its advantages and possible applications. We consider this output from ChatGPT domains of work to be studied, W_1, W_2, W_3, …, W_{10}, which adds to the milieu by presenting an array of approaches and concepts. The group asked $Q_{1,1}$: "expand on inferential statistics", which means unfolding W_3 further. ChatGPT responded along the same lines by listing ten concepts and methods: hypothesis testing, confidence interval, sample distribution, central limit theorem, type I and type II errors, power analysis, effect size and assumptions. We consider this ChatGPT-supported enrichment of the milieu by introducing multiple new works, W_{11}, …, W_{20}, students needed to consider. Thus, we can describe the initial modelling process with the schema:

$$S(X_2; y; Q_o, Q_1, Q_{1,1}) \rightarrow \{A_1^{\circ}, A_2^{\circ}, \dots, W_1, W_2, \dots, W_{20}, D_1\}$$

We include also prior knowledge here in the milieu as the background for prompting ChatGPT.

Focusing on hypothesis testing, W_{11}, the students asked ChatGPT $Q_{1,1,1}$:"how do I go about hypothesis testing" (students of X_2). Here ChatGPT outlined the steps involved: formulate hypotheses, select a significant level, choose test statistics, etc., W_{21}, …, W_{30}. In this case, ChatGPT provided an overview of the process but also required further study. For instance, while ChatGPT defined the null hypothesis, it only provided a brief description of test statistics, W_{23}, replying "test statistic depends on the type of data and the hypothesis being tested. Common test statistics include *t*-test, *z*-test, χ^2-test, ANOVA, etc." (ChatGPT output). In the case of the null hypothesis, ChatGPT provided a definition directly applicable to data, D_1, which closed the above described path of studying various works, and students were able to reconstruct the knowledge required to pose the null hypothesis. Thus, we saw how the dialogue with ChatGPT enriched the milieu, and enabled X_2 to produce $A_1^{\blacktriangledown}$, being the preliminary and partial answer to Q_0, which is crucial for the data modelling. At this point, the students turned to other static media to study specific test statistics in further detail. E.g., they used a YouTube video to answer Q_2 :"What can a bootstrap analysis be used for? $Q_{2,1}$:How to perform it?", and a webpage for learning $Q_{2,2}$: how to "conclude on bootstrap analysis, the importance of confidence intervals" but also $Q_{2,3}$: "what are the shortcomings of a bootstrap analysis". This type of media provided specific, comprehensive knowledge on single subjects, $W_{31} - W_{34}$, enriching the milieu with specific techniques applicable to their context and crucial for data modelling.

In their project report, the students argued for using simulation to determine if the observed difference in means was significant, $A_2^{\blacktriangledown}$: "multiple random samples based on our already existing population…[will] provide an overall range within which we can expect the mean of our dataset to fall" (X_2 report). They performed a simulation of 10000 data points, generating a new data set, D_{2,x_2}, and two frequency plots of the mean grades for males and females respectively, which became partial

answers produced using R. Thus, we consider this the result of their research process, but also self-produced answer they needed to study further to answer Q_0. Drawing on their prior knowledge, they discussed the confidence intervals of the mean grades for both genders, concluding that the observed difference in grade means is due to randomness, $A^{\blacktriangledown}$. Thus, the knowledge developed by the students is tested against the milieu consisting of their prior knowledge, and new works studied from digital resources including their own productions using computer software.

Concluding remarks

This preliminary work aligns with calls for research on the opportunities for leveraging technology to broaden the learning context and foster autonomous, informed modelling practices (Pfannkuch et al., 2018; Noll et al. 2022) by examining students' free use of digital resources, to analyse complex datasets. The lens provided by the Herbartian schema, allows us to identify 3 types of influence on the milieu from technology: ChatGPT both broad domains to be studied, but also provides definitions. YouTube videos and webpages enrich the milieu with concrete techniques and methods to be used. Simulation enriches the milieu as a technique, and a model, with which we can test our hypothesis. This links to the purpose of digital technologies for modelling education both in terms of extended mathematical capabilities and accessing other resources relevant to applied data science and simulations. In this SRP as a task design tool (Barquero & Jessen, 2020) nudging the continuous questioning done by students (Jessen, 2017), seems productive to engage university students in stochastic simulations. Still, the two cases span a variety of approaches employed by the students in the applied statistics course. More research is needed into our data regarding more detailed analyses of students' study of works, $\sum W_i$, and how they use different digital technologies, but also why some students were reluctant to go beyond their existing knowledge. A hypothesis could be the effects of the didactic contract, which is known to affect students' actions in mathematics courses in tertiary education, especially when it comes to the use of resources beyond lectures and textbooks (Gueudet & Pepin, 2018).

How do teachers manage the phase of horizontal mathematization during the implementation of a modelling task? A case study

Marina De Simone[1] and Yana Lacek[2]

[1] University of Geneva, University Institute of Teacher Education, Geneva, Switzerland; marina.desimone@unige.ch

[2] University of Geneva, Faculty of Psychology and Educational Sciences, Geneva, Switzerland

This paper is issued from a qualitative exploratory study preceding a larger research project aiming to study the implementation of modelling objectives in secondary schools in Geneva. In this paper, we propose to analyse how teachers manage the phase of horizontal mathematization when implementing modelling activities. The aim is to identify and characterize the conditions that foster the transformation of a real-life situation into a problem treatable mathematically. We propose a qualitative analysis of the modalities of the implementation of a well-known modelling task (The Giant's Shoes) in order to enrich the existing empirical results.

Keywords: Mathematical modelling, horizontal mathematising, mental representation, teacher's interventions, lower secondary school.

Introduction

Mathematical modelling is an important part of mathematical activity, however, its implementation and teaching is rather a complex issue (Blum, 2015).

For Blum (2015) "mathematical modelling is a cognitively demanding activity since several competencies involved, also non-mathematical ones, extra-mathematical knowledge is required, mathematical knowledge and, conceptual ideas are necessary, and appropriate beliefs and attitude are required, especially for more complex modelling activities" (p. 78). This may result in students potentially encountering difficulties because

> each step in the modelling process is a potential cognitive barrier for students, a potential "blockage" or "red flag situation" (Goos 2002; Galbraith and Stillman 2006; Stillman 2011). "The weakest link in their modelling chain will set the limits on what they can do " (Treilibs et al.1980). (Blum, 2015, p. 79)

In particular, Blum and Leiss (2007) "describe the transition between real situation and situation model as a phase of understanding the task" and consider it "as an important phase during the modelling process." (Vorhölter et al., 2019, p. 103). In addition, Borromeo Ferri (2006) emphasizes that in this transition "a mental reconstruction of the situation given in the problem takes place, which is rather on an implicit level and mostly unaware for the individual" (p. 92). For Schukajlow et al. (2023) an important characteristic of the situation model "is its holistic structure that allows making inferences during problem solving" (p. 261). Several empirical studies as reported by Schukajlow et al. (2023) "identified students' blockages while understanding the situation described in modelling problems" (p. 261) on the one hand and showed "a positive relation between understanding by constructing a real model and successful solution of modelling problems (Krawitz et al., 2021; Leiss

et al., 2019)" (p.261) on the other hand. On top of that, "neither reading strategy training, nor prompting understanding by using reading comprehension questions, showed positive effects on worded modelling problems in subsequent studies (Hagena et al., 2017; Krawitz et al., 2021)" (Schukajlow et al., 2023, p. 261). These results show that the complexity of constructing a real model and the resulting difficulties cannot be reduced to reading comprehension. It is therefore of utmost importance to continue to identify favourable conditions in which the transitions from a real situation to a mathematical problem take place.

Presentation of the context

In the Swiss education system, the French-speaking cantons, follow a common a curriculum "Plan d'Études Romand" (PER[1]), which was progressively introduced from 2011, with a central place dedicated to problem-solving and modelling. There is, however, a rather scarce documentation of modelling in the PER. Indeed, the only direct comment concerning the objective of modelling is that it is not worked per se but is activated through the other thematic axes. Modelling is also considered as a common objective for mathematics and natural sciences and a clear demarcation line is drawn. In natural sciences the essence of the approach resides in the modelling of the phenomenon, including the problematization of the situation, the formulation of hypotheses, the setting up of an experiment or repeated observations, the analysis of results and the verification of hypotheses by confrontation with reality but the mathematization is left out. On the contrary, in mathematics, the work focuses on the mathematical treatment of the problem which takes place after the "modelling". We thus identified an institutional gap in the mathematics curriculum and are asking what takes place "during the modelling" before the mathematical treatment of the problem. This gave birth to a collaboration with the Department of the public instruction in Geneva and led to the creation of a working group composed of two researchers and four lower secondary mathematics teachers (two of them are also science teachers) in order to develop complementary material and accompanying resources for the implementation of the modelling objective in the Geneva Canton. This project started by an exploratory empirical case study in which we wish to document teachers' spontaneous practices during mathematical modelling as a starting point for the collaboration. In this paper, we present some preliminary results issued from this exploratory study concerning the implementation of two modelling tasks in May and September 2024 in two lower secondary classes (students aged 14 – 15 years old) with two different teachers. The second task, whose detailed analysis is proposed in this paper was conducted with one of the teachers and the same class.

Theoretical background

In this work, we refer to the research of Yvain-Prébiski (2021) and in order to conduct our analysis, we use her adaptation (Figure 1) of the modelling cycle (Blum & Leiss, 2007).

Indeed, Yvain-Prébiski (2021) characterizes *the horizontal mathematization* and, building on the work of Israël (1996), further describes the process recognizing two phases. From an extra-mathematical situation, it is through the selection of *fragments of reality* characterizing it and the

[1] https://portail.ciip.ch/per/learning-objectives/151

identification of their *relevant aspects* in relation to the question that it is possible to elaborate *a problem susceptible to mathematical treatment (PSMT)*. Then, continuing from this *PSMT* and through establishing relationships between the selected aspects, *the mathematical problem* takes shape. According to Yvain-Prébiski (2021), these two phases correspond to stages 1 (construct/understand) 2 (simplify/structure) and 3 (mathematize) of Blum and Leiss's (2007) modelling cycle. This "zoom" on the first three transitions of the modelling cycle provides a more precise characterization of what is done within these steps.

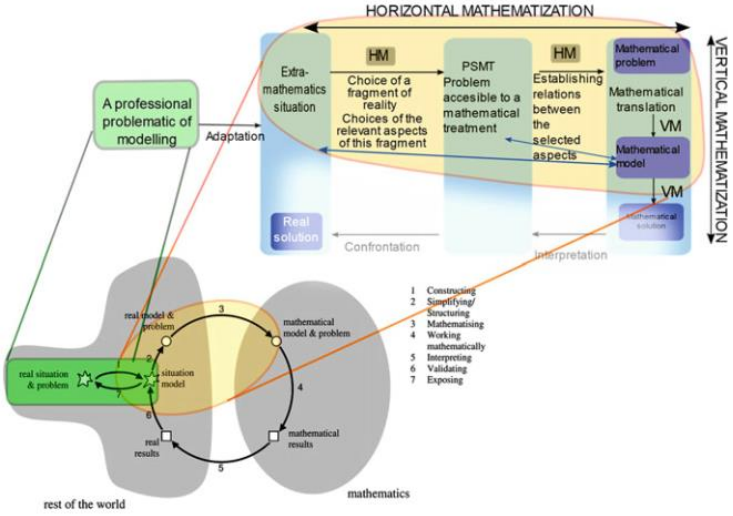

Figure 1: Diagram describing the modelling process (Yvain-Prébiski, 2021, p. 309)

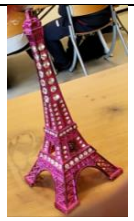
These theoretical elements enable us to specify what is institutionally related to by "after the modelling" in the PER as the *horizontal mathematization* and formulate the following research questions: When proposing a real-life situation, how do teachers manage the horizontal mathematization? More precisely, how can teachers facilitate the construction of a mental representation of this situation, the identification of different fragments of reality, the selection of the relevant aspects leading to the construction of a PSTM, and the establishment of connections resulting in the formulation of a mathematical problem?



Methodology of the research

In this exploratory study we observed the implementation of two tasks: Giant's shoes (Blum & Borromeo Ferri, 2009, p. 45) provided in Figure 2 on the left and the Eiffel tower, where a small souvenir (Figure 2 on the right) was brought to the classroom and the students were invited to question its fidelity towards the real Eiffel tower.

During the preparation, the teachers (Tom and Noah) were aware of the potential difficulties concerning the horizontal mathematization and we left it up to them to manage this phase as well as the possibility to make adaptations to the proposed activities. Tom implemented the Eiffel tower task and the Giant's shoes task in the lowest performing track class whereas Noah explored the Eiffel tower task with his scientifically oriented high-performance students. There were 12 students (14-15 years old) in each class.

Example 1: "Giant's shoes"
In a sports centre on the Philippines, Florentino Anonuevo Jr. polishes a pair of shoes. They are, according to the Guinness Book of Records, the world's biggest, with a width of 2.37 m and a length of 5.29 m.
Approximately how tall would a giant be for these shoes to fit? Explain your solution.

How faithful is this souvenir?

Figure 2: The proposed tasks (Blum & Borromeo Ferri, 2009, p. 45)

Concerning our data, we have an audio-recording of the Giant's shoes task, a video recording of the Eiffel tower lessons as well as the students' work captured through action cameras. This data was completed through pictures of the open board and of the white board and the observer's notes. and all recordings were transcribed. Due to the space available we only propose the analysis of the Giant's shoes task in Tom's class.

Data analysis

Introduction of the situation

Tom decided to allocate one 45-minute period for the implementation of this task. To introduce it, Tom displayed on the open board (OB) only a photo of the shoes and a sketch showing their dimensions (Figure 3) deliberately leaving out the question.

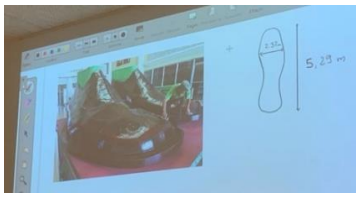


Figure 3: Projection of the real situation

Below is a transcript showing how Tom introduced the task to the students:

1	Tom:	What's important when you're doing math is knowing how to ask yourself good questions, so I'm not going to give you anything... Can anyone describe the picture to me (photo of the shoes displayed at OB)? Eric?
2	Eric:	slightly deformed shoes
3	Tom:	shoes a bit deformed, ok. What do you see in this picture? How do you understand this picture?
4	Students:	big shoes, giant things

This extract clearly shows Tom's vision of mathematics (line 1) as a discipline in which it is important to pose good questions giving thus a "real status" to the horizontal mathematization. Tom asks the students to describe the picture displayed on the OB. At this stage, we are facing an extra-mathematics situation but no question has been asked.

Construction of the mental representation of the situation and constitution of the PSMT

In order to encourage his students to formulate questions about the situation, Tom choses to tell a story providing the students with a sort of a mental experience of the situation (line 12) which

contributed to the construction of the mental representation of the situation and resulted in the formulation of the first questions about the situation (lines 13 and 15). The formulation of questions about the situation created favourable conditions that helped the students to make the first choices of the fragments of reality. Afterwards, Tom guides them to focus on the relevant aspects (line 16). This intervention contributed to a better understanding of the situation on the one hand and enabled the students to start making connections between these aspects (lines 21 – 23) on the other hand. The extract below illustrates our previous points:

12	Tom:	Put yourself in someone else's shoes, imagine you're an archaeologist and one day you find footprints of these shoes in the forest. What questions do you ask yourself?
13	Student 1:	who made them?
14	Tom:	who made them? *Tom writes the question on the board*
15	Student 2:	who's going to wear them?
16	Tom:	who's going to wear them? Why is this an interesting question?
17	Student 3:	no one wears shoes of this size.
18	Tom:	no one wears shoes of this size, so why did we make these shoes? these shoes have to fit someone?
19	Student 1:	it's artistic
20	Tom:	it's artistic all right, but let's put ourselves in the shoes of someone who finds these shoes and wonders who's going to wear them?
21	Student 4:	he must be a size 45.5
22	Tom:	Jay says he's a size 45.5, I'm a size 46.
23	Student 5:	size 100?
24	Tom:	size 100? What's the question about what you're saying?
25	Student 5:	foot size
26	Tom:	what is it? there's a term
27	Student 6:	shoe size
28	Tom:	size. *(writes the question on the board)* obviously 46 no, because I'm a size 46 and my feet should be 5.29 meters long.

Indeed, the mental image of an archaeologist finding these footprints brought up the idea of "someone who would wear them" (line 15) and his foot size (line 21). At this stage, we are witnessing a veritable back-and-forth between the phase of creating the problem, that of building a mental representation of the situation and the beginning of making connections between the relevant aspects of the chosen fragments of reality.

Later on, other questions about the giant's height and weight arise from the students. The choice of fragments of reality such as: shoes → giant → but what kind of a giant? and the focus on the relevant aspects → what size and what weight? provide evidence of the students' understanding of the task and give substance to the problem.

In the intervention below, Tom insists on the importance of posing questions in order to solve this type of problems, provides positive feedback to the students qualifying the questions as relevant and makes a summary on the advancement of the problem:

45	Tom:	So, let's say that what's important in this kind of problem is to be able to ask yourselves questions - I'm showing you shoes like this (*referring to the picture on OB*), there are no questions - but to be able to pose questions like the three you gave me are relevant. What's the size of these shoes? How tall

is he? I think that's interesting, what's his mass, his weight? That's interesting too.

The modality of letting the students pose questions about a real-life situation results in a variety of choices of fragments of reality: some of them are interested in the height of the giant while others mention its weight or shoe size. It also seems that the mental experience (imagine yourselves as an archaeologist) orchestrated by the teacher resulted in the mental image of the "person who would wear these shoes", providing thus an important fragment of reality. Therefore, these two intertwined elements (asking questions about the situation supported by a mental experience) seem to have contributed to the construction of the mental representation of the situation and thus to the understanding of situation and created favourable conditions for a variety of fragments of reality to emerge. Indeed, for some students it was not even relevant to investigate the height of the giant (*I don't care about the height […] I don't bother*) and would probably not engage in the problem in the original version.

The constitution of a PSMT and the mathematical problem

Once the three questions are formulated (line 45) and marked on the OB, Tom asks the students if they could find an exact answer to this problem and the students respond collectively that it is not possible. This intervention shows even though in a very implicit way that Tom wanted to make the students aware of the fact that the answer would depend on certain amount of assumptions. This question also in acted as a trigger for the gradual transformation of the extra-mathematical problem into a *PSMT*, which also continues with Tom's intervention:

51	Tom:	What else? Eric said it earlier, Jay said it, Gill said it, who wears size 40, raise your hand! 40 no one, 41, 42, 43 (*4 students raised their hands*), look around you, so you have the same foot size. Do you have the same height?
52	Students	No
53	Student	Approximately but not exactly the same height

Indeed, Tom asked to students with the same shoe size come up to the whiteboard and made a mark of their height showing a certain variability but also a proximity.

This intervention (line 51) also helps the students focus on the relevant aspects of the chosen fragments (height of a human being, shoe size) and start to make connections between them: making appear that there is a relation between the height and the length of the foot or the shoe size of a human being (line 58). These two elements led students to evoke the concept of "proportion" even if in a very naïve way (line 58):

56	Ben:	So, if the shoe is 2 meters long, for example, you (*referring to Tom*) are 1 meter and …?
57	Tom:	80
58	Ben:	1.80, you have a small foot, he (*the giant*) has a big foot (*inaudible "proportion"*)
59	Tom:	did you hear what Ben said?
60	Students:	yes
61	Tom:	could someone repeat it? It concerns what...?
62	Students:	proportion
63	Tom:	louder
64	Students:	proportion

65 Tom: proportion, what Ben said was that my feet are quite small compared to my height, but these shoes should be in relation to his height. That means he'd have to be really big if the proportions were the same.

This last moment of the collective discussion finalizes the construction of the PSMT and students begin to work in groups of 3-4.

During the group work, various strategies based on the choice of different fragments of reality and different relations between the selected aspects appeared. Some groups focus on the relations between their height (using a meter given by the teacher) and their shoe size while other groups consider the relations between their shoe size and the length of their shoes as shown in Figure 4 (left).

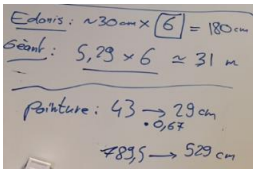

Figure 4: Students' procedures and results

In both cases, students create and solve a *mathematical problem* by using the concept of proportionality (*mathematical model*) as illustrated during the collective moment of sharing different solutions (see Figure 4 on the right).

In this last intervention (line 121), Tom handles the *interpretation* of the mathematical results and validates the coefficient 0,67 as a *real result* and invites the students to check it out on the internet.

121 Tom: his shoe size is 789, he's a 789 and what I found out, and I didn't know it but this is the real thing, is that if you check on the internet how you go from foot size in cm to shoe size, well you have to divide by 0.67. It was exceptional, you've done a great job, I'm delighted, we could go on like this for hours.

The interpretation and validation of the results was quickly handled by Tom at the end of the lesson. Because of the lack of time, Tom did not address the assumptions under which the model was chosen or question the empirical data and their effect on the result, nevertheless, he was aware of it and addressed this issue when implementing this same situation in another class.

Discussion and conclusion

This exploratory study enabled us to observe spontaneous practices of two teachers concerning the implementing two extra-mathematical situations (one of which was analysed in this paper) and identify some practices that created favourable conditions helping students to transform a real-life situation into a mathematical problem. The fact that Tom exposed the real situation without any question ("describe the picture") and supported it by a mental experience ("imagine you are an archaeologist") seemed to have contributed to the construction of a mental representation of the situation. All the more this was reproduced by the same teacher in another class for the situation "Giant's shoes" and in the same class for the situation "Eiffel tower". Another promising path are the interventions in the form of questions that help students sort out the fragments of reality and orient them towards relevant aspects of these fragments, permitting the construction of a PSMT and finally the formulation of at least two mathematical problems. The experimentation of the Eiffel tower

problem further highlighted the importance to dedicate enough time for students to build a mental representation of the situation before selecting the fragments of reality and identifying their relevant aspects that are indispensable for construction of the PSMT. Indeed, in Tom's class students' understanding of the situation affected positively their engagement in the task even though they encountered difficulties because their mathematical knowledge was fragile or not always available. On the contrary, in Noah's scientifically oriented class where the construction of the mental representation was left up to the students, we observed serious difficulties in identifying fragments of reality their relevant aspects leading to the recognition a proportional reduction in the pink souvenir of the Eiffel Tower as key argument of fidelity. This analysis confirms empirical results that a well-aimed balance between students' independence and teacher's guidance contribute to a successful resolution of a modelling task even in a low performing class on the one hand and raises the awareness to not to underestimate the treatment of the horizontal mathematization the high-performing classes.

These results open a new perspective of questioning the transferability of these elements to other tasks and other teaching contexts. To do so, we continue to explore, for other tasks, the effects of an "induced mental experience" on the construction of the mental representation of a situation and the selection of fragments of reality and their relevant aspects on the one hand and to what extent this could be anticipated *a priori*, incorporated in a teaching resource and adapted by other teachers, on the other hand.

Assessment in a two-dimensional curriculum: The case of solid geometry and modelling supported by an empty modelling cycle

Stig Eriksen and Martin Nordskog

University of Agder, Institute of Mathematics, Norway, stig.eriksen@uia.no

This paper reports from a study where groups of 9th graders were given opportunities to show their modelling competency. The goal was to create practical feasible ways of assessing both dimensions of a two-dimensional curriculum. An empty modeling cycle was used to support students in the process towards a video they produced for assessment. These first trials show that the empty modelling cycle was used by students to show their insight into modelling.

Keywords: Modelling, assessment, two-dimensional curriculum

Introduction

Many countries now have a two-dimensional curriculum in mathematics, as in Norway, which incorporates both content-oriented objectives and process-oriented objectives, such as mathematical modelling (Højgaard & Sølberg, 2019). In Norway, the legislation was adapted to the two dimensions with the new curriculum in 2020 by stating that the content-oriented objectives should be assessed "in terms of" the process-oriented objectives. The process-oriented descriptions should therefore somehow be assessed together with the mathematical content, without the curriculum explaining how this should be done.

The process-oriented dimension of modelling of the Norwegian curriculum is explicated as:

> A model in mathematics is a description of reality using mathematical language. The pupils shall gain insight into how mathematical models are used to describe everyday life, working life and society in general. Modelling in mathematics means creating such models. It also means to critically evaluate whether the models are valid and what limitations the models have, evaluate the models in view of the original situations, and evaluate whether they can be used in other situations. (Utdanningsdirektoratet, 2020, para. 2).

This description closely aligns with many descriptions or models of modelling processes. In the modelling cycle presented in Blum & Leiß (2007), seven steps are described: *constructing*, *simplifying/structuring*, *mathematising*, *working mathematically*, *interpreting*, *validating* and *exposing*. This model is developed as an aid for cognitive analysis of modelling tasks. These steps do not follow each other linearly or in a tidy cycle, but the students follow different modelling routes. However, the authors clarify that this model of a cycle is not meant to be used as an aid for the student. As a substitute, a simpler cycle is preferred and seems to be more appropriate for students. Beckschulte (2020) and Schukajlow (2015) used such simpler cycles as aid for learning modelling.

We have developed a technique using an *empty* modelling cycle as students' aid for this process of making meaning of modelling (Eriksen & Madsen, 2023). In short, during modelling activities the class do time-outs and students explain what they are doing and choose where to place their current actions in a simplified description of a modelling cycle. As this emerging modelling cycle becomes

a tool for learning modelling, it seems also possible to use it as a tool for students to show their modelling competency. This paper therefore explores: How do the students use the empty modelling cycle to show their insights of modelling competency?

The challenges given to the students were all within the content area of solid geometry. To answer the research question, we then need to describe what we mean by modelling competency, and the nature of the relation to solid geometry.

Assessing modelling x solid geometry competency

Maaß (2006, p. 139) concludes that sub-competencies should be paid attention to in class, but also that her students developed a holistic meta-perspective in the latter part of 15 months of modelling activities. Cevikbas et al. (2022, pp. 207-209) also divides into an analytical bottom-up perspective to modelling and show how this differs from a holistic top-down perspective. Freid (2013) calls for a better theoretical foundation of assessing modelling and we seek to address his challenge by starting from the top-down theoretical landscape of Niss & Højgaard (2019) where modelling competency, and its relation to solid geometry, precisely, but still in a general holistic sense, is combined in a matrix that shows competencies × mathematical areas. We connect our holistic departure to the atomistic descriptions from Blum and Leiß (2007) in Table 1.

The KOMPIS project in Denmark has shown us that it is possible to conduct a large summative oral assessment where students demonstrate their modelling competency by working with a mathematical area (Højgaard, 2023). While the KOMPIS project demonstrates that assessing modelling competency "top-down" is possible, it also describes assessment practices which are both comprehensive and time-consuming. In the project, Højgaard (2023) emphasizes that the main focus is on high validity, i.e. does the assessment measure what it is supposed to measure? This can be achieved by ensuring that what students demonstrate in the assessment situation aligns with the learning objectives in the prior instruction (Biggs & Tang, 2011).

Reliability in this context means making the assessment transparent and independent of who is doing it (Højgaard, 2023). Coherent assessment amongst who is doing it, will necessarily increase reliability, and can therefore be achieved by making explicit the answers to questions like: What is a model of solid geometry and what is modelling x solid geometry competency?

As we know well, an algebraic expression or a formula can be general descriptions of reality, for instance, in solid geometry, $2ab$ or $\sqrt{3}a^2$ could be a model for the surface of a tetrahedron-shaped food container. However, the definition includes more. With a tetrahedron at hand $10\sqrt{27}$ is also a description of the reality, or even the number 32.8 is a model for the same reality. An algorithm in a programming language, or a textual/oral/pictorial description of how to find a surface area would most probably include mathematical language and are therefore also models, e.g. "Four times the area of the triangular sides". However, the students' *actions* leading to these models may not portray the same modelling competency and, as we explain below, the students' *insight* may be different.

Niss & Højgaard (2019) define "A *mathematical competency* is someone's insightful readiness to act appropriately in response to a *specific sort* of mathematical *challenge* in given situations." (italics in original, p.14). They discuss how this definition is oriented towards action and that this action can be

done with or without insight, but the latter do not convey the same competency. The challenge depends on the practice the activity is embedded within, and hence, is both related to the individual and the social and cultural context. Keeping in mind this notion of *challenge*, we define for our project:

Mathematical modelling × solid geometry competency is someone's insightful readiness to act appropriately in response to a challenge of modelling x solid geometry.

In a classroom situation it will be the teacher's role to decide what is appropriate, whereby the students will show their insightful actions. Of course, the duality of action and insight are closely weaved, and the two-sidedness of the conceptualisation in the table below is mainly a construct to create a more reliable assessment. The students' insight is assessed by what they manage to show, but the descriptions in the Table 1 are of a cognitive nature. Hence, in their form in the table, the insights are not assessable, but the students may show their insight by language, writings, drawing or gestures. For example, the upper left cell in Table 1, describing insight into pre-mathematics includes "Knowing that the challenge...." and "Being aware that ..." but none of these are assessable. Nevertheless, they both could lead to some action that can be assessed. In our examples where the student orally explained their actions, often insight was made assessable by language.

Table 1: Modelling competency × solid geometry

Phase	Insight	Action
Pre-mathematics	Being aware of this phase of structuring and simplifying. Knowing that the challenge is to show modelling x solid geometry competency. Knowing how simplifications affect the model and results. Being aware of the phases to come e.g. planning for them. Consider alternative assumptions and choices. Knowing that the physical model provided is just one example.	Make sense of the situation and construct a situation model. Make assumptions and choices to simplify the problem, in order to mathematise into solid geometry, e.g. finding shape rather than weight of a potato. Finding relevant measures.
Mathematics	Being aware that working mathematically is separated from the other. Thinking of calculations and numbers as models, e.g. discussing how numbers change if measures or shapes were simplified differently. Knowing how mathematics is a simplification of the situation and that the model has limitations.	Finding correct measures. Do calculations and do them correctly. Working mathematically with area and volume and using mathematical operations correctly. Using geometrical units and using them correctly. Make a model that is appropriate to measurements and the situation.
Post-mathematics	Being aware of this phase. Knowing that models and results is based on assumptions and choices from earlier phases, e.g. accepting that there will not be one correct answer to this activity. Thinking "what if...". Consciously consider actions from other phases of the cycle.	Using mathematical results to conclude. Interpreting the mathematical results and comparing model and situation. Validating answers by checking calculations and units. Recommend or expose solutions to the real situation.

The table is not meant to be used by the students, but rather by teachers and researchers as an aid to establish what would constitute as good modelling competency regarding solid geometry. The table highlights which insights and actions would be connected to an adequate modelling competency. By translating the steps of the modelling cycle into insights and actions it could help determine what to look for when assessing modelling competency. To align the insights and actions to student work, we vertically divide the table of modelling competency to the simplified empty modelling cycle of just three phases used by the students (Figure 1). And while insights and actions showing modelling x solid geometry competency are described a priori, it still remains for teachers to interpret students' various actions. We have seen a way of operationalizing the holistic definition of modelling competency in relation to a mathematical subject area and the sub-competencies of modelling. In this paper we do not focus on students' actions but their insight.

Method section – the tasks and the empty modelling cycle

Two 9th grade teachers in two different schools participated with three researchers in the study. We conducted three teaching sessions in both schools, six teaching sessions in total, all including one modelling challenge. The students worked in groups of three. In the third session within each school, the groups were given a task in which they had to submit a cellphone video on how they responded to the challenge. The video was assessed by their teacher and the researchers and was given a numeric grade. The students were told that the assessment of their solution of the task would play a part in their year-round grade.

All tasks were invitations to develop mathematical modeling competence, and all tasks were meant for short terms, approximately 60 minutes. All the tasks were selected as knowledgeable situations for 9th graders and, and they were all supported by a physical example. The two training tasks were formulated as "How many dices could you put into a cup?" and "How long strip could you get from a toothpaste container?". The assessment task was given orally as: How many French fries do you get from a potato?

The assessment task is similar to a task found in Reit (2018, pp. 180). The physical example for the assessment task was a potato for each group to use as a starting point, and the students had access to a tape measure and a kitchen scale.

Blum & Borromeo Ferri (2009, pp. 54) states that "[…] teachers have to know ways how to support adequate student strategies for solving modelling tasks". The 7-step model is suitable for teaching and research purposes, but not necessarily as a strategic aid for students in problem solving. We introduced a simplified empty cycle consisting of three phases, i.e. no explanations of the phases were given in the cycle, see Figure 1. The empty cycle was to be used practically in work with modeling tasks. Both in work on the first two tasks, and as part of the presentation of task 3, the students used the empty cycle. In the videos that were to be assessed, the groups showed their modelling cycle and explained what they had done in the various phases. We made a qualitative content analysis of the videos.

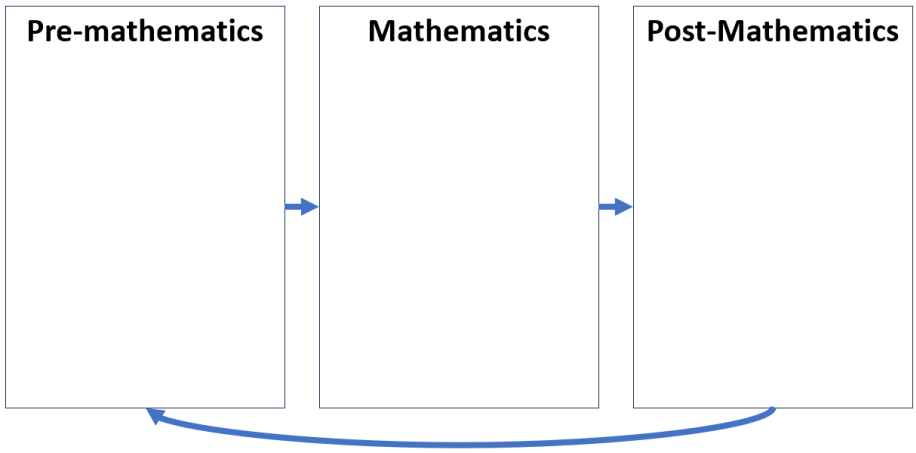

Figure 1: The empty modelling cycle

The empty modelling cycle was introduced as an aid both for the teachers and students. Firstly, we thought that it would help the researchers and teachers to get an insight into the students' modelling competency, and how they worked within the different phases of the modelling cycle. It was therefore useful in the assessment process, as one could see specifically what competence the students showed in the different phases of the modelling cycle, and one could compare this with what we had categorized as satisfying answers beforehand. Secondly, the empty modelling cycle was introduced as an aid for the students to organize and be aware of their modelling activities and prepare for assessment. As Blum & Borromeo Ferri (2009) suggest, a simpler model would be appropriate as an aid for students when working with modelling problems, and the empty modelling cycle is an example of this. By structuring their solution process into the three phases, it would be easier to explicitly illustrate their pre-mathematics work, their mathematical work, and their post-mathematical work.

Results - use of the empty modelling cycle to show insight

The empty modelling cycle was introduced to the students as an aid to both working with the modelling tasks and showing their insights and actions in terms of an assessment situation. We present here three episodes where students plan ahead, consciously navigate in the modelling cycle and show awareness of how their assumptions affect their results.

Firstly, the students used the empty cycle as an aid to determine what they needed to do to solve the problem. In the videos several groups reported on how they made a plan for what to come.

> Student: OK, so before we started the calculations, we started with measuring the potatoes and made a plan to find how many french fries you get from a potato.

When using the empty modelling cycle, it is evident that the students were encouraged to think about a plan to solve the problem. They had to consider what bits of information were needed to fill out the empty cycle, and what bits of information they were missing.

Secondly, it can be hard for both teachers and students to determine which step in the cycle one might find themselves in at a given point during the problem-solving process. Our findings suggest that with

the use of the empty modelling cycle, the students were aware of their whereabouts in the modelling cycle and became self-aware about their movement from one phase to another.

Student 1: And then we went back and started cutting the potato and set new measurements [Points at "pre-mathematics" in the poster].

Student 2: Yes, and then we cut the potato in half, so then it was easier to measure the area in the middle, so we measured new measurements, and then we drew it on the potato, to check, and then we calculated the same way as we had done previously, only with the new measurements.

Student 3: And then we looked at the new answers we had received, and then we looked at the difference between before and after we had cut the potato. And then what [answer] was most realistic.

Here we see that the students actively refer to the cycle, using terms like "we went back" to refer to their position in the cycle. This may suggest that the cycle works as an aid to raise the students' awareness about their own modelling process, and the cycle is also used as an aid to show their insights.

Thirdly, our findings also suggest that by using the empty modelling cycle, the students tend to evaluate their answers in an explicit matter. The box "post-mathematics" encouraged students to explicate their thoughts about their solution process, and what their answers would mean in an authentic context.

Student: It may not be the best model. So, it doesn't work if there are ugly potatoes. They must be round or oval potatoes for it to work.

This group shows insight by distinguishing between the complex aspects of real life and the precise matter of mathematical calculations, and they also proceeded to present a more general formula that could be used for any given potato:

Student: And then the formula. It's the weight of the potato, minus 10%, because it is some redundancy, potatoes are not perfect. And then divided by 4.3, and then you get the number of fries.

The group is both aware of their own model's limitations and criticizes this, and also presents a more general answer, by commenting on how one could solve a similar problem with any given potato, and not just the specific potato the students had in hand.

Ferri (2007) states that the modelling cycle is not linear, and it is not unusual for the problem solver to create their own modelling routes. It can also be necessary for the problem solver to adjust assumptions and go round the loop a second time (Blum & Borromeo Ferri, 2009, pp. 47).

Conclusions

The episodes illustrate how these students used the empty modelling cycle to show their insight into modelling. Firstly, the empty modelling cycle gave the students a predetermined structure that helped

them to plan their work. They showed insight into modelling by putting that insight forward for assessment. Secondly, the empty cycle raised the students' awareness of the last phase of modelling, knowing they were expected to present to the post-mathematics box, and there they evaluated their model against the origin of the situation. Thirdly, we see how the students consciously and insightfully moved back and forth in the modelling cycle, looking at assumptions when validating their model.

The results show that the students use the empty cycle to navigate through the modelling cycle, and that there is a need to go round the loop and adjust the initial assumptions. These results also correspond to the findings from Ferri (2007). The use of the modelling cycle encourages explicitly to this, and the students in this study used it as an aid to navigate through the loop.

As Blum & Borromeo Ferri (2009) suggests, teachers must know how to support adequate student strategies for solving modelling tasks. Introducing and using aids to do modelling tasks are examples of such strategies, and this study shows that the empty cycle can be used as such a tool.

The tasks turned out to be feasible and suitable for the three 60-minute lessons leading to the video for assessment. Other tasks may challenge students more in all phases of the modelling process, especially before and after the calculations are done. The empty cycle seems to be a tool to raise awareness and keep track of modelling activities – both for students and teachers.

When we graded the students together with the teachers, we experienced high reliability through compliance in our gradings and discussions. Our scheme for grading, based on Table 1, seems to be an important factor in this. Explicating insight in a scheme helped us to know what to look for when the students managed to turn their insight into action. But luckily, students continue to surprise us and come up with ideas we did not think of in the first place.

How do pre-service teachers interact with IA to solve modelling problems? Characterising the use of ChatGPT in solving Fermi problems

César Gallart[1], Irene Ferrando[1], Carlos Segura[1] and Lluís Albarracín[2]

[1]Universitat de València, Spain; irene.ferrando@uv.es

[2]Universitat Autònoma de Barcelona, Spain

In recent years, the use of AI systems has intensified, particularly in the field of education. It is a tool that could be useful in solving modelling problems, such as Fermi problems. These types of problems are suitable for introducing modelling in primary education classrooms. In the present study, we want to explore how pre-service primary school teachers use ChatGPT when solving two Fermi problems. The qualitative analysis of the interactions with ChatGPT and the written solutions produced by 94 pre-service teachers allows us to categorise the prompts by distinguishing categories that come from the prompting techniques from those that emerge from the phases of the modelling cycle. Through this system of categories, we characterise the use of AI by distinguishing three levels depending on the degree of responsibility given to the AI (from full delegation to instrumental use) in the modelling process: use of ChatGPT as problem problem-solving expert, assistant and support.

Keywords: Modelling, Fermi problems, Artificial Intelligence, pre-service teachers, prompts.

Introduction

Integrating Large Language Models (LLM) in the classroom –on which ChatGPT generative artificial intelligence (AI) is based– is a topic of current debate (Lo, 2023). The novelty and potential of this technology raise challenges and opportunities for education at all levels (Zhang & Aslam, 2021). Its use could facilitate teachers' teaching, for example, through automated assessment of their students' responses, adaptive feedback and content generation (Ausat et al., 2023).

In Mathematics Education, generative AI could be used to support problem-solving, including mathematical modelling activities, thus facilitating its effective implementation in the classroom. One proposal for introducing mathematical modelling in primary education is to use Fermi problems (Ärlebäck, 2009). Fermi problems are a type of modelling problem in which a question is posed in a real context, without data, requiring reasoned estimations and simple calculations to reach the answer.

Consequently, pre-service teachers need to be familiar with Fermi problems, including their solutions and application in the classroom. Our purpose is to explore how pre-service primary school teachers use ChatGPT to solve Fermi problems. To this end, we characterise how they interact with ChatGPT to develop the models generated by solving Fermi problems.

Fermi problems as modelling activities

Ärlebäck (2009, p. 331) describes Fermi problems as "open-ended, non-standard problems that require solvers to make assumptions about the problem situation and estimate relevant quantities before often performing simple calculations". Since these problems ask for an estimation without providing specific data of the real situation, their solution unfolds a process that can be interpreted as

the development of a mathematical model (Robinson, 2008). The process follows the modelling cycle (Blum & Leiß, 2006), as it requires: (i) understanding, identifying and structuring variables of the real situation; (ii) constructing a mathematical model by estimating these variables and mathematising their relationships or structures; (iii) working mathematically within the model to obtain the final estimate; (iv) validating the estimate in reality, being able to revise the model and incorporate new realistic assumptions that, when quantified, can provide greater accuracy to the final estimate. Although Fermi problems' solution process follows the modelling cycle, it can be considered "miniature", as it requires simple calculations, so authors such as Albarracín and Gorgorió (2014) have highlighted its accessibility, recommending its use as an introduction to modelling in Primary education. However, the results of Segura and Ferrando (2021, 2023) show that pre-service teachers have difficulties when solving Fermi problems. Perhaps AI support can help overcome these difficulties (Noster et al., 2024), but the first step is to understand how this tool is used in solving Fermi problems, which to our knowledge has not been studied previously.

Use of generative AI in problem-solving

It has been shown that LLMs can solve some mathematical problems, depending on their complexity and the mathematical domain to which they belong (Schorcht et al., 2024). However, AI can confusingly solve them, due to the lack of transparency in its decision-making processes, and because its answer can be plausible, but incorrect (Noster et al., 2024). In modelling problems, where context plays a major role, research by Spreitzer et al. (2024) concludes their open-ended nature does not appear to have a significant impact on the modelling capabilities of AI, although the greater complexity of the context may affect its reliability.

An important aspect of the use of AI for problem-solving is the interaction through prompts, namely questions asked to the LLM to progressively obtain the solution (Noster et al., 2024). The literature on prompt engineering details the main prompting techniques. In the Zero-shot technique, the AI is presented with the complete problem, seeking to obtain a direct solution (Kojima et al., 2022). The Few-shot technique involves giving the AI some prior instructions to improve its response by conditioning the model with a few examples (Snell et al., 2017). It has been shown that AI's problem-solving efficiency can be improved by "let's think step-by-step" instructions combined with Zero-shot instructions, a method called Chain-of-Thought prompting (Wei et al., 2023). Another type of prompt allows for the personalisation of these responses (Output customisation), by imposing certain rules or specific characteristics (White et al., 2023).

Few previous studies have explored the competence of pre-service teachers using AI tools for mathematical problem-solving (Noster et al., 2024). Indeed, no detailed analysis has been undertaken to characterise the use of these tools by analysing the prompts formulated by pre-service teachers to solve a modelling problem.

Methods

The study was carried out with a sample of 94 pre-service teachers, all of them belonging to the third year of the Primary Education Degree at the Faculty of Teacher Training of the University of Valencia (Spain). All participants had previous experience solving Fermi problems, as they had worked on

solving a sequence of problems in the faculty environment (described in Segura and Ferrando, 2023). None of the participants had previous experience of using ChatGPT to solve mathematical problems.

Data collection was conducted during a 2-hour class session, supervised by two of the researchers. Beforehand, the participants were asked to register in ChatGPT (version 3.5 free access) and to bring their laptops with internet access. At the beginning of the session, we explained that they had to solve individually two Fermi problems, but this time they could ask ChatGPT questions. The problems were contextualised in an environment familiar to the participants but presented hypothetical situations far removed from their immediate experience. Problem P1 asked to estimate how many people could attend a concert held at the Valencia football stadium, and problem P2 asked to estimate the number of people inside the IKEA in Valencia at the time of maximum influx of customers. The statement of these problems was accompanied by an aerial image of the place (Google Maps). The written solution reports produced by each participant and the ChatGPT interaction document generated by using this tool were collected for data analysis.

The results that allow us to address the objective of this study derive from a qualitative analysis of the data collected, specifically from the analysis of the prompts collected in the interaction document with the AI. To categorise the prompts, the written solutions of each participant were also analysed. In this way, we can confirm whether the solution is based solely on delegating the problem-solving to chat GPT or if, on the contrary, the solver has, at some point, followed the phases of the modelling cycle. In the first case, the written productions contain exactly the information provided by ChatGPT, and the prompts are categorised as Zero-shot (Kojima et al., 2022), Few-shot (Snell et al., 2017), Chain-of-Thought prompting (Wei et al., 2023) or Output customisation (White et al., 2023). In other cases, when the solutions contain details (e.g. drawings, diagrams or sentences) that allow us to distinguish the participant's solution from his/her interaction with the AI, we have categorized the prompts following the phases of the modelling cycle. The categories that were finally agreed upon by the researchers combine (albeit in a differentiated way) both perspectives, as described in Table 1. It should be noted that Table 1 does not indicate that there is a correspondence between the prompting techniques and the phases of the modelling cycle, they are two parallel and independent categorisations.

Table 1: Categorisation of prompts

Categories of prompting techniques	**Categories of the modelling cycle**
0.1. Zero-shot: the problem itself is used as input, copying the statement directly into the chat, without having asked any other previous question neither including any specification or additional information. For example: “How many people can fit in the Levante soccer stadium if we want to organise a concert?” in P1.	*1.1. Understanding and structuring the problem:* these prompts seek a better understanding of the problem and an identification of what aspects or data are needed (variables and their relationships), For example: “What data should be taken into account to calculate the maximum capacity of a shop?” in P2.
0.2. Few-shot: unlike the previous one, in this case, specific questions are asked about some aspects of the problem. For example, the dimensions of the space to be	*1.2. Construction of the model:* we include all those prompts related to the estimation (quantification) of the variables that make up the model. They are divided into three types:

occupied ("How many people can fit in 7140 square metres?" in P1), and then directly ask how many people can occupy the total area of the problem. We also include in this category those prompts that seek to refine the solution and make it more accurate by introducing a realistic assumption (without explicit relation to a specific mathematical model) for example: "(...) you should consider that there will be a stage, an area reserved for technical equipment and sound facilities" in P1.	- Questions related to the dimensions of the space to be occupied (*subcategory 1.2.1*), e.g. "What is the area of a football pitch?" in P1 or "How big is the IKEA in Valencia?" in P2. - Questions related to density or the space occupied by a person (*subcategory 1.2.2*), e.g. "How much does one person occupy?" or "How many people fit in one square metre?" - Direct questions about new realistic assumptions to make the participant model more accurate (*subcategory 1.2.3*), e.g. "How many square metres are occupied with shelves and furniture in IKEA?"
0.3. Chain-of-Thought: after a direct (Zero-shot) or quasi-direct (Few-shot) question, the participant gives the ChatGPT several consecutive prompts about the procedures involved in the solution. For example: 'How could you calculate it? [to clarify how the AI can calculate how many people fit in the total area from the data in a smaller area, which requires an explanation of proportional reasoning].	*1.3. Mathematical work:* in this category, we include all the prompts that require mathematical calculations, using ChatGPT as if it were a calculator, e.g. "Multiply 4 times 7140".
0.4. Output customisation: after a direct (Zero-shot) or quasi-direct (Few-shot) question, a specific output format is specified to the ChatGPT. For example, if the AI has explained the solving procedure in a general way, without calculations, the participant formulates the following prompt: "Solve it with mathematical operations", or "I need a quantity".	*1.4. Model validation and review:* these prompts seek to check the validity or conformity of a result or assumption, e.g. "Do you think 420 people can fit on a football pitch if there is a concert?" in P1, or "Is five square metres per customer too much?" in P2.

Results

The first step to characterise the use of ChatGPT in the solution of Fermi problems was to code, for each pre-service teacher, the prompts formulated by applying the categorisation described in Table 1. Table 2 shows the percentages of use of each of the categories of prompts (each category is counted only once in each solution) in the two Fermi problems. For a correct understanding of Table 2, note that the use of prompts is not exclusive: for example, the same participant may have first used a Zero-shot (0.1), not been satisfied with the result and asked questions to detail the process (0.3).

The results in Table 2 show that the most frequently formulated prompts refer to direct questions of the Zero-shot type (appearing in 54% of the productions) and questions about the construction of the model, specifically in relation to the dimensions of the total space available (subcategory 1.2.1, which appears in 69% of the productions). In addition, there is a slight change of trend in the type of prompts

asked in the second problem, as the number of prompts related to the model construction process and mathematical work decreases, while Zero-shot, Few-shot and Output customization prompts increase.

Table 2: Percentage of use of each prompt in the two Fermi problems

	Prompts									
	0.1	**0.2**	**0.3**	**0.4**	**1.1**	**1.2.1**	**1.2.2**	**1.2.3**	**1.3**	**1.4**
P1	50%	27%	11%	4%	4%	70%	51%	22%	20%	2%
P2	59%	30%	7%	10%	7%	68%	18%	12%	13%	4%
Global	54%	28%	9%	7%	6%	69%	35%	17%	16%	3%

From the results analysed in Table 2, together with the analysis of the problems' solutions, we determine three different characterisations of the pre-service teachers' use of ChatGPT to solve Fermi problems.

1) *Using ChatGPT as a problem-solving expert (PS-Expert). S*ome participants delegate the solution of the problem exclusively to the tool. By prompting, they want the AI to eventually come up with a satisfactory solution. In this category of use, pre-service teachers only formulate instructions of the type Zero-shot (0.1), Few-shot (0.2), Chain-of-Thought (0.3) and/or Output customization (0.4). An example of this type of use for solving P1 is the following:

Participant B12: You are an expert in solving mathematical problems, you have to help me by explaining step by step how to solve it and the procedures you would use to reach the solution. [*0.3*]

Participant A26: How many people can fit in the Valencia football field as an audience (only in the grass area) if we want to use that space to hold a concert of a famous artist? [*0.1*]

2) *Using ChatGPT as a problem-solving assistant (PS-Assistant)*. Some participants try to complete the modelling cycle using, for each phase, model prompts (1.1, 1.2, 1.3, 1.4) but also use the prompts from prompting techniques (0.1, 0.2, 0.3 and 0.4) to get ChatGPT to give them an answer. Eventually, they get an assisted solution. The example below shows the interactions of Participant A41 who, in solving problem P1, avoids making decisions about estimating the magnitude value of the model variables, and ends up leaving it up to ChatGPT to decide how many people fit in a bounded enclosure:

Participant A41: What is the size of the grass area of the Valencia football pitch? [*1.2.1*]
How many people can fit in a space of 7140 square metres? [*0.2*]
OK, now if we take into account the size of the stage of the singer who is going to sing in that venue. [0.2]

3) *Use of ChatGPT as a problem-solving support (PS-Support).* Other participants use ChatGPT as a specific tool during the solution process, developing the model autonomously. These pre-service teachers only formulate specific prompts to support their own development of the phases of the modelling cycle (1.1, 1.2, 1.3 and 1.4). An example of this type of interaction can be seen in the following sequence of prompts formulated by a participant:

Participant B09: How many people can fit in one square metre? [1.2.2]
Length and width of the Valencia football pitch. [1.2.1]

Length and width of a standard concert stage on a football pitch. [1.2.3]

Table 3 shows, for each problem, the number of pre-service teachers (and the percentage) who have used ChatGPT according to each of these three characterisations.

Table 3: Proportion of each characterisation of the use of ChatGPT to solve Fermi problems

	ChatGPT as PS-Expert	ChatGPT as PS-Assistant	ChatGPT as PS-Support
P1	25 (27%)	32 (34%)	37 (39%)
P2	24 (26%)	48 (51%)	22 (23%)

Thus, we observe that in both problems, almost a fourth of the pre-service teachers merely 'transfer' the responsibility of finding a solution to ChatGPT itself, as an expert (in the category “ChatGPT as PS-expert”). In those cases, in the productions with the written solution, we observe that many of them simply reproduce ChatGPT's answer directly, without adding any justification. We also find participants who only indicate the process to be followed to reach the solution, but without quantifying it, taking the reasoning provided by the AI.

On the other hand, we identified those participants who make instrumental use of AI (and who are the majority for both problems), i. e. their instructions do not seek ChatGPT to solve the problem directly (in the categories “ChatGPT as PS-assistant” and “ChatGPT as PS-support”). In these cases, the instructions seek the support of the AI in some (or all) phases of the modelling cycle, in particular by quantifying the variables selected in their model. It is the future teacher who reaches the final solution of the problem by choosing the strategy and identifying the relationships between the variables. The responsibility for the solution process thus lies with the solver himself, and the AI becomes a complementary tool. In these cases, a clear distinction is made between those pre-service who use it only as a support, asking very specific questions that allow them to progress in the solution process (as problem-solving support), and those who in some way bypass some phases of the modelling process by delegating to the AI tool (as a problem-solving assistant).

Furthermore, according to the results shown in Table 3, we can observe a certain evolution in the use of ChatGPT in this experience, based on the solution of two Fermi problems. For the problem P1, there is a higher proportion of participants who only use ChatGPT as PS-support. However, for the problem P2, which is slightly more complex and where participants have some experience in using ChatGPT, the majority (51% of participants) use the tool as PS-Assistant, combining instructions related to the solution process. The proportion of participants using ChatGPT as a PS expert remains the same.

Conclusions, limitations and further research

This study presents a categorisation of the prompts given to ChatGPT, during the solution of a modelling problem that requires obtaining the reasoned estimate of the number of elements from a statement without numerical data. The categorisation of prompts is based on the one hand, on prompting techniques described in the process systems literature (Kojima et al., 2022; Snell et al., 2017; Wei et al., 2022; White et al, 2023). But, on the other hand, the experience carried out, in which not only the prompts given to ChatGPT but also the written productions with the solutions to the

problems have been analysed, has allowed us to enrich this initial system of categories with others that derive directly from the modelling cycle. The categorisation of the prompts in Table 1 has enabled the identification of three categories of future teachers' use of ChatGPT in solving a Fermi problem. By combining the exclusive or non-exclusive use of prompts based on prompting techniques and those based on the modelling cycle, three categories of use have been established and are described in Table 2.

From one side, we distinguish future teachers who completely delegate the solution of the Fermi problem to the ChatGPT tool. These solvers never take into account the solution process described in the modelling cycle (Blum & Leiß, 2006), this can be seen from the solution reports in which they simply copy the answers obtained by the LLM-based system. On the opposite side, we have those participants who follow every step of the modelling cycle during the solution process, relying only on ChatGPT with prompts that can be helpful when interpreting the problem, constructing the model, working mathematically and validating the solution. In the middle, we find those participants who also make instrumental use of ChatGPT, avoiding a total delegation of the solution process, but, skipping some phases. Those participants use, in most of the cases, prompting techniques such as Few-shot and Chain-of-Thought, and tend to skip the construction of the model leaving this responsibility to the LLG-based system.

Thus, within these three categories, two attitudes can be distinguished when using ChatGPT to solve modelling problems: delegating responsibility for the solution or making instrumental use of the tool. This allows us to overcome certain reluctance to its use, as well as to provide a culture of AI to future teachers that will enable them to integrate this tool in their classrooms, in addition to developing competencies to evaluate ChatGPT productions. However, a limitation of this study is that it does not rigorously investigate at what phases of the modelling process pre-service teachers feel the need to delegate the solution to the ChatGPT tool. Moreover, the results in Table 3 suggest that the user's experience in solving problems with the help of ChatGPT or the complexity of the problem may be factors that influence the use of prompts and, therefore, the way of interacting with the tool. To confirm whether this is indeed the case, it is necessary to address studies that analyse, on the one hand, the effect of previous experience, and on the other hand, the effect of problem complexity, on the use that solvers make of ChatGPT.

The modeling project approach allows apprentices to study a topic of their interest and subsequently develop a project in which they formulate and solve a mathematical problem. The aim of this study is to understand the mathematical knowledge deployed by a group of two future teachers when developing a modeling project. This study analyses a project related to healthy living, specifically, to the number of steps an individual takes per day. The mathematical knowledge deployed in the development of the project was categorised using the Mathematics Teachers' Specialised Knowledge (MTSK) model, focusing on the Mathematical Knowledge (MK) domain. The data collection instruments were the project report with its video presentation, and a narrative. The results show that the modeling projects approach mobilised the subdomains Knowledge of Topics (KoT), Knowledge of the Structure of Mathematics (KSM) and Knowledge of the Practice of Mathematics (KPM).

Keywords: Mathematical modelling, modeling projects, mathematical knowledge, teacher knowledge, prospective teachers.

Introduction

While there are various interpretations of mathematical modeling (e.g. Kaiser & Sriraman, 2006), it typically focuses on the relationships between mathematics and real-world situations, often involving the formulation and solution of problems (Niss et al., 2007). In this paper, modeling is viewed from the perspective of modeling projects that emphasizes student engagement. Learners, working in small groups, select a topic to explore and, based on this topic, pose a problem or question to investigate (Borba & Villarreal, 2005).

The preparation of teachers in mathematical modelling involves fostering the development of their competencies to both teach mathematics through modelling and to teach modelling itself (Blum, 2015; Doerr, 2007). Additionally, it is crucial to equip teachers with the skills to incorporate modelling activities into their lessons, helping them gain confidence in using these activities and the courage to challenge conventional approaches to mathematics teaching and learning. In this context, modeling should address both the knowledge required to engage in mathematical practices and the application of modelling in the teaching process (Doerr, 2007), in line with the fact that the teaching of mathematics in teacher training differs from that of other professions, as it is specialized. This study addresses the mathematical knowledge deployed in the practice of modeling, based on the conceptualization of the Mathematics Teachers' Specialised Knowledge (MTSK) (Carrillo, et al., 2018).

There is a lack of literature reporting on problem-solving practice and specifically modelling, particularly within the framework of MTSK. Studies by Carrillo et al. (2017), Escudero-Ávila et al. (2015) and Galleguillos and Ribeiro (2022) report on mathematical knowledge in relation to problem-solving practices, and Zapata-Jaramillo (2023) proposes a separate category for modelling practices.

The need to delimit these practices related to mathematical knowledge respect to modeling was a key motivation for the present study. Thus, the aim of this study is to understand the mathematical knowledge deployed by a group of two pre-service teachers while working on a modeling project.

Framework

In this paper, modeling projects is seen as a pedagogical approach that emphasises learners, working in small groups, choosing a topic to study of their interest, and from it proposing a problem or question related to that topic (Borba & Villarreal, 2005). Modeling projects approach use problem posing strategy, which consists of formulating and reformulating problems (Cai & Hwang, 2021; Siller et al., 2024) that, in our perspective, allow students to first engage in an extra-mathematical topic, making strong connections between mathematics and reality and, thus, allowing students to visualize the usefulness of mathematics. In the case of teacher training, Ferrando et al. (2025) point out that training in problem-posing can effectively improve teachers' ability to pose and evaluate modeling tasks. An example of this approach with future teachers is found in Galleguillos (2024).

Accordingly, the MTSK model (Carrillo et al., 2018) was adopted to categorise the knowledge dimensions that can be mobilised by working on a modeling project. In this article, focus is given to the Mathematical Knowledge (MK) deployed by a group of two prospective teachers who worked together on a modeling project. The specialized knowledge of MTSK mathematics teachers is used as an analysis framework, in their MK domain, which is divided into three subdomains: Knowledge of Topics (KoT), Knowledge of the Structure of Mathematics (KSM) and Knowledge of Practices in Mathematics (KPM), which are defined below.

- KoT describes what and how the teacher knows about the topics he/she teaches, which implies a deep understanding of mathematical knowledge and its meaning. According to Vasco and Moriel (2022), KoT comprises the following categories: (1) procedures, (2) definitions, properties and foundations, (3) representations, and (4) phenomenology and applications. As an example, the application by teachers of the properties of logarithms shows a knowledge of KoT in definitions, properties and foundations (2) in logarithms topic.
- KSM corresponds to the teacher's knowledge of the connections between mathematical elements. This knowledge considers inter-conceptual connections and the role of mathematical items in the construction of other items. It is related to an increase in complexity or to simplification. As noted by Flores-Medrano (2022), KSM comprises four categories: (1) complexifying connections, (2) simplifying connections, (3) transverse connections, and (4) auxiliary connections. For example, the use of properties of logarithms in conjunction with exponentiation shows a knowledge of mathematics structure in transverse connection (3) between these contents.
- KPM corresponds to any mathematical activity carried out systematically, which is the basis of mathematical creation. This knowledge includes knowing about proof, justification, definition, making definitions and inductions, giving examples, and understanding the role of counterexamples. In addition, knowledge of problem-solving strategies and aspects of mathematical communication such as precision in the use of language is part of the practices in mathematics. According to Delgado-Rebolledo et al. (2022), KPM comprises the following four categories: (1) the practice of proving, (2) the practice of defining, (3) the practice of

problem solving, and (4) the role of mathematical language. For example, using drawings or diagrams to solve a problem shows KPM's knowledge of problem-solving practice (2).

Extensive research has been conducted on the mathematical knowledge of topics (KoT), yet studies focusing on the subdomains of KSM and KPM remain limited (Climent & Montes, 2022; Delgado-Rebolledo et al., 2022). Specifically, studies in which teachers engage with problem-solving, modeling, or teaching problem-solving offer valuable insights into KPM. For instance, Carrillo et al. (2017) examined the development of a mathematics teacher working on a problem, revealing aspects of knowledge related to simplifying the problem to find its solution. Escudero-Ávila et al. (2015) identified the teacher's knowledge in breaking down a problem into specific cases to enable a detailed analysis of the problem. Galleguillos and Ribeiro (2022) explored knowledge related to conjecture justification in an optimization problem. Finally, Zapata-Jaramillo (2023) investigated modeling tasks, highlighting a category focused on modelling practices, such as in explorations and model formulation.

Methods

This study was approached as basic qualitative research (Merriam & Tisdell, 2016), which aims to understand how participants make sense of their experiences. The study was conducted within the context of a mathematical modeling course taught during the seventh semester of initial mathematics teacher training at a Chilean university, where preservice teachers were tasked with developing a modeling project. This article specifically examines one of the projects, developed by Fabiola and Néstor. Course participants were guided through a supporting framework that included the following steps based in Almeida et al. (2016): project title and information about the chosen topic, questions or problems posed, mathematization, explanations, reflections, and conclusions. The project was assessed using a rubric that evaluated elements such as problem formulation and statement, problem solving, interpretation of results, reflections and conclusions, along with a video presentation of the results. The participants chose to collaborate on a project focused on healthy living, specifically examining the number of steps taken daily by an individual. Upon completion of the project, they were asked to write a narrative of their experience, which was written by Fabiola. The narrative was neither assessed nor mandatory. The data related to this project are analysed here using the MTSK model, focusing on the MK subdomain.

Analyses and Results

The project is titled: "A few small steps each day, an investment in the future". It is founded in which: "Physical activity is a preventive measure for the development of non-communicable diseases such as cardiovascular diseases, and it also has a positive impact on mental health, maintaining a healthy weight, and the general well-being of people. Promoting the performance of different types of physical activity, especially in girls, boys, and adolescents, is crucial, since the prevalence of childhood obesity in our country has increased from 9.69% in 2008 to 14.06% in 2022, according to data provided by the Department of Nutrition and Food (2023). Walking, in particular, is an affordable and accessible activity for the majority of the population. But how many steps should we take daily to obtain benefits in our health status? […]" (Project of Fabiola and Nestor).
The problem addressed by the participants is given follow:

A female high school student decides to progressively increase the number of daily steps she takes to improve her cardiovascular health. To do this, she was advised to increase the number of steps taken each day by 5%.

a) If she initially took 2,500 steps a day, how many weeks would it take her to reach a target of 7,000 steps a day?
b) If a person's height is 1.64 metres, how many kilometres would the total number of daily steps they take on the last day of each week amount to?

The Figure 1 shows some slides related to the project, which were presented in a video format.

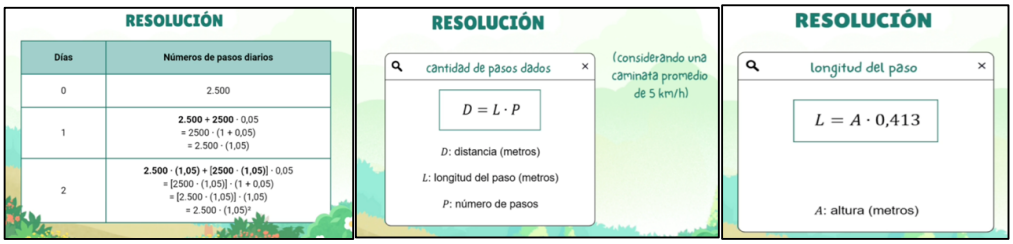

Figure 1. Some slides of the project shown in the video

Solution to Problem (a)

Table 1. Generalisation of number of daily steps

Day	Number of daily steps
0	$2{,}500$
1	$2{,}500 + 2{,}500 \cdot 0.05 = 2{,}500(1 + 0.05) = 2{,}500(1.05)$
2	$2{,}500(1.05) + 2{,}500(1.05) \cdot 0.05 = 2{,}500(1.05) = 2.500(1{,}05)^2$
3	$= 2{,}500(1.05)^2 + 2{,}500(1.05)^2 \cdot 0.05 = 2{,}500(1.05)^2(1 + 0.05)$ $= 2{,}500(1.05)^2(1.05) = 2{,}500(1.05)^3$
⋮	⋮
n	$= 2{,}500(1.05)^n$

In response to problem (a), the group presented a table (Table 1) delineating the number of steps per day, based on a 5% daily increment. To determine the number of days required to reach 7,000 steps the participants formulated the following exponential equation:

$$7{,}000 = 2{,}500(1.05)^n \quad (1)$$

Applying properties of logarithms, the group found that the goal of walking 7,000 steps a day can be achieved in 22 days.

$$\begin{gathered} 7{,}000 = (2{,}500)(1.05)^n \ /\log_{1.05}(\ ) \\ \log_{1.05}(7{,}000) = \log_{1.05}(2{,}500 \cdot (1.05)^n) \\ \log_{1.05}(7{,}000) = \log_{1.05}(2{,}500) + \log_{1.05}(1.05)^n \\ n = \log_{1.05}(7{,}000) - \log_{1.05}(2{,}500) \\ n = 21.103 \ldots \approx 22 \end{gathered}$$

The solution presented by the participants show that the participants develop the necessary knowledge to model the problem and answer it, showing knowledge of the three subdomains. Some of these actions are related to mathematisation, reflecting both a knowledge of practices in problem solving and modelling (KPM). First, they applied a 5% increase to the initial number of daily steps, which corresponds to the category of procedures (KoT – *procedures*). Then, they constructed a data table

by applying this increase in the given percentage (KPM – *problem solving*). Thus, they found a general pattern of the situation, which relates to a modelling practice (KPM – *modelling practices*). Continuing, to solve equation (1), they applied different properties of logarithms to find the number of days needed to reach the target (KoT – *definitions, properties and foundations*). Thus, the modelling of an exponential function in a situation of growth from a known percentage was carried out.

In this process, emerge relationships between distinct mathematics elements. A transverse connection results when different mathematical items have features in common (Carrillo et al., 2018). Thus, the participants show their knowledge on a relationship between an exponential equation and logarithms (KSM − *transverse connection*).

Solution to Problem (b)

> b) If a person's height is 1.64 metres, how many kilometres would the total number of daily steps they take on the last day of each week amount to?

As this problem assumes a relationship between a person's height and step length, the solvers established the relationship between distance, step length, and number of steps, as shown below:

$$D = L \cdot P \tag{2}$$

where D is the distance (metres), L is the step length (metres), and P is the number of steps. While this equation can be deduced or found on the Internet, the participants needed to apply it to the height specified in the problem. Fabiola and Nestor produced equation (3) below, where A denotes woman's height and L corresponds to the step length.

$$L = A \cdot 0.413 \tag{3}$$

Therefore, for a woman measuring 1.64 m (height given in the problem statement), step length is approx. 0.68 m. To answer the question, the distance equivalent to the steps taken on the last day of each week, i.e., on the 7 th, 14th, and 21st day, is given in Table 2, while the number of steps is presented in Table 3.

Table 2. Number of daily steps per week

Days	Number of daily steps
7	$2{,}500(1.05)^{7} \approx 3{,}518$
14	$2{,}500(1.05)^{14} \approx 4{,}950$
21	$2{,}500(1.05)^{21} \approx 6{,}965$

Table 3. Distance covered each week

Days	Distance (meters)	Distance (km)
7	$D = 0.68 \cdot 3{,}518 \approx 2{,}392$	$2{,}392 \cdot 0.001 \approx 2.4$
14	$D = 0.68 \cdot 4{,}950 = 3{,}366$	$3{,}366 \cdot 0.001 \approx 3.4$
21	$D = 0.68 \cdot 6{,}965 \approx 4{,}736$	$4{,}736 \cdot 0.001 \approx 4.7$

To solve the problem (b), the participants used the internet to search for information relating the average step length and the distance covered, as well as the height and the step length for a woman, based on the 5 km/h walking speed (Figure 1). Finally, they used the exponential model equation (1) developed for problem (a) to determine the steps taken on the corresponding days. In subsequent steps, they applied equation (2) and (3), which involved the deployment of knowledge of the *practices of modelling* (KPM) on knowing how to apply different models to answer a question. Finally, the participants show how to solve a problem of exponential nature (KPM – *practice of problem solving*). Extracts from the narrative of Fabiola's experience are analysed below.

Fabiola's narrative

By analysing Fabiola's narrative, it is possible to gain reflections of her experience, such as her difficulties and learning.

Fabiola: At first, I found it difficult to select a topic that was of interest to me and that could also be approached from a mathematical point of view. For a moment I thought about using other topics such as sleep time or sugar consumption, but I could not manage to translate this into a concrete question that would allow me to develop a mathematical model. I consider this to be the biggest challenge when starting a modeling project. Once I chose to work with the number of daily steps, I made use of models and knowledge that we had previously worked on in the course, for example, the exponential model. This was a great support. I also enjoyed being able to take the steps problem to a more complex and relevant situation […].

If I could summarise what I learned, I would keep the importance of defining the problem that motivates the modeling project, with all that goes with researching and selecting a suitable topic and being able to pose relevant questions to critically reflect on real life situations or, in this case, habits related to our health and […]. In addition, I feel that I really understood how the elaboration of a project like this one allows us to empower our own learning, since during my basic and middle school stage I always considered this type of work or evaluations as just another responsibility, without taking it seriously.

Fabiola mentions in her experience that it was difficult for her to pose (or formulate) a problem that she could relate to mathematical modelling. She expresses that in the process she developed the ability to propose a problem in which she was able to use the mathematics previously covered in the course and considers that this experience enhanced her learning. Thus, she shows that developed the knowledge of posing a problem based on a real-life, culturally relevant topic of interest to her, in this case a problem of an exponential nature (KPM – *practices of modelling*).

Table 4 summarises the mathematical knowledge deployed by the prospective teachers in their project, both for the project developed and for the experience reported in the narrative.

Table 4. Knowledge prospective teachers deployed in developing a modeling project

Sub-dom	Categories	Knowledge deployed	
KoT	Procedures	KoT-p:	How to increase a quantity in a determined percentage
	Definitions and properties	KoT-d:	Apply logarithm properties to multiplication, addition, and subtraction, as well as logarithms involving powers
KSM	Transverse connections	KSM-tc:	Know logarithmic and exponential expressions are related, since one is the inverse of the other
KPM	Practices of problem solving	KPM-ps1:	How to build a data table by applying a given percentage increase
		KPM-ps2:	How to solve a problem by applying different models
	Practices of modelling	(Indicators) Knowing how to find a model from to identify a pattern. How to apply models for solve a problem Posing a problem based on a real-life in this case a problem of an exponential nature as part of a project	

Conclusions

The modeling project approach, as part of which participants were required to formulate and solve problems, has enabled prospective teachers to formulate mathematical problems, in which their mathematical knowledge (MK) was deployed or developed in the process. The evidence presented here indicates that the prospective teachers developed knowledge in the KoT, KSM and KPM subdomains. Different knowledge emerged in the posing and solving the problem along with important reflections on taking care of the health through daily walking.

The exponential nature of the problem developed by them allowed the prospective teachers deepen their knowledge regarding said topic, as well as to make connections between the chosen topic and the mathematical knowledge involved. In this study, actions of mathematising a situation or problem can be considered as practices of modelling, in the same way that Zapata-Jaramillo (2023) establishes it in a different way of practices of problem solving. Likewise, this study shows that the prospective teachers applied models to solve the problem posed. Thus, the strategy used indicates an interesting way to implement modeling in teacher training. Although modeling project approach is a challenging strategy, it allowed the prospective teachers to pose and solve real-life problems by making concrete connections with the mathematical knowledge with edges and connections between mathematical topics and other models. As this study focused on the development of mathematics knowledge (MK), the dimension of didactic knowledge should be examined in future research in which this approach (or project) can be implemented in classrooms.

Making the Invisible Visible: Exploring the Situation Model

Isabella Gogesch[1] and Matthias Ludwig[1]

[1]Goethe University, Frankfurt, Germany; gogesch@math.uni-frankfurt.de

It is a central goal of mathematics education to convey practical life skills and to present mathematics as an integral part of culture and society. Mathematical modelling, as the transfer between reality and mathematics, plays a central role in this goal. Such modelling processes can be represented stepwise in a modelling cycle. In this the first three steps focus on the creation of a mathematical model and lead to different stages of development of it: the situation model, the real model, and the mathematical model. Several studies focus on students' development of a real and mathematical model. However, the situation model, in particular, seems elusive, and its concrete formation is not well-researched. In this study, the formation processes of the situation model are made visible by means of eye-tracking. Our results show that the different stages of development are clearly identifiable.

Keywords: Modelling, situation model, eye tracking, outdoor mathematics.

Introduction

Mathematics education aims imparting practical life skills and at presenting mathematics as an integral part of our culture (Greefrath et al., 2013). Furthermore, professional organizations such as the National Council of Teachers of Mathematics (NCTM, 2000) suggest that integrating real-world problems into the curriculum can increase the motivation among students and help with both mathematical contents and strategies (NCTM, 2000). At its core, mathematical modelling consists of translating a real-world problem to mathematics, working with mathematical methods and transferring the mathematical results back to the real world (Greefrath et al., 2013). One way of representing such modelling processes is the modelling cycle by Blum & Leiß (2005). The first three steps (understanding, simplifying/structuring and mathematicising) lead to different stages of development of the model: the situation model, the real model, the mathematical model. The question how the first two stages of development (namely the situation model and the real model) can be differentiated has been discussed for several years with existing arguments for the necessity of such a separation as well as against it (Borromeo Ferri, 2006). Researchers who include the situation model in their modelling cycle focus on the cognitive processes of the solving process (Borromeo Ferri, 2006). Other researchers jump right into the mathematical model and do not distinguish between the first two stages of development. They focus more on the solution processes since they work with more complex models (Borromeo Ferri, 2006). Especially the imagination of the situation model is elusive and has not been visualized yet. In addition, currently only a few information, about how such a mental representation of a situation evolves is available (Leiß et al., 2010). So it is not trivial to explicate in detail which cognitive processes take place in a student's mind while solving a mathematical modelling task (Reusser, 1997), and in particular while processing the first steps in creating a model.

The *Eye-Mind Hypothesis* (Just & Carpenter, 1980) states that there is a direct connection between a person's view and the mental process of the person in this moment. There are studies using eye

tracking in the fields of modelling (i.e. Schmitz & Schukajlow, 2020) but no results on the question how the constructed situation model looks can be derived from them. It is still unclear how the situation model is created. To close the identified research gap, this paper aims at presenting an explorative study that investigates, how mathematical modelling processes can be discovered through eye tracking technology and which differences can be found between the first stages of development of the modelling cycle. Through the explorative character of the study, the modelling processes are limited to real-world objects. This choice is underpinned in the theoretical background.

Theoretical Background

Mathematical modelling

A mathematical model needs to be constructed to mathematicise real-world problems (Blum & Leiß, 2005). Accordingly, modelling is understood as the interplay between reality and mathematics (Blum & Leiß, 2005). Mathematical models should be self-consistent, coherent and expedient (Greefrath et al., 2013). Despite this characterization, they are not explicit because it is just a depiction of the reality (Greefrath et al., 2013). Thus, the modelling cycle by Blum and Leiß (2005) becomes a model of mathematical modelling itself (Greefrath et al., 2013). The modelling cycle describes the modelling process in seven steps, from which this paper focuses on the first three steps: understanding, simplifying/structuring and mathematising. In the first step, the real problem situation needs to be understood. In this process the students have to create a mental model which leads them to a situation model. In the second step, the real model should be created out of the situation model, by separating important from unimportant information. In the third step the real model is converted into a mathematical model, by adding suitable terms, equations, designations, etc., thus mathematising the real model and reducing it to the essential aspects (Greefrath et al., 2013; Blum & Leiß, 2005).

Situation model

The situation model is in the literature synonymously used with mental representation of the situation (Borromeo Ferri, 2006), mental model (Greefrath et al., 2013) or problem situation (Kintsch & Greeno, 1985). It forms the basis for all further modelling activities (Borromeo Ferri, 2006). The situation model is the individual cognitive structure that is built based on the situation understanding (Leiß et al., 2010). It needs to be assumed that the structure of a situation model can also be schematic (van Dijk & Kintsch, 1983) and that it can be described in form of a picture of auditory, visual or tactile information (Leiß et al., 2010). Besides a semantic situation model there is also a communicative one needed (van Dijk & Kintsch, 1983). Blum and Leiß classify the situation model as one of the, if not even the most important phase of the modelling cycle (Borromeo Ferri, 2006). Van Dijk and Kintsch (1983) also postulate that the basis of problem solving is not directly the text, but the resulting mental model. While numerous graphical representations (i.e. Schmitz & Schukajlow, 2020) for real and mathematical models exist, this is not the case for the situation model, which is both more difficult to grasp and has been less researched. Previous studies show that the

difficulty of text tasks cannot only be attributed to logical-mathematical factors and that especially the situation model plays a very important role (Kintsch & Greeno, 1985).

Modelling at real objects

The term outdoor learning refers to educational experiences that take place outside traditional classroom settings, involving activities in which students directly work in natural environments or real-world contexts. Outdoor learning makes it possible to experience mathematics on a daily basis (Cahyono & Ludwig, 2017) and therefore provides possibilities for mathematical modelling at real-world objects (Ludwig & Jablonski, 2021).

Mathematical modelling at real objects has already been investigated in different studies (i.e. Ludwig & Jablonski, 2021). Cahyono and Ludwig (2017) found out that the outdoor activities had a clear positive effect on the motivation of the students. Furthermore, there are different modelling settings, i.e. different types of representing the real situation in modelling tasks (cf. Jablonski, 2023). Next to the traditional way of presenting the text together with a picture of the real object, there is the possibility to use a 3D-printed manipulative of the real object or to solve the modelling task in an outdoor environment right at the real object (Ludwig & Jablonski, 2021).

State of the Art and Research question

As previously stated, it is a challenging effort to characterise the specific cognitive processes that occur within the student's mind while attempting to solve mathematical modelling tasks (Reusser, 1997). To gain a deeper understanding of the cognitive processes involved, Schmitz and Schukajlow (2020) explored the impact of decorative and representative images on modelling tasks. The researchers tracked the eye movements of the students while they were solving the tasks and discovered that the total number of fixations was significantly higher on representative images than on decorative ones (Schmitz & Schukajlow, 2020). The use of eye tracking revealed that, in the analysis of all the modelling tasks, right triangles were identified, indicating the generation of a model (Schmitz & Schukajlow, 2020). From this study, we can assume that eye tracking makes students' (mental) situation models visualisable. Nevertheless, it remains unclear from the study whether this finding reflects the situation model or the real model. Our first research question arises from this:

> [RQ] Is it possible to make the situation model visible (through eye tracking) while solving mathematical modelling tasks outdoors at real objects?

Methodology

The *Eye-Mind Hypothesis* (Just & Carpenter, 1980) posits a direct correlation between an individual's visual attention and the cognitive processes occurring at that moment. To record the eye movements there a multiple different eye tracker to use. We decided on the mobile eye tracker Neon from Pupil Labs because our participants need to move freely around the objects, and we can analyse the data with the different enrichments on Pupil Cloud: Heatmaps and Scanpaths. *Heatmaps* provide information about which objects in the learning environment are viewed. It ranges from not at all (0%) to the most (100%) (Heatmap, n.d.). Heatmaps are placed on a reference image that represents the actual three-dimensional situation, as well as the scanpaths. *Scanpaths* are a visualisation of the interplay between fixations and saccades. *Fixations* arise when the eye pauses on a region and

saccades are the rapid shifts that occur between fixations (Graham et al., 2022). For a certain time lapse, we manually map all the fixations on the reference image and see the numbered fixations (green circles) and the respective saccades (black connecting lines) on the reference image.

The research question is firstly investigated in an explorative study. We asked three lecturers in mathematics education to participate in our explorative study. During the data collection each participant solved three different geometrical modelling tasks on real-world objects. We used this special eye tracker recording during these processes and asked the participants to verbalize their solving processes and to write down their intermediate steps.

Referring to the different representations of modelling tasks, it was our decision to use the outdoor setting due to technical and mathematical reasons: To be able to analyse the eye movements appropriately, we decided to start with big geometrical objects without perspective or scaling. So, we decided for real-world objects that appear in their originality outdoors. For the scanpaths, we manually mapped around 400 fixations on a reference image. The fixations that are mapped onto the reference photo can be located in the period of time from the arrival at the object to the moment when the participants started their sketch.

First results

Observations from the exploratory study show that the solving processes at various stages of development are identifiable. In the modelling task "Stone Circle", participants were asked to calculate how many stones lie in the area framed by the grey ring and the gutter (Figure 1, left). Figure 1 (right) shows the related scanpath of one participant. In this scanpath, the radius and diameter are visible as they were the focal areas of the participant's considerations and the path to the solution. The participant first counted how many stones fit into the radius and the diameter. Since the stone circle is not a perfect semicircle, an average radius was determined from the values for the radius and diameter, and the result was approximated using the area formula for a circle.

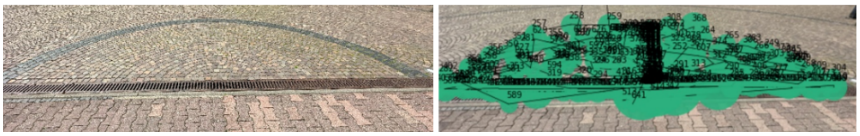

Figure 1: reference image "Stone Circle" (left), scanpath to the task "Stone Circle"

Figure 2 (left) shows the individual real and mathematical model of the task "Stone Circle". As can be observed the scanpath and the real model of the task show similarities regarding the diameter and the radius of the semicircle. The thick black stripes on the scanpath are a consequence of the participant's repeated visual exploration of these areas in both directions, which has resulted in the presence of numerous saccades in these regions. The heatmap in Figure 2 (right) shows the importance of the semicircle's radius in the eyes, respectively, the focal points of the participant. In

the real model we can obviously see the prominent areas from the scanpath building the base for the sketch.

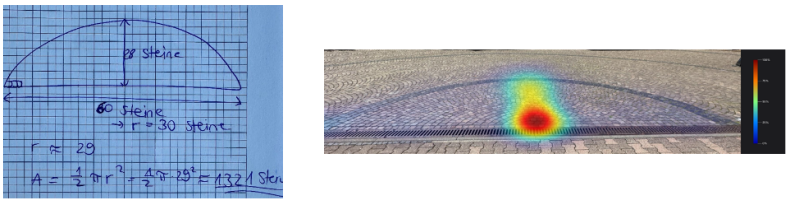

Figure 2: real and mathematical model of the task "Stone Circle" (left), heatmap (right)

In the modelling task "Archway", the objective was to determine the height from the ground to the highest point of the arch (Figure 3, left). The Scanpath (Figure 3, right) of one participant's problem-solving process clearly indicates that the participant identified both the height up to the arch and the diameter of the arch section. With these two measurements, the height was calculated.

Figure 3: reference image "Archway" (left), scanpath to the task "Archway" (right)

In Figure 4, similarities between the real model of the task "Archway" and the scanpath are evident once more. The area in which the participant took all the most significant measurements was observed with greater frequency than other areas of the reference image. This observation is corroborated by the Heatmap in Figure 4 (right). As can be observed in the provided scanpath, the column height and diameter are highlighted on the heatmap, forming a right angle. If the column height and half of the diameter were joined together and stretched, this would result in the archway height.

Figure 4: real and mathematical model of the task "Archway" (left), heatmap (right)

In the task "Subway Window", participants were required to determine the circumference of the large circular window (Figure 5, left). All participants counted the diameter using the wall stones and then calculated the circumference based on this measurement. The associated scanpaths reveal this process, and interestingly, two different approaches were observed: Participant A attempted to

measure the diameter starting from the bottom left corner (Figure 5, middle), while Participant B did the same from the top edge of the circle (Figure 5, right).

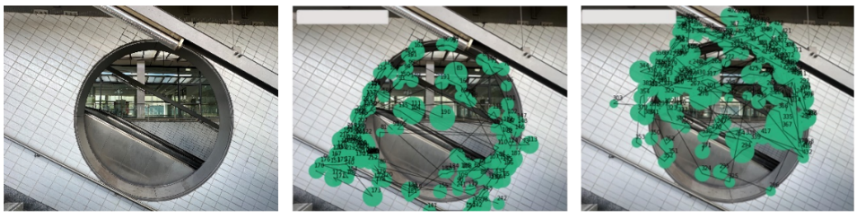

Figure 5: reference image "Subway Window" (left), scanpath A to the task "Subway Window" (middle), scanpath B to the task "Subway Window" (right)

The two different mathematical models of Participant A (top left) and Participant B (bottom left) are shown in Figure 6. Referring to Figure 5, we can observe that the related scanpaths again build the foundations of their real and mathematical models. Also, the heatmaps show the different focuses the participants set. On the top right (Figure 6) we see the focus of Participant A which was on the bottom left of the Subway Window. On the bottom right (Figure 6) we can almost perceive a right angle between the focus areas where Participant B turned the gaze to the top of the Subway Window.

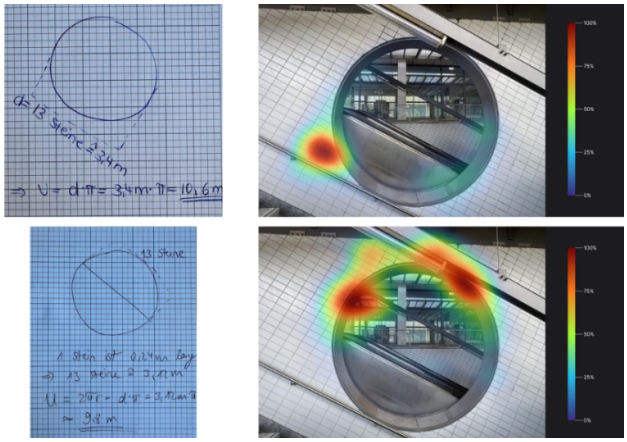

Figure 6: real and mathematical model of the task "Subway Window" of Participant A (top left), real and mathematical model of the task "Subway Window" of Participant B (bottom left), heatmap of Participant A (top right), heatmap of Participant B (bottom right)

In conclusion, the results of the three modelling tasks demonstrate that the scanpaths can be identified in all cases within the sketches, which represent the real models. This formation of the scanpaths within the sketches can be considered the precursors to the real and mathematical models. At the same time, it is possible to identify the mathematical ideas that lead to results of the tasks in the scanpaths. We conclude that the scanpaths represent stages of development of the solution processes.

Discussion and Outlook

Using the mobile eye tracker in combination with verbal and written reports of the solution processes supports our hypothesis that various solution models and cognitive processes can be identified through the analysis of eye movements. One explanation could be as follows: As the sketches can be identified as the real models and the scanpaths function as their precursors, the scanpaths could be

regarded as the situation models of the task. We propose that the scanpaths represent one stage of development of the model, given that the analysis of the eye movements represents a model created from the mental structures that lead to the subsequent sketches (real and mathematical models).

The theoretical background to the situation model emphasises its central importance, as appropriate problem solving of the task is not possible without an adequate situation model. In the present study, all participants achieved correct results. The analysed scanpaths, which are possibly interpreted as visual representations of the respective situation models, indicate an adequate situation model. This study therefore confirms the theoretical assumption that a well-developed situation model is crucial for achieving a correct solution.

In the present study, right-angled triangles, radii and circles were identified in the eye movements of the participants. These results are consistent with the findings of Schmitz and Schukajlow (2020).

As a limitation, it should be noted that the participants as lecturers of mathematics already were familiar with mathematical modelling, which may have influenced their approach to the tasks. Additionally, the study focused exclusively on geometry-based tasks, making the findings less generalizable to other types of mathematical modelling tasks. The use of real objects as a basis for modelling further limits the transferability of the results, as similar analyses have not yet been conducted with purely text-based tasks. Finally, the study examined longer time segments, which, while providing a comprehensive view, may have overlooked the insights gained from analysing shorter, more specific intervals of the problem-solving process.

As an outlook, the next step will focus on conducting a study with students at the lower secondary level. This new study aims to examine whether student's mental (situation) models can also be visualized through their eye movements. To this end, a strictly structured experimental procedure will be implemented, requiring that the task is fully understood prior to the initial observation of the object. This is intended to ensure an integration of task comprehension and object perception during the first viewing. Additionally, it is assumed that the comprehension process will be largely completed by the time participants begin to take notes. A central research question for this study is whether the characteristics of the object can already be mentally structured during observation, indicating a possible convergence of the situation model and the real model.

In addition to further elaborating on the primary research question – whether scanpaths can effectively describe the situation model – future investigations will explore whether eye movements can provide insights into performance and efficiency in solving mathematical modelling tasks.

Financial literacy and mathematical modelling: an analysis of PISA sample tasks

Gilbert Greefrath[1] and Katharina Kirsten[1]

[1]University of Münster, Faculty of Mathematics and Computer Science, Münster, Germany;
greefrath@uni-muenster.de

This study explores the integration of mathematical modelling and financial literacy within the educational context, analyzing 26 PISA financial literacy items from 2012, 2018, and 2022. Using qualitative content analysis and considering the OECD's framework on financial education, we identify the significant mathematical modelling competencies that are beneficial for understanding financial literacy items. Our findings reveal that competencies such as understanding, mathematizing, working mathematically, and interpreting are often required to solve these PISA items, highlighting a potential for co-developing financial and mathematical literacies. The analysis suggests that while current PISA items occasionally engage mathematical competencies, greater emphasis on modelling could further enrich financial literacy education. This study contributes to the broader discourse on educational synergies between mathematics and financial literacy.

Keywords: Mathematical modelling, financial literacy, PISA, qualitative content analysis.

Introduction

Looking at the term financial literacy from a mathematics education perspective, it is expected that mathematical competences, as contained in the concept of mathematical literacy, defined as

> individual's capacity to formulate, employ and interpret mathematics in a variety of contexts, it includes reasoning mathematically and using mathematical concepts, procedures, facts and tools to describe, explain and predict phenomena. (OECD, 2019, p. 75)

are also required for financial literacy:

> knowledge and understanding of financial concepts and risks, and the skills, motivation and confidence to apply such knowledge and understanding in order to make effective decisions across a range of financial contexts, to improve the financial well-being of individuals and society, and to enable participation in economic life (OECD, 2019, p. 128).

These correlations could also be empirically proven, even if other factors such as reading play a role (Acar, 2023; Ozkale & Erdogan, 2022). It was shown that financial literacy questions have the potential to promote conceptual and process-related competences for mathematics and financial education.

The well-known mathematical modelling cycle is also currently a central feature of the PISA framework for basic mathematical education. It serves to define the mathematical processes that students go through when solving problems (OECD, 2023b, p. 20). In PISA items on mathematics, however, it is often not necessary to go through all phases of the modelling cycle. In practice, significant parts of the mathematical modelling cycle are often performed by others, while the end user only performs some steps of the modelling cycle (OECD, 2023b, p. 25).

The relevance of modelling in relation to contextual problems, especially those from the financial domain, necessitates a consideration of the links between financial literacy and mathematical modelling based on the PISA concept. We therefore consider the overarching question of how mathematical modelling and financial literacy are related. Specifically, we answer the question of which steps in the modelling cycle are most important for the completion of PISA tasks on financial literacy.

Financial literacy competences

The OECD's competence framework (European Union/OECD, 2023) for improving financial literacy for children and young people aged 6 to 18 comprises a total of 244 competences. It focuses on the subject areas of 'money and transactions', 'planning and managing finances', 'risks and benefits' and 'financial landscape' and formulates 55 competences for the 6 to 10 age group, 87 for 11 to 15-year-olds and 102 for 16 to 18-year-olds. In addition to these subject areas, four different context areas are distinguished that are relevant for children and young people, namely 'School and work', 'Home and family', 'Individual' and 'Social'. This considers the fact that some young people are already in paid work and have to make decisions for the future, that financial decisions are often made in the context of family and household, that financial decisions have to be made for personal needs and that many risks have to be taken by individuals. The social aspect, for example, is about sustainable finances or paying taxes. In addition, process-related competencies, i.e. processes, are named, e.g. 'Evaluate financial issues' or 'Analyse information in a financial context'.

There are also competence models for financial education in individual countries; for example, the competence model for general financial education developed by Retzmann and Seeber (2016) in Germany. It comprises the competence areas 'decision and rationality', 'relationship and interaction' and 'order and system'. Each area describes three sub-competencies; they are, for example, 'Analysing situations', 'Evaluating alternative courses of action' and 'Designing possible courses of action'. Such competence models overlap with the European Union/OECD concept (2023), but there are also differences in detail.

Mathematical modelling and financial education

We consider mathematical modelling to be a central mathematical competence of mathematical literacy (OECD, 2023b). Modelling competence can be described as the ability to adequately carry out the necessary steps in the process of moving back and forth between reality and mathematics as well as analysing and evaluating models (Niss et al., 2007).

Modelling cycles describe the various sub-processes of mathematical modelling with varying degrees of detail and focus. The ability to perform such a sub-process adequately is described as a sub-competence of modelling (Kaiser, 2007; Maaß, 2006). They distinguish between the following sub-competences:

- to understand a real-life problem (understand),
- to set up a real-life model (simplify),
- to set up a mathematical model from a real model (mathematise),
- to solve mathematical problems within a mathematical model (working mathematically),

- to interpret mathematical results in a real model or a real situation (interpret),
- to question the solution and, if necessary, carry out a modelling process again (validate).

The connection between mathematical and financial competences has already been established by the OECD (2017). Financial literacy tasks have the potential to promote conceptual and process-related competences for both financial and mathematical literacy (Ozkale & Erdogan, 2022). However, only a few publications address the joint promotion of these competences (Dituri et al., 2019; Ozkale & Aprea, 2024). Modelling tasks in particular have this potential to develop students' financial literacy (Cabrera-Baquedano et al., 2022), because mathematical models can be used to describe and process financial situations in order to make a decision.

Although there are already approaches to developing mathematical tasks that can be integrated into mathematics lessons using financial literacy concepts (Ozkale & Aprea, 2023), these do not explicitly take into account mathematical modelling approaches. For mathematical modelling, however, it was shown qualitatively in a case study that students with experience in financial contexts were more successful in formulating financial comments and linking mathematical knowledge. It is possible that the mathematical modelling tasks encouraged them to discuss and apply different approaches that enabled more advanced financial thinking (Tural-Sonmez & Erbas, 2023).

Research question

In order to work out the connections between the concept of financial literacy from PISA and mathematical modelling as a competence, and to be able to answer the overarching question of how mathematical modelling and financial literacy are related, we focus here on the OECD's concept of financial education (OECD, 2019, p. 128) and the definition of mathematical modelling competence according to Niss et al. (2007) as well as the concretisation in sub-competencies (Kaiser, 2007; Maaß, 2006).

Based on the correlations between mathematical and financial literacy that have already been investigated (Ozkale & Erdogan, 2022), correlations between mathematical modelling and financial literacy in PISA are also to be expected (Tural-Sonmez & Erbas, 2023). What is interesting here is the precise overlap between mathematical modelling and financial literacy. It remains to be seen which sub-competencies of mathematical modelling play a particular role here. We therefore ask the question:

For which sub-competencies of mathematical modelling do the PISA tasks on financial literacy provide an opportunity for promotion and how are these distributed across the various processes of the competence framework for financial literacy?

Method

All 26 published PISA items on financial literacy were analysed. These were 3 items from the 2022 study, 14 items from the 2018 study and 9 items from the 2012 study (OECD, 2023a). The study was conducted as a qualitative content analysis according to Mayring (2015) with the sub-competences of modelling as deductive categories (Kaiser, 2007; Maaß, 2006). For this purpose, all items were rated to determine which sub- competencies they offer an opportunity for. The categories were as follows: understanding, simplifying, mathematising, working mathematically, interpreting and

validating. None, one or more sub-competencies were assigned to each item. The coding was carried out independently by both authors. The interrater reliability is on average almost perfect $\kappa = .88$ (Landis & Koch, 1977). In case of disagreement, a consensus rating was performed. Further categories on subject areas, context areas and processes for financial education as well as the competence levels of the items were taken from the information on the items (OECD, 2023a).

One example is the item 'Music system' from the 2018 PISA study (OECD, 2023a, p. 208). The stimulus of the item describes that Kelly asks her bank to lend her 2000 zeds to buy a music system and that there are two options for the repayment period, with the interest rate being the same in each case. For the repayment period of two years, the information is given in Table 1.

Table 1: information for repayment period of two years

Repayment period	Monthly repayment (zeds)	Total repayment (zeds)	Total interest paid (zeds)
Two years	91.67	2200.08	200.08

The question is then how the conditions for a loan of 2000 Zed over three years differ from the repayment terms over two years. Two statements are to be marked with True or False. These are:

- The monthly repayment will be higher for a loan over three years.
- The total interest paid will be larger for a loan over three years.

The task is therefore about determining the effects of extending the loan repayment period from two to three years on the monthly interest payments and on the total interest payments if the annual interest rate does not change. It is therefore classified in the subject area 'Planning and managing finances', the context area 'Individual' and the process 'Analysing information in a financial context'.

If you want to solve this task with the help of a calculation, the difficulty is that the interest rate is unknown. However, it is possible to compare corresponding models with an assumed interest rate and thus solve the task with the help of modelling. A simplified calculation with annual interest payments and a term of two or three years already clearly shows that the annual repayments are lower in the case of three years, but the total interest is higher with the same annual interest rate. For example, with an interest rate of 10% and annual repayment, the rate for 2000 € would be around 348 € higher, but the interest would be around 108 € lower. These considerations show the potential of using mathematical models for these tasks. This required the modelling steps of understanding, simplifying, mathematising, working mathematically and interpreting. However, no calculation is expected to solve the item, as it is a combined multiple-choice item, meaning that this task could also be answered using experience from previous calculations or 'world knowledge'. This would also require fewer modelling steps. However, this task was coded with the sub-competences mentioned, to recognise the potential of mathematical modelling and because this 'world knowledge' cannot necessarily be assumed for solving the task.

Results

The subject areas, context areas and processes of the 26 items analysed are distributed differently across the categories. The subject area ‘Money and Transactions’ and the context area ‘Individual’ occur most frequently (see Table 2). It should be noted that the ‘Risk and reward’ category and the ‘Education and work’ and ‘Societal’ contexts occur very rarely or rarely. Except for the rare ‘Apply financial knowledge and understanding’, there is an even distribution of processes.

The sub-competence ‘understanding’ of mathematical modelling can be assigned to every item, while ‘validating’ was not explicitly coded in any of the published items. The other sub-competences occur in 10 to 15 of the 26 items, as listed in Table 3. There were 11 items in which none of the four categories from Table 3 occurred and 10 items in which all four of the categories occurred. Working mathematically in a mathematical model occurs least frequently (approx. 40 % of the items) and simplifying most frequently (approx. 60 % of the items).

Table 2: Distribution of financial categories

Content	Number	Context	Number	Process	Number
Money and Transactions	11	Individual	15	Identify financial information	7
Planning and Managing Finances	7	Home and family	7	Analyse information in a financial context	8
Risk and reward	2	Societal	3	Evaluate financial issues	8
Financial landscape	6	Education and work	1	Apply financial knowledge and understanding	3

Table 3: Distribution of the Competency Categories

Simplifying	Mathematising	Working mathematically	Interpreting
15	13	10	11

In order to examine the connection between the various processes of the competence framework for financial literacy and the sub-competences of modelling in more detail, these are presented in detail. If the proportion of the respective sub-competencies is shown individually for the processes of the financial categories, a distribution emerges in which more sub-competencies are required to complete the tasks for the processes ‘Analyse information in a financial context‘ and ‘Apply financial knowledge and understanding’ than for the other two processes (see Figure 1).

Percentages are used here because different numbers of items are assigned to the four processes. In the three processes to which roughly the same number of items are assigned, the proportion of modelling sub-competencies is highest for ‘Analyse information in a financial context’ and lowest for ‘Evaluate financial issues’. The comparison with the ‘Apply financial knowledge and understanding’ process is more difficult here, as this process is based on only 3 items (see Table 2).

In all cases, the sub-competencies of simplifying and mathematising are more strongly or equally represented than working mathematically and interpreting.

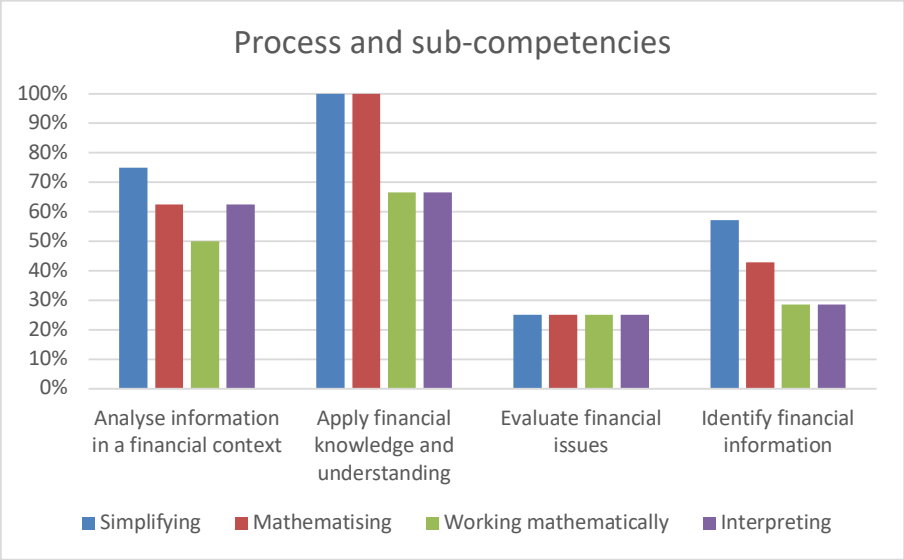

Figure 1: Distribution of the sub-competence categories for the processes

Discussion

The analysis of the published PISA task examples shows that the 26 items for financial literacy from PISA map different subject areas, contexts and processes for financial literacy in varying numbers. On average, the sub-competencies of understanding, mathematising, working mathematically and interpreting mathematical modelling are required or at least useful for solving about half of all items.

The importance for mathematical literacy is therefore likely to be even greater, as only one part, albeit a very important one, is considered here, namely mathematical modelling. It can therefore be assumed on average that mathematical competences are fundamentally useful for the processing of financial education tasks for at least half of the sample items. This is in line with ideas for the simultaneous promotion of mathematical and financial competences (Dituri et al., 2019; Ozkale & Aprea, 2023, 2024). The positive correlation between modelling competences and financial literacy, as seen by Tural-Sommez and Erbas (2023), can also be partially confirmed by these results. However, it should be noted that significantly less than half of the financial literacy items require calculations in the mathematical model at all. It is rather the sub-competencies of simplifying and mathematising that are useful in at least half of the sample items. The reason for the rather low proportion of required mathematical competences could also be due to the design of the PISA tests to measure financial literacy and mathematical literacy separately. However, this could also signal that mathematical competences are only of minor importance for financial education.

It is also interesting to take a differentiated look at the four processes of financial literacy. It can be seen that there is more modelling in the two processes ’Analyse information in a financial context’ and ’Apply financial knowledge and understanding’. This may offer the greatest potential for the joint promotion of financial literacy and mathematical modelling. It should also be noted that the existing

tasks could have a much stronger modelling component with few changes. For example, in the example task 'Music system', the extent of the change in the total interest rate could also be made clear by means of a concrete calculation, thus also enabling validation. Although the PISA documents tend to see financial situations only as a context for mathematical competence, the result reinforces the idea of teaching financial literacy together with modelling competences (Ozkale & Erdogan, 2022). Similar results can also be expected for other models of financial education, such as that of Retzmann and Seeber (2016), because the areas of competence described there overlap with the OECD's concept (European Union/OECD, 2023).

One limitation, however, is that there are relatively few published examples of tasks on financial literacy, which may not fully reveal the connection to mathematical competences and specifically to mathematical modelling. It should also be noted that the items relating to the four processes from the financial categories are not equally distributed, but that three processes occur somewhat equally frequently and one less frequently (s. Table 2). What is even more striking is that only one content and one context occur particularly frequently and there is even a context that only occurs in one item. So there could be distortions here for this reason. In addition, the extent to which learners actually carry out the coded modelling processes during actual processing would also have to be discussed.

In summary, there is potential to promote both areas of competence, i.e. modelling and financial literacy, which is currently not being fully exploited. For some items, it would also be possible to demand more specific mathematical activities in the areas of mathematising, mathematical work, interpreting and validating.

Acknowledgment

We would like to thank our colleagues Anja Bonfig, Tim Engartner, Harald Hantke and Reinhold Hedtke for the joint discussion on the concept of socially inclusive financial education.

One step at a time? – An empirical study on the use of graphical representations for solving Fermi problems

Simone Jablonski[1], Julia Ehemann[2], Deng-Xin Ken Oehler[2] and Matthias Ludwig[2]

[1]University Paderborn, Institute of Mathematics, Germany; jablonsk@mail.uni-paderborn.de

[2]Goethe University, Mathematics and Computer Science Education, Frankfurt, Germany

Fermi problems have been established as underdetermined tasks in mathematics education and require students to make their own assumptions. So-called Fermi graphs can be created by the students when solving a Fermi problem and contain information about their activities. In this study, we empirically compare the solution of Fermi problems and the use of Fermi graphs by primary and secondary school student. The results show that both primary and secondary students can solve the Fermi problem completely or with calculation errors only. When creating the Fermi graphs, the eighth graders are more often able to implement the structure of the Fermi graphs, whereas the third graders also create visualisations that cannot be recognised as Fermi graphs. Based hereon, it is possible to identify consequences for the practical use of Fermi graphs in mathematics education.

Keywords: Mathematical models, Fermi problems, primary school, secondary school, graphs

Fermi problems and their graphical representation

Since the introduction of Fermi problems by Enrico Fermi (1901–1954), this type of problem has aroused great interest not only in the scientific community, but also in education, e.g., in mathematical modelling (Ärlebäck & Bergsten, 2010). Fermi problems can be characterised as underdetermined open tasks with "very little or no information given" (Efthimiou & Llewellyn, 2007, p. 254) which therefore – at first glance – appear to be *unsolvable*. Still, through decomposing the problem in several parts and recombining them later on, a solution can be obtained, which is known as the *Fermi method* (Carlson, 1997). Hereby, it is up to the problem solver to consider what data is needed and how it can be collected, which makes data acquisition essential for processing Fermi problems (Meyer & Greefrath, 2023). The missing data can be obtained by research, making estimates and assumptions, but also by using general knowledge or even experimental approaches. Consequently, Fermi problems are characterised by the fact that they do not have one exact result but are approximations that can be represented in a solution interval (Ärlebäck, 2009). This task type is particularly relevant in mathematics education when certain steps of the modelling cycle (cf. Blum & Leiss, 2007), e.g., simplification and mathematisation are to be promoted (Gallart et al., 2017). Further, dealing with inaccuracies can be addressed, i.e., working with unknown quantities and estimating (Ärlebäck, 2009). However, the open nature of the tasks makes it difficult for students to structure their assumptions and approaches as well as for teachers to recognise the students' difficulties.

For this reason, an effort is to make the solution process for Fermi problems visible and analysable. In terms of a tool that supports teachers in analysing their students' processes, Ärlebäck and Bergsten (2010) use the *modelling activity diagram* to connect the processes of students engaging with Fermi tasks to the steps of the modelling cycle by Blum and Leiss (2007). Another example is the *Fermi problem activity template* which aims at supporting the analysis of Fermi problems through the

different methods of data collection that have been acquired (cf. Ärlebäck & Albarracín, 2023). Both examples have mainly been used from the teacher's perspective aiming at an analysis of a Fermi problem in the context of task design and finished solution processes. Besides giving teachers an idea of their students' work, so-called *Fermi graphs* can additionally be used by *students* already during their solution process, aiming at supporting them in terms of structure and interrelation of assumptions (cf. Borys & Hartmann, 2022).

A Fermi graph captures the solution to a Fermi problem using a network structure consisting of *nodes* and *edges* (Borys & Hartmann, 2022). Using the terminology of graph theory (cf. Tutte, 2001), the Fermi graph is connected and acyclic which makes it a tree. The tree is directed with all edges having an orientation to one node that is distinguished as the graph's *root*. To reduce complexity, the orientation is not presented through arcs in the visualisation. One can speak of the *in-tree* type which means that all considerations lead to the Fermi problem's solution. In the Fermi graph, the assumptions made and (intermediate) results achieved are noted on the edges. In the nodes, the data received from the edges is processed and the respective arithmetic operations are noted. The respective *Fermi activities* (cf. Borys & Hartmann, 2022) are located above the nodes, e.g. activate general knowledge (GK), set an assumption (S), extrapolate (EX), estimate (E) or validate (VA). In Figure 1, we present an example of a Fermi graph that summarises a possible solution process for the task: *How many Christmas cookies are eaten in Germany in one year during advent season?*

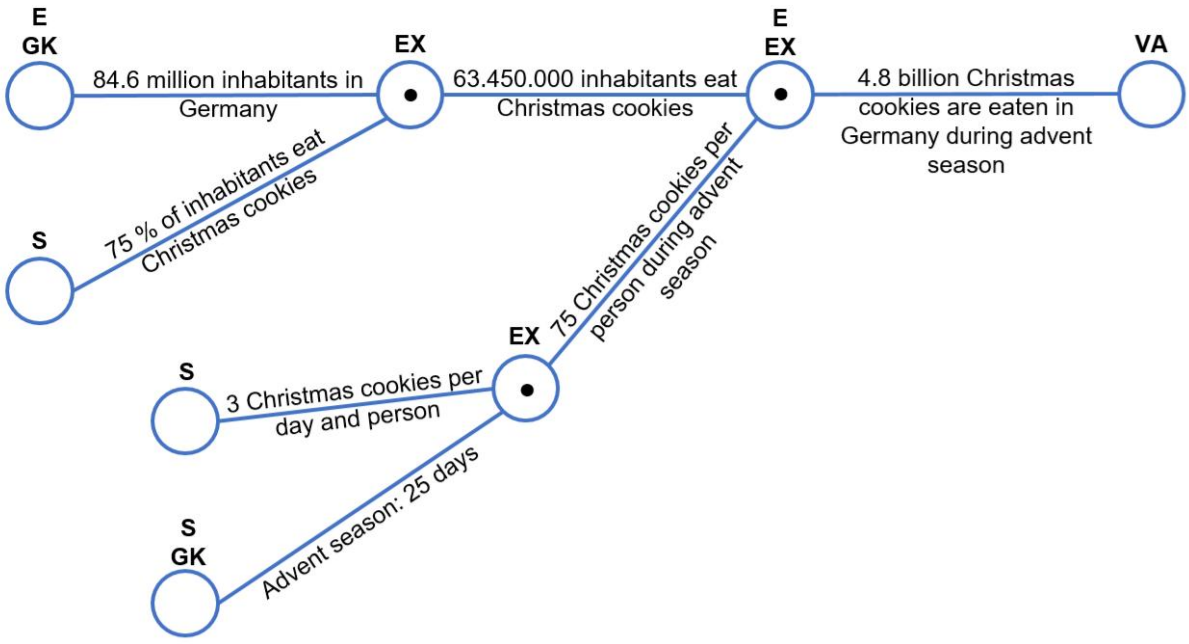

Figure 1: Example of a Fermi graph with assumptions and intermediate results on the edges and arithmetic operations and Fermi activities linked to the nodes

As indicated, this example is just one way of visualising the task's solution process: Based on the students' assumptions and calculations, different graphs appear. This allows us to ask why the graphs differ in appearance, so that students recognise that there is more than just one plausible solution to a Fermi problem (Borys & Hartmann, 2022).

Research question

From previous studies it is known that Fermi tasks can be used in both primary and secondary schools in the context of mathematical modelling (e.g., Ärlebäck, 2009; Ferrando & Albarracín, 2021). Haberzettl et al. (2018) noticed in a study on primary level that grade-three students are interested in the different possible solutions, still, it causes uncertainty at the same time. It turns out that the children make few to no assumptions when working on their first Fermi task with little knowledge of both procedure and documentation of the solution process. In addition, it is unclear to them which values are required for the calculation and how they could be meaningfully integrated into a calculation (Haberzettl et al., 2018). Some of the findings can also be seen in studies on secondary level, too. When students are confronted with underdetermined tasks for the first time, they often find it difficult to make estimates, assumptions and simplifications (Surel & Greefrath, 2023).

In view of the above-named goals of the Fermi graph (cf. Borys & Hartmann, 2022), we assume it to be a tool for primary and secondary school students to visualise their solution process, including the documentation and interrelation of their assumptions made. It could therefore make their own results comprehensible and justifiable for themselves and others. We see the Fermi graph as an opportunity to practically implement the work with underdetermined tasks and to structure them more clearly for the students. Still, studies that empirically analyse its use in general and in a comparison of different age groups are, best to our knowledge, currently missing. In addition, we see that the visualisation tools on Fermi problems presented so far focus on task design and analysis. Findings on how students use Fermi graphs are interesting for the practical use of Fermi problems and Fermi graphs in mathematics lessons. This paper aims to address this field of interest by answering the question: *How do primary and secondary school students use Fermi graphs and which challenges can be observed?*

Method

To answer the research question, an empirical, qualitative study was conducted in the context of an extra-curricular enrichment programme for potentially mathematically gifted students (cf. Jablonski & Ludwig, 2019) at Goethe University Frankfurt during Winter 2023. We chose gifted and interested students for the explorative approach hoping that the children would engage with the potentially unknown type of task and the graph structure. The sample of the study consists of two groups: 19 grade-three students (9-10 years old) and 12 grade-eight students (14-15 years old).

The data collection in both groups happened in the context of a 90-minutes session each. The sessions were conducted identically for both grades but independently of each other. In the first phase of the session, an introduction of Fermi problems in general was given. Based hereon, the students got to know the idea of a Fermi graph via an example and 14 Fermi activities for their solution process (examples are presented in Figure 1; Borys & Hartmann, 2022). In the second part of the lesson, the students were divided into teams of two or three (seven teams in grade three and five teams in grade eight). Each team received material with the above-introduced Fermi problem “Christmas cookies”, an overview of the Fermi activities as well as an example graph. In addition, each team received a laptop for research and a poster for designing the Fermi graph. In the last part of the session, the Fermi graphs were presented and compared in a gallery walk.

With reference to the research question, we particularly focus on a comparison of the processes and challenges in primary and secondary grade. In terms of the data analysis, several steps are undertaken: In a first step, the calculated results are analysed in terms of their completeness. No interval is specified at this point, as the focus should be on the step-by-step justification and calculation of the teams. A result is categorised as *complete* if the result is comprehensible in terms of the assumptions, values and calculations. We also use this category if the procedure is comprehensible, but the handling of (large) numbers is incorrect or if calculation errors occur. A result is categorised as *incomplete* if it is unclear where the result comes from, as, for example, important information (e.g., the number of inhabitants or the duration of advent season) is not taken into account.

In a second step, the designed graphs are analysed. In terms of justifying our analysis of the *structure* of a Fermi graph, we refer to selected definitions from graph theory (cf. Tutte, 2001). Per definition, a Fermi graph should be a directed tree with all edges leading to one node, the graph's root. The formula $|E| = |V| - 1$ (with *E: edges* and *V: nodes*) together with the Fermi graph being acyclic and having a root can prove this condition (*criterion I*). The students' initial assumptions for the task solution are external nodes. We set that a Fermi graph needs to have at least two external nodes in order to involve more than one assumption for the Fermi problem and follow the Fermi method, i.e., decomposition and recombination (cf. Carlson, 1997). Additionally, we refer to the incoming degree of each node which is defined as the amount of neighbour nodes on the left hand side. The incoming degree of each internal node is set at least two (*criterion II*). In addition, each node should be related to at least one (adequately linked) Fermi activity and each edge should summarise an assumption of (intermediate) result (*criterion III*). Based hereon, we distinguish whether a graph can be categorised as a Fermi graph and if so, whether it fulfils the criteria completely or partially. We categorise a graph as a *Fermi graph* if all three criteria are fulfilled. It is a *partial Fermi graph* if Fermi activities are used or named incorrectly, if any activities are used (*criterion III*) and/or if the start and end nodes or connecting edges are forgotten to be drawn (*criterion I*), but the general approach of a Fermi graph can still be seen from the representation. It is *no Fermi graph* if the representation is only a "line", so that the degree of the incoming internal nodes and the number of leaves is not at least two (*criterion II*). From those graphs, in which we found problems, particular challenges of the groups are examined.

Results

We start the report with the *calculated results*. Figure 2 (left) summarises these results. The seven teams from grade three have a span from 928 million – 17.9 billion Christmas cookies and the results of the five teams from grade eight range from 2.1 billion – 28 billion. The mean values are 5.5 billion in grade three and 8.8 billion in grade eight. As an impression, we refer to our example calculation in Figure 1, in which we obtained a result of 4.8 billion Christmas cookies. Included in our result are the population of Germany, a fixed proportion of people who eat cookies, an assumption of how many cookies are eaten per day and the approximate duration of the advent season.

Considering the *completeness* of assumptions as well as the calculation processes of the grade three teams, the results of five of the seven teams are categorised as complete, whereof we saw incorrect calculations in the solution of one team. The five teams used the aspects of the population of Germany, the fixed consumption of Christmas cookies per person per day (ranging from two to ten)

and the duration of the advent season (lasting between 22 to 24 days). Of these groups, three assumed that all people living in Germany eat cookies during advent. The other two teams assumed, based on research or their own judgements, that there are people who do not eat Christmas cookies during advent. The results of the two remaining teams were incomplete. They did not take the advent season into account. For grade eight, the categorization results in four out of five teams having complete results, with incorrect calculations in one team. One team achieved an incomplete result. In general, a greater variation in the assumptions made can be observed, which also led to the greater variation in the group's results: In terms of population, four of the five teams assumed that everyone living in Germany eats Christmas cookies during advent and one team made restrictions here. The fixed consumption per person and day was done by four teams, ranging from one to 15 Christmas cookies. The remaining team instead assumed the consumption of cookies per person throughout the year, meaning that they did not take the advent season into account and answered the task incompletely. The other groups assumed the advent season to be 22 to 25 days long.

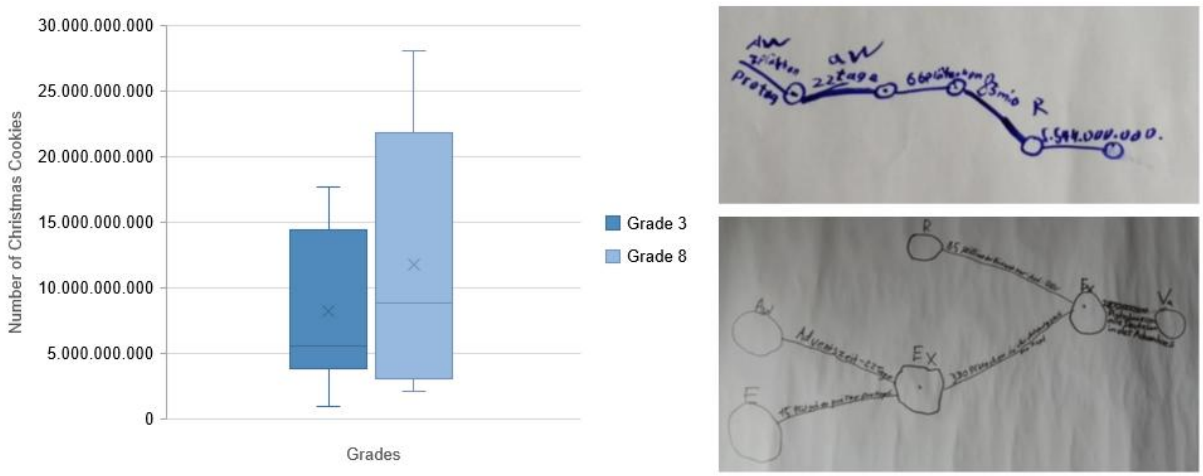

Figure 2: Calculated results (left) and two graphs from grade 3 (right above) and grade 8 (right below)

We focus on the category *structure* of the Fermi graph in the following, starting with grade three. In terms of *criterion I*, three of seven teams had problems in creating the general structure of the Fermi graph with an incorrect difference in the number of edges and nodes. Also three (partly different) teams showed difficulties in fulfilling *criterion II* and the idea of the Fermi method. Instead, the teams created a *line representation* (e.g., Figure 2 right above). Concerning *criterion III*, we can see that, except one team, all teams had problems in the area of linking Fermi activities (adequately) to each node of the graph. Some (internal) nodes were not labelled with activities at all. Similar problems can be seen in the labelling of edges. With the categorization based on these criteria, it can be stated that four teams from grade three created a partial Fermi graph, whereas the graphs of the remaining three teams were not categorised as Fermi graphs. In grade eight, all five teams fulfilled *criterion I* and *criterion II* which means that the general structure of the Fermi graph could be observed. This explains why every graph was categorised as a Fermi graph. Two teams fulfilled all criteria of a Fermi graph (e.g., Figure 2 right below), whereas the other three teams created a partial Fermi graph. The challenges in these teams came from *criterion III* concerning the labelling of nodes and edges with missing or wrongly linked Fermi activities, assumptions and intermediate results.

Linking the results from both categories (see Table 1), it can be reported for grade three that the combination of a partial Fermi graph and a complete result appeared most often. With the partial Fermi graph giving an idea of the overall structure despite missing elements, a potential guidance for a complete result can be assumed. Still, even for the category *No Fermi graph*, results on both levels of completeness were observed. For grade eight, the combination of a complete result and a Fermi graph appeared twice. Also here, the partial Fermi graphs came together with both complete and incomplete results. It is therefore not possible to make a general statement on the Fermi graph's usefulness for a result's completeness on the basis of the data.

Table 1: Combined categorization of the teams' results and graphs (grade 3 / grade 8)

		Fermi graph	Partial Fermi graph	No Fermi graph
Grade 3	Complete result	-	3	2
	Incomplete result	-	1	1
Grade 8	Complete result	2	2	-
	Incomplete result	-	1	-

Discussion

From the results, we can draw conclusions concerning our research question on the use of Fermi graphs in primary and secondary level. The teams from both grades were able to work on the Fermi task and most of the teams achieved a result that was categorised as complete. We can therefore confirm the observation of previous studies (e.g. Ärlebäck, 2009; Ferrando & Albarracín, 2021) that both primary and secondary students are able to meaningfully work on Fermi problems.

Concerning the results, it is remarkable that the teams from grade three calculated more homogenous results in contrast to the teams from grade eight. In addition, we can see that the teams from both grades generally took similar assumptions into account, i.e. in terms of the population of Germany, some people not eating Christmas cookies, the idea to estimate the amount of cookies per day and person as well as the duration of advent season. With the above described exceptions, it can be stated that the teams of both grades worked on a comparable level of completeness and detailedness which is a remarkable result in terms of implementing Fermi problems in primary school. At this point, it has to be limited that the students were participants of an enrichment programme, which might have made them more familiar with open tasks in general. So it might have been easier for them to set assumptions and to deal with the open character (cf. Haberzettl et al., 2018; Surel & Greefrath, 2023). Special knowledge about Fermi problems was not acquired beforehand.

Differences between the grades can be seen in the analysis of the Fermi graphs. It is noticeable that all graphs from grade eight were at least partial Fermi graphs. The reason for this categorisation is that the eighth grade teams only forgot/wrongly named Fermi activities, but the created graphs generally have the character of a Fermi graph. The grade three teams, in contrast, also produced

graphs that were not categorised as Fermi graphs since a line representation arose for some teams. Perhaps the older students' knowledge of probability trees, for example, helped them to realise the graph structure. This knowledge cannot yet be assumed in the third grade. Also, the use of Fermi activities was more consequently done by the grade eight students. This means that these teams placed more mathematical activities on the nodes than the primary school children, who often omitted the node labelling with activities. It can be assumed that the students from the third grade did not understand some Fermi activities, e.g. extrapolation, so that they did not use these mathematical activities or used them incorrectly. Possibly, some teams were already overwhelmed by the graphical representation of the solution process and paid less attention to mathematical activities. Based on this observation, the question arises as to whether the activities could already be adequately understood after a brief introduction. In order to explain the underlying reasons in more detail, it would be necessary to interview the individual groups to find out why they used no or incorrect mathematical activities. Based on the problems described above, it can be assumed that the Fermi graph might be too complex in its structure for primary school children or that the intervention was too short/not incorporating fundamental graph-theoretical knowledge to better understand the idea of the graph.

The results show that a Fermi graph can generally be created and used by eighth-graders after its first introduction. Due to the sample size, the combination with the results obtained does not yet provide any indication of how the graphs can, for example, support the solution quality of a Fermi problem. Similarly, the usefulness perceived by the students is an open question for further research. Both should be examined with a control group (solving the Fermi problem without a Fermi graph) in future research. For grade three, the question arises how the introduction of Fermi graphs can be revised and simplified. For example, it seems reasonable to first practise with the children to transfer their arithmetic solution process into the graph structure before mathematical activities are added (in a reduced form). As an outlook, we will further investigate a long-term intervention on Fermi graphs. In a gallery walk with all produced graphs following the lesson, the children independently mentioned criteria for the complexity and comprehensibility. They recognised, for example, that the line representation cannot fully reflect the solution process. It is possible that these criteria could lead to clearer structures and documentation when creating their next Fermi graph.

The role of transpositive analyses when discussing modelling in disruptive times

Britta Eyrich Jessen

Department of Science Education, University of Copenhagen; britta.jessen@ind.ku.dk

In this discussion paper we address the potential need for curriculum reforms due to technological development and pressing wicked problems in the disruptive times we live in, and how these may affect what is to be taught and learned regarding mathematical modelling in schools. The paper draws on the Anthropological Theory of the Didactic (ATD) in terms of the notion of didactic transposition. Recent research proposals for including STEM modelling, data modelling, critical and responsible citizenship, and data science point to the need for more detailed analyses of what practices and knowledge can and should be transposed to school mathematics, before imposing radical changes of curriculum, difficult for teachers to implement and navigate.

Keywords: Didactic transposition, curriculum analyses, modelling, interdisciplinarity, technology

Introduction

The most recent ICTMA (International Community of Teachers of Mathematical Modelling and Applications) book series is published under the title "Researching mathematical modelling Education in Disruptive Times – an introduction" (Siller et al., 2024). It states that mathematical modelling is a fundamental activity in general education, and we see from events like the pandemic and political decision making e.g. regarding climate changes (e.g. Strømskag, 2023) that a significant amount of decision making is based on modelling in various forms:

> "Thus, an understanding of mathematical modelling and models needs to be promoted across schooling and in other institutions devoted to education. Recent events and phenomena have also demonstrated the key role of mathematics in forming judgements and making decisions within societal contexts." (Siller et al., 2024, p. 3).

It has been argued that we need further research on data modelling and statistical modelling (Kawakami & Ärlebäck, 2022; Noll et al., 2022), which are key concepts for data (science) modelling. English and Watson (2018) claim that the increasing prevalence of data-driven environments emphasize the importance of teaching students diverse approaches to navigating data modelling presenting a case study differing between mathematical and statistical actions taken by students when addressing a real world situation. Dealing with large amount of data, will often require explicit uses of digital technologies and therefore, they may take a more dominant role in modelling education in the future. But further research is needed in classrooms and for the education of pre-and in-service teachers (Siller, Geiger & Greefrath, 2023). Thus, proposing modelling education capturing modelling in a digitalised and data driven world, needs to consider the skill set of teachers to teach the activities within school mathematics. An issue which only will increase as modelling is considered crucial to citizenship education (Maass et al., 2022), where elements of critical evaluation of one's own and others' modelling are crucial. This relates to 'technocritical mathematics education', which urges mathematics education to let students explore and unpack hidden mathematics in technological

solutions to realise how this impact our daily lives (Jankvist et al., 2023). But does this change how we perceive the notion of modelling?

For decades, different approaches to modelling education have been discussed, leading to different epistemological reference models affecting task design for modelling. The most dominant employed and discussed in TWG06 is modelling competency and modelling cycles, models and modelling, Fermi problems and study and research paths (Ärlebäck et al., 2023). Barquero and Jessen (2020) analyse how some of these theoretical approaches for task design impact what students can learn of and from being engaged with modelling activities. However, the cases analysed do not heavily draw on digital technologies nor large amount of data. For this we may seek inspiration in literature addressing e.g. data science. Heinemann an colleagues (2018) proposes a curriculum for out of school activities held at universities in Germany, explicitly drawing on both mathematics and computer science. But is it sufficient to leave modelling in terms of data science as mere add-ons to ordinary teaching? In Denmark private funding has led to development of initiatives concerning data science for upper secondary mathematics, though still limited to transmission of techniques and methods (Jessen, 2023; Tarp & Frantzen, 2023), not linking data science and mathematical modelling to inquiry based education, though modelling has been considered so in research (Artigue & Blomhøj, 2013). If mathematics education is supposed to prepare students to navigate a data driven reality through modelling activities, curriculum changes may be needed to accommodate other practices than already existing in modelling curricula. Below we elaborate how didactic transposition, from the Anthropological Theory of the Didactic (ATD), can guide and inform such changes, before presenting current challenges linked to transposition efforts, and modelling activities proposed in connection to this debate.

Curriculum reforms and transpositions

If future task design on modelling needs to capture the above stated trends of disruptive times promoting data driven modelling, we must consider how this affect curriculum changes with respect to modelling. The most dominant approach to curriculum analyses and reform efforts is the distinctions presented by Mullis (2019) as part of the TIMSS studies: the intended curriculum (national, societal and educational context), the implemented curriculum (home, school, teacher and classroom contexts), and the attained curriculum (student achievements and attitudes). Despite its wide uses, the curriculum model does not take the dynamic shaping of curriculum into account, as "[…] curricula interact with the conditions and constraints of their functioning to catalyse change in the state of educational systems." (Barquero et al., 2023, p. 193). Few theoretical approaches seem appropriate for analysing coherence (or lack of coherence) in mathematics curriculum reforms in terms of unintended consequences of reforms, implications of teachers being active in developing implemented curricula, rather than mere receivers of curriculum, to identify lost opportunities etc. Moreover, a

> "finding that does stand out and is likely to be generally applicable is that […] many reviews of mathematics curriculum reforms are not well supported by a clear theoretical basis that guides the methodology used. This necessarily limits the robustness of the analyses and, very likely, the impact of the work. […] (Barquero et al., 2023, p. 214)

In the context of mathematical modelling, we need to consider is such analyses are need on how to implement data modelling, stochastic modelling, data science and techno critical mathematics education. More concretely, what does it mean for school mathematics to develop students to responsible and critical citizenship? What actions, should students be able to perform? What methods should they apply? Answers to these questions depends on level of education and we should draw on existing research regarding the shaping of modelling in different school contexts. Barquero et al. (2023) point to ATD and particularly the notion of didactic transposition as one theoretical construct allowing us to provide somehow objective analyses of what and how to teach school mathematics. The process of didactic transposition is depicted in Figure 1.

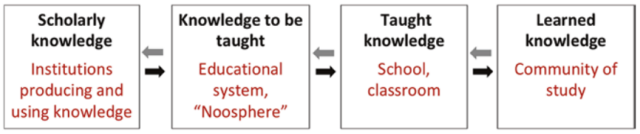

Figure 1: The process of didactic transposition from producing institutions to learned knowledge (Barquero et al., 2023, p. 198)

One of the main contributions of didactic transposition theory when linked to the question of curriculum reforms and implementations is to take scholarly knowledge into account. Bosch (2015) argues that:

> "Before focusing on how children learn and how we can teach them—the viewpoint of the teachers' institution—the attention is first put on what is learnt and taught, its nature (what it is made of), origin (where it comes from) and function (what it is for)." (Bosch, 2015, p. 54-55)

Still, an integral part of the curricular conundrum, as Chevallard (2018) calls it, is the fact that we have to consider the situation from a holistic societal viewpoint, where people in different positions have different relations to the knowledge at stake. In the scholarly context, researchers in public and private positions are developing and using knowledge, such as data science tools and notions, but is that relatable to school mathematics? Most often the external didactic transposition is carried out by the noosphere which is constituted differently from one country to another. The noosphere e.g. covers curriculum developers from ministry of education, politicians, different stake holders, educational researchers, textbook authors etc. (Jessen & Kjeldsen, 2021). Through their production of curriculum documents of various forms, they produce the knowledge to be taught. The internal didactic transposition is mainly managed by the teacher delivering the taught knowledge, based on selections and interpretations of the curriculum documents. The last step in the transposition is learned knowledge within the students. And as all teachers know, this may again be slightly different from what was taught. Thus, to realise the above needs regarding data modelling and practices together with the development of responsible and critical citizenship, transposition of knowledge may need more transparency through well drafted examples making it explicit the knowledge and methods being transposed.

In the following we presents examples of didactic transposition of mathematical modelling, data science and links to tasks proposed to capture and further develop the critical mindset strived for in literature. We do that by pursuing the following research question: What is the potential role of

didactic transposition in research proposing changes of how we teach modelling during disruptive times in a data driven world? And how do the proposed modelling activities link to these findings?

Didactic transposition of mathematical modelling

Didactic transposition analyses of mathematical modelling already exist. Jessen and Kjeldsen (2021) have analysed the external didactic transposition of modelling in upper secondary mathematics, using historic cases of model construction from STEM fields going across disciplinary boundaries reflecting school mathematics and interdisciplinary settings for STEM education. Jessen and Kjeldsen compare the historic representations of modelling with 'knowledge to be taught' in terms of curriculum documents, textbooks and exam exercises, finding a certain impact of e.g. modelling cycles. Still, other crucial aspects of modelling construction such as explorations, uses of analogies and the negotiation of epistemic value across intra- and extra-mathematical domains were missing when compared to the scholarly domain. Frejd and Bergsten (2016) analyse current modelling practices in workplaces, meaning mapping the scholarly knowledge of modelling practices form public and private institutions and how these may relate to school practices. They conclude that models constructed by students are rarely put into use, and the division of labour between expertise is not realised, as students often take same classes and is considered to have similar prerequisites. As such they argue that

> "These major differences between modelling work in educational and non-educational contexts seem to entail that mathematical modelling in school becomes an unrealistic utopia in terms of coherence to non-educational professional practice." (Frejd & Bergsten, 2016, p. 31).

This may also hold true for other domains in school mathematics, but certainly needs to be addressed when promoting future modelling activities or curriculum changes. Moreover, if scholarly knowledge justifies the teaching of school mathematics, rethinking meaningful connections may be relevant (Jessen & Kjeldsen, 2021). Also in statistics education, data science and digital technologies may shape the future of education and research, leading to similar considerations as seen in mathematical modelling:

> "The advent of data science has provided new challenges and opportunities for statistics education researchers to re-think what it means to model. […] How can new simulations and visualizations using technological tools increase students' access and agency for telling data stories, and enrich understanding in modeling processes?" (Noll et al., 2022, p. 331).

A first attempt of transposing data science into a mathematics curriculum for upper secondary mathematics is presented by Boaler and colleagues (2024), who report on a high school applied mathematics course exploring basic elements of data science. Their analyses indicate that the course leads students to take more mathematics courses, and students anticipate carriers in STEM (Science, Technology, Engineering and Mathematics). The course is project based and organised around the data science cycle of inquiry starting with posing questions, gathering and organising data. As such the course aligns with the proposed data science curriculum developed for upper secondary students in Germany proposed by Heinemann and colleagues (2018). However, the replacement of classic mathematics courses with data science has been criticised for hindering students in pursuing higher

education in STEM due to the lack of calculus preparing courses (Conrad & Mazzeo, 2022), though the data science course has proved an important addition to calculus pathways, allowing students to exercise agency while learning mathematics and applications:

> "[…] for all students, data science courses help students develop the ability to read data, create mathematical models, use technological tools, and interpret findings—important understandings for young people taking their place in our newly data-filled world." (Boaler et al, 2024, p. 15).

Despite these descriptions of data science aligns well with the initial justifications for teaching modelling as a fundamental activity in mathematics education generally, none of the new initiatives explicitly link data science with mathematical modelling, which already is part of mathematics curricula across the world. Below we briefly look at example of activities proposed to promote students' critical citizenship in data driven worlds, based on application of digital technologies in various forms.

Proposed cases of modelling with technology and data

Jankvist and colleagues (2023) do not discuss mathematical modelling, but problematise current state of society and mathematics education where hidden mathematics represent challenges in equity in access to democratic decision making. They question if students gain full autonomy over their learning processes due unreflect uses of digital technologies. They argue that:

> "Even though these insights reveal different takes on the consequences of packing and unpacking mathematics for students' learning, none of them talk about the processes of packing and unpacking as goals in their own right. This is the purpose of *technocritical mathematics education*" (Jankvist et al., 2023, p. 10).

They propose public-key cryptography (RSA) as knowledge allowing student to unpack hidden mathematics highly important to society. The case certainly meets the goal of engaging with genuine models drawing on notions like prime numbers, greatest common divisor, but the models also draw on Eurler's theorem, Fermat's little Theorem and the Chinese remainder theorem. This may go beyond school curriculum, and we lack proposals for how this can be taught inquiry based in order to secure autonomoy.

Tarp and Frantzen (2023) has redesigned an activity from on data science from being transmission of knowledge to more inquiry based concerning the notion "k nearest neighbour" (kNN), as a way for "the students to gain insight into the role of modelling in ML [Machine Learning] and broader knowledge concerning the notion of mathematical modelling" (Tarp & Frantzen, 2023, p. 19). Students are given data they need to import in the program Orange, where they conduct their ML activities through block programming. Students are asked to determine gender of a person based on data concerning this person. A priori the students can solve the problem using either ML models, e.g. kNN and a distance measure, or using mean calculations. All are preparing students to revisit linear regression and smallest residuals for finding the best fit of models. The case study show productive uses of the simple programming and different views on models: plots, data tables, the programming, and how this mirror probabilities for certain gender in new data. Still the inquiry approach to modelling challenged some students: "Connecting the pooled data to the tree-model […], they train

the model all over again on the merged data set, not sure what the newly added data looks like." (Tarp & Frantzen, 2023, p. 72). The study show potential of creating coherence and making sense of existing curriculum elements when introducing data science and ML in ordinary mathematics lesson in upper secondary school. However, they argue that this requires knowledge of task design and content knowledge much beyond current requirements.

Jessen (2024) presents a case study of a teacher's attempt to teach students how mathematics can form the basis of technical solutions they know from their everyday uses of e.g. smartphones. The teacher posed the student with the question of which three measures they would need and why, if they were to design a facial recognition system (Jessen, 2024, p. 296). Some students engage in very productive explorations of mathematical concepts calculated based on three measures, when the picture of a face is imported to a coordinate system in GeoGebra. The students used and validated their models taking and importing new pictures to the digital tool and made sure their proposals met the requirements for facial recognition, they found online. Not all groups were equally productive, and none connected the modelling activities to programming, or the mathematics involved in facial recognition systems – the scholar knowledge justifying the activity.

The last example addresses the development of responsible and critical citizenship through modelling of climate changes through the Civimatics project (Strømskag, 2023). The chapter is both an introduction to teachers regarding inquiry based mathematics from the point of view of ATD, but also how to model solutions for climate changes such as carbon storage. The materials meant for teachers (proposed curriculum document), promotes the idea of considering algebra as a modelling tool, while still taking its outset in research on carbon storage. As such it has the potential being genuinely interdisciplinary, though drawing on more classic modelling techniques from algebra – and as such not really exploring the potentials of stochastic modelling through and with digital technologies.

Concluding remarks and looking ahead

In literature we see similar trends regarding how to prepare students for critical and responsible citizenship, but addressed from different theoretical perspectives: statistics education, mathematical modelling with technology, critical mathematics education etc. This will according to Barquero and Jessen (2020) indicate different learning outcomes from and about modelling, though at a first glance the aim of the research trends points in the same directions. Therefore, we see a strong potential insisting on didactic transposition analyses regarding mathematical modelling insisting on knowing the its nature, origin, and function (cf. Bosch, 2015) of these proposed practices before they are implemented in schools. We see initial noospherical works as the proposed curricula (Boaler et al, 2024; Heinemann et al., 2018), proposed teaching material for teachers (Strømskag, 2023), and researchers promoting technocritcal mathematics education content. From classrooms we see mixed success from case studies either imitating the knowledge and practices involved in ML, or cases imitating facial recognition systems reduced. We also see a lack of coherence between what justifies potential curriculum changes linked to data driven modelling in STEM contexts, and what is currently happening in classrooms. Thus, we see a clear need for research aiming at mapping the knowledge justifying the teaching of modelling which prepare students to navigate modelling in disruptive times (Siller et al., 2023). Moreover, this require significant professional development of teachers as well.

Secondary students' multifaceted perceptions of the role of data from the perspectives of models, modelling and information

Takashi Kawakami[1] and Jonas Bergman Ärlebäck[2]

[1]Utsunomiya University, Cooperative Faculty of Education, Tochigi, Japan;

t-kawakami@cc.utsunomiya-u.ac.jp

[2]Linköping University, Sweden

This study explored secondary school students' multifaceted perceptions of the role of data from the perspectives of models, modelling, and information, following two or three lessons focused on a data-informed modelling activity with mathematics and statistics at its core. The results showed that half of the students perceived data not only as a well-organised basis to directly achieve the real goals set in the modelling activity, but also as an unorganised basis to be manipulated or mathematised to generate information and knowledge or wisdom from the data. The students' perceptions were also supported by the real-world contexts of the activity used in the lessons. However, the role of data as an aspect of reality was not found to be naturally recognised and emphasised by the students in the context of the lesson. We argue that students need to experience a range of data-informed modelling activities with a variety of tasks in order to recognise the multifaceted role of data.

Keywords: Modelling, models, data use, information, data literacy.

Introduction

In today's data-informed society, new types of data emerge owing to the expansion of media channels and technology. As such, information and discussions about disruptive events (e.g. the COVID-19 pandemic, climate change, population change, and food disruption) based on complex data-informed models and modelling are becoming increasingly prevalent. To cope with such societal changes, it is necessary to develop data-literate citizens who can recognise what data can and cannot do based on an understanding of the nature and role of data (e.g. Engel, 2024).

Recently, research at the boundary of the mathematical modelling education community and the statistics and data science education community has centred around data-informed modelling with mathematics and statistics at its core to develop mathematical and/or statistical literacy and/or disciplinary learning (Biehler et al., 2024). This was also evidenced by more Congress of the European Society for Research in Mathematics Education (CERME) working groups on "Applications and Modelling" in which the educational use of data, models, and modelling was discussed in relation to statistics and data science education (Barquero, 2023). In this area of research, we seek to connect mathematical modelling education with statistical modelling or statistics and data science education (e.g. Ärlebäck & Kawakami, 2023; Kawakami & Ärlebäck, 2024). In this study, we focused on the role of data as a perspective for elaborating this connection.

Regarding the role of data, Engel (2024) stressed that awareness of the role of data and models in knowledge generation is crucial in the information age, as it helps individuals critically evaluate and interpret the information they encounter. Podworny and Frischemeier (2024) examined primary

school students' perspectives on data through a teaching sequence on statistical modelling, using decision trees as an example. Kawakami and Ärlebäck (2024) identified the role of data in teaching statistical modelling based on a literature review. Despite the importance of data in today's data-driven society and modelling educational community, research focusing on the detailed aspects of secondary school students' perceptions of the role of data in data-informed modelling is sparse. This study examined Grade 9 (aged 14–15 years) students' multifaceted perceptions of the role of data in data-informed modelling from the perspectives of models, modelling, and information.

Theoretical framework

Data

Data are essential in data-informed modelling (Ärlebäck & Kawakami, 2023; Kawakami & Ärlebäck, 2024) and represent 'numbers with context' (Cobb & Moore, 1997, p. 801). Thus, it is imperative to understand and interpret data in real-world contexts relevant to getting information about the data. Furthermore, the data contain signal (regular patterns) and noise (irregular random patterns) structures (Konold & Pollatsek, 2002). Data are subjected to mathematisation to unveil or abstract their underlying structure for various reasons, accompanied by sources of mathematical and statistical models and knowledge (Wild & Pfannkuch, 1999).

The potential role of data from the perspective of models

Data are key in generating, validating, and modifying models in data-informed modelling. Blomhøj and Jensen (2003) emphasised the role of data *as evidence to test model validity* in the modelling process. In addition, data can be considered as a model of reality (Podworny & Frischemeier, 2024). That is, data can *simplify complex reality*, recognising the limitations of data as an aspect of reality from a critical stance (Engel, 2024). Understanding the role of data in modelling reality is also crucial for critically reflecting on the route along which the models have been generated.

The potential role of data from the perspective of modelling purpose

In data-informed modelling, data are generally used to solve real-world problems. To understand the role of data from this perspective, we refer to the following description by Niss (2008), which succinctly summarises the purpose of mathematical modelling as follows:

> (P1) to understand (represent, explain, predict) parts of the world;
>
> (P2) to subject parts of the world to some kind of action (including making decisions, solving problems);
>
> (P3) to design parts or aspects of the extra mathematical world (creating or shaping artefacts, i.e. objects, systems, structures). These purposes are pursued by constructing or utilizing mathematical models to describe or prescribe aspects or parts of some domain. (p. 77)

These purposes align with the aims of data-informed modelling, emphasising the prediction and explanation of phenomena in data science and statistics education (Biehler et al., 2024). P1 requires using data *to understand (representing, explaining, predicting) parts of the world*. P2 requires using data *for decision-making to lead to better actions*. P3 requires using data *to set the standard or norm*, such as best-practice guidelines for lockdowns during the COVID pandemic. From a critical stance,

this role also carries the risk of having the power to shape human perception and behaviour that responsible citizens need to critically reflect on (Skovsmose, 2023).

The potential role of data from the perspective of information

Citizens should elicit information from data and understand the process of generating knowledge from data to judge the credibility of information and its sources in society (Engel, 2024). In information science, the DIKW (Data-Information-Knowledge-Wisdom) hierarchy (Figure 1) has attracted attention as a framework for describing the process of transforming raw data into meaningful information, appropriate knowledge, and useful wisdom for making informed decisions (e.g. Rowley, 2007). The hierarchy has also been emphasised in data-informed modelling (Engel, 2024).

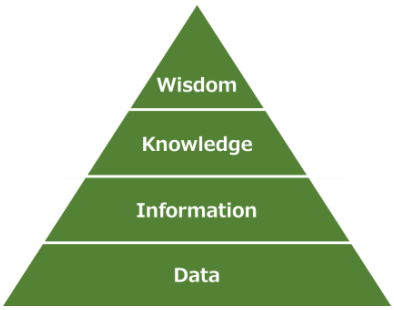

Figure 1: DIKW hierarchy (e.g. Rowley, 2007)

In the DIKW hierarchy, data are the foundation that generates information, knowledge, and wisdom. Generally, data are viewed as unorganised raw materials lacking meaning, context, value, or structure. Information is defined in terms of data and is considered as data with a purpose, context, structure, and meaning. There are various definitions of knowledge, but in this study, knowledge derived from data in the DIKW hierarchy is viewed as the integration of information into existing knowledge, experience, values, and so forth. Wisdom is also multifaceted; however, we view it as a higher level of understanding and the application of knowledge based on thoughtful and ethical judgment (Engel, 2024; Rowley, 2007). According to Engel (2024), moving upwards in the hierarchy is enabled through data-informed modelling. The transition from data to information involves building models to elicit and represent patterns, trends, and relationships in the data, which corresponds to part of the mathematisation in the modelling process. The transition from information to knowledge and wisdom involves interpreting organised information, integrating information into existing knowledge and previous experience, and combining and applying knowledge and models to other situations. In some cases, the explanatory power of a model can be increased by combining multiple data-based models (Ärlebäck & Doerr, 2020). This process corresponds to the interpretation and validation in the modelling process as well as real-world applications of models and modelling. Thus, data could be *the basis for information, knowledge, and wisdom*.

Research question

To examine and elaborate on the theoretical framework using the perspectives of models, modelling, and information, we formulated and addressed the following research question: *What perceptions do Grade 9 students express about the role of data in relation to models, modelling, and information after data-informed modelling?*

Methods

Participants and context

To answer the research question, we used data from lessons (two or three of 50 minutes each) involving data-informed modelling for the population prediction and post-lesson individual report assignments implemented for Grade 9 students (aged 14–15 years). An overview of the lessons and analysis of students' modelling work are given in Kawakami and Mineno (2021). However, the current study substantially differs from this previous work in that it analysed students' perceptions of the role of data in modelling data-rich situations. The participants comprised 151 students from four classes in Grade 9 at a junior high school in Japan. They previously learned descriptive statistics (i.e. representative value, histogram, and relative frequency), probability, and linear functions. However, they did not learn about modelling using complex data.

In the lessons, the students worked in groups and collaboratively tackled *the population prediction task* (Kawakami & Mineno, 2021). This task was to predict the 2010 census population of Japan based on Japanese population data in 1995, 2000, and 2005 by 5-year age groups and other data (e.g. population based on age groups, number of births, birth rate, mortality during 1990–2005, number of births based on mothers' age, and population pyramid graphs). The students constructed, validated, and revised various models while flexibly combining mathematical, statistical, and contextual approaches to knowledge. In the lessons, they shared each other's models going to each group to explain their approach while presenting the model drawn on a small whiteboard; the role of the data was not explicitly discussed in class. In the post-lesson, they were asked to prepare a report including various tasks and questions, one of which was the focus of this study: *What is the role of data in modelling data-rich situations such as population prediction?*

Data collection and analysis

We analysed all participating students' responses to the question about the role of data in their reports. First, seven coding categories for the roles of data (R1–R7 in Table 1) were developed based on the potential role of the data, as explained in the theoretical framework section. As the distinction between knowledge and wisdom in the DIKW hierarchy is not always clear (Rowley, 2007), we combined the two into one category. Then, students' responses were assigned to one or more of the seven categories based on their statements, as indicated in Table 1. The first author performed this coding in Japanese and translated it into English, and the second author reviewed and checked the translated coding performed by the first author. Differences in interpretation between the two authors were discussed until an agreement was reached. The analysis was revised as necessary.

Results

Figure 2 shows the percentages of 151 students' perceptions of the role of the data for each category (R1–R7). Each percentage is calculated based on a sample size of 151. All students described the role of data that fell into one or more of the seven categories. Of these, the most common was description of the roles of the data, classified as R3 (understanding), R6 (information), and R7 (knowledge/ wisdom). Very few students (less than 10%) wrote about the role of data in categories R1 (testing), R2 (simplifying), R4 (decision-making), and R5 (standard or norm).

Table 1: Category for analysing students' perceptions of the role of data

Category	Criterion	Example of description
R1: For testing model validity	Describing the use of data as evidence to test model validity.	"By comparing the predicted values with the actual measured data, you can check whether the method used to make the predictions is accurate." (student C17)
R2: For simplifying complex reality	Describing the use of data to simplify complex reality or the limitation of data as an aspect of reality.	"It is important to check the subject and purpose of the data, and to make sure we understand what we can read from the data." (student B2)
R3: For understanding parts of the world	Describing how data is used to understand (represent, explain, or predict) parts of the world.	"Informing us of the current situation and facts." (student B18); "Clues for prediction." (student D6)
R4: For decision-making	Describing the use of data for decision-making to lead to better actions.	"Leading to the decision-making of national policy." (student D25)
R5: For setting the standard or norm	Describing the use of data to set the standard or norm.	"Enabling methods such as calculating the mean." (student C34)
R6: The basis for information	Describing the use of data to elicit and represent patterns, trends, and relationships in the data.	"The data allow us to understand trends and make evidence-based predictions." (student B5)
R7: The basis for knowledge and/or wisdom	Describing how they use data to interpret organised information, integrate the information into existing knowledge and previous experience, or combine and apply knowledge and models to other situations.	"When we load the data, we can see the changes in society, such as the declining birthrate, the ageing population, the rise in the number of unmarried people, and the trend towards late marriage." (student A15)

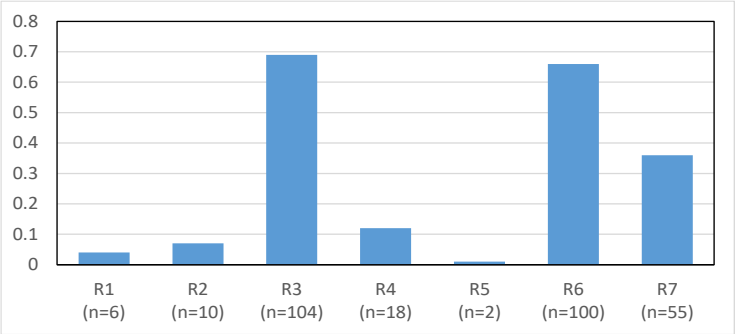

Figure 2: Proportion of students (out of *N* = 151) in each category

First, 69% of the students described the role of data in understanding, describing, and predicting parts of the real world. Most of them related the role to the specific context of the population predictions in the classes (e.g. “Data plays an important role in predicting population trends, as it is possible to predict the future to some extent based on past trends.” [student D2]). In addition, some students described the role in a general way, removing or inducing from the context (e.g. “The data can also be used to make accurate predictions about how it will affect society” [student B27]).

Second, 66% of the students described the role of data as the basis for information. Most mentioned eliciting patterns and trends from data and linking this to using it for prediction assigned to R3 (e.g. “The data gives us clear trends and specific declines. These are the first clues needed to make predictions.” [student A8]). Many students’ descriptions showed they recognised the data as highly objective, accurate, and reliable representations of facts. For example, student B23 explained the robustness of the data as evidence, conveying a metaphor in Figure 3: “Only on the basis of different data can conclusions be drawn and objections of others be defended.”

Figure 3: Student’s data metaphor

Third, 36% of the students described the role of data as a basis for knowledge or wisdom. Many mentioned that by using multiple data sets, it is possible to create multiple models (i.e. equations and graphs for prediction), and by using these together, it is possible to make new discoveries and evidentially explain the data from different perspectives (e.g. “If there is more than one piece of data, it is possible to find trends from multiple perspectives, so it is possible to find more realistic trends and increase the evidence.” [student D12]). In addition, some students wrote that by considering multiple data sets, they could view the social context and make predictions based on integrated contextual knowledge (e.g. “If you compare the data with the history of the baby boom and the falling birth rate, etc., the data increases and can be superimposed on current trends in Japan to make detailed predictions.” [student B2]). These student responses reflected the specific context of using different data to predict the population in class.

Fourth, in contrast to the fact that many students recognised the data as factual and highly credible, only 7% mentioned the role of data in simplifying reality. Some focused on the process of generating data from data sources and listed the limitations and points to note about the data (“When verifying data, it is necessary to confirm that it is true. For example, it is necessary to confirm that the person releasing the data is a trustworthy person.” [student B35]).

Finally, 52% of the students (n=79) described the role of the data in R3 and R6/R7. The breakdown was as follows: 45 students were classified as R3+R6, 13 as R3+R7, and 21 as R3+R6+R7.

Discussion and conclusion

This study explored secondary school students’ multifaceted perceptions of the role of data from the perspectives of models (R1 and R2), modelling (R3, R4, and R5), and information (R6 and R7). The

results indicate that half of the students recognised data not only as a well-organised basis to directly achieve the real purposes set in modelling (e.g. R3) but also as an unorganised basis for manipulating or mathematising the data to generate information and knowledge or wisdom for achievement (R6 and R7). In mathematical modelling education, the importance of the interaction between *thinking with models* and *thinking about models* has been noted (Ärlebäck & Doerr, 2020); those results suggest that in data-informed modelling education, the interaction between *thinking with data* and *thinking about data* is just as important as in the case of models. Thus, this study revealed that secondary school students understood the dynamic nature of the data through modelling.

In addition, secondary school students' awareness of these roles was supported by their concrete experience of data-informed modelling, which dealt with the real-world contexts of population prediction. The role of context in understanding these data roles reflects the nature of data as "numbers with context" (Cobb & Moore, 1997, p. 801). This also confirms the results of Podworny and Frischemeier (2024), who found that most primary school students' understanding of the data was reflected in the decision trees used in the lessons. On the contrary, the roles R1, R2, R4, and R5 that were not emphasised in the classroom tasks were not easily identified by the students. In particular, R2 and R5 are essential for data-literate citizens to think critically about the data itself and the process of its generation while participating in society in a well-informed and critical manner (Engel, 2024; Skovsmose, 2023). Therefore, we suggest that students need to experience a range of data-informed modelling activities with a variety of contexts and tasks in order to recognise the multifaceted role of data. Our findings are based on an analysis of students' report descriptions following short-term lessons. It is also necessary to analyse in detail the development of students' perceptions of the role of data through interviews and its impact in the longer term.

Acknowledgements

This study was partially supported by the JSPS KAKENHI Grant Number JP21K0251. We would like to thank Kousuke Mineno for kindly allowing us to use the student report data.

The role of recursivity and reversibility in mathematical modelling: The bakery mould

Marcos Marí[1], Berta Barquero[1] and Marianna Bosch[1]

[1]Faculty of Education. Universitat de Barcelona, Barcelona, Spain; mmari@eisbarcelona.com

This paper focuses on the properties of recursivity and reversibility of mathematical modelling through the implementation of a complete cycle of the didactic engineering process, as outlined by the anthropological theory of the didactic. A preliminary analysis of an algebraic-functional modelling process is provided, and the design and a priori analysis of a study and research path (SRP) about the 'The Bakery Mould' are developed, addressing questions related to the determination of the most suitable mould dimensions for baking a cake. We use the a posteriori analysis of the SRP first implementation to analyse the recursivity and reversibility properties of modelling. Results from students' productions allow us to analyse the emergence and evolution of models and their role in the development of the SRP.

Keywords: Mathematical modelling, anthropological theory of the didactic, didactic engineering, study and research paths, covariation.

Introduction

This research aims to integrate two lines of work from the anthropological theory of the didactic (ATD, Chevallard, 2019). The first line focuses on the study of algebra and covariation in secondary education, based on the reference epistemological models for algebraic and functional modelling (as developed by Bolea et al., 2004; Ruiz-Munzón, 2010). The second line focuses on analysing the conditions that can facilitate the transition of current educational systems towards the paradigm of questioning the world, particularly through the proposal of study and research paths (SRPs, Barquero et al., 2022). We present the analysis of an SRP for secondary school, where these research lines converge. In this paper, we mostly consider the essential characteristics of mathematical modelling when dealing with situations involving the covariation of quantities within the ATD perspective.

Theoretical framework and research method

Mathematical modelling within the framework of the anthropological theory of the didactic

In the ATD, the modelling process is described through the following stages, which may alternate throughout the process (Chevallard, 1989, p. 53): (1) delimitation of the *system* to be studied, understood as the part of the reality to be modelled, specifying its relevant aspects, (2) construction of *model*(s) and work within the model; (3) work with the model to generate knowledge about the system. A fourth stage can be added with the formulation of new problems that can be addressed thanks to the development and work within the model. More generally, modelling is conceived as a tool to structure school mathematics (García et al., 2006) through the use or development of models and systems that succeed one another throughout the modelling process. The models used (if they are already known) or constructed (if they need to be created) are added to the system under study, transforming the model-system set into a new system, which might be modelled again. In this sense, the modelling process constantly evolves generating successively new system-model sets, each step

calling for more complex models. This property can be identified as the *recursivity* of modelling. The *reversibility* property in the modelling process highlights the fact that, at certain steps, systems and models can reverse their functions: for instance, when a previous system is used as a model of a new system or of the used model. As Barquero (2023) has already indicated, there is not much research literature on analysing the recursivity and reversibility properties. In this paper, we aim to investigate the emergence of these properties in the modelling process and their impact on it.

Study and research paths

In the ATD, the proposal of study and research paths (SRPs) is presented with a dual purpose. On the one hand, they serve as a general framework to design and analyse teaching and learning processes, including those based on inquiry and modelling. On the other hand, they are used to propose inquiry-based didactic approaches and to analyse the conditions required for their sustainable implementation. SRPs are structured in such a way that they begin with the proposal of an open question, called the generating question Q_0, which triggers an inquiry process to solve it. This process consists of a series of new questions that the study community (composed of students and teachers) must explore, and whose answers contribute to the joint development of a solution to Q_0. Along this path, the learning of new knowledge and techniques is integrated with information gathering, empirical data analysis, and the creation of new knowledge (Chevallard, 2019). SRPs are presented as a didactic tool intrinsically linked to the teaching of mathematical modelling, which appears as a productive way to develop answers to the questions posed. Research in the context of proportionality and functions (García et al., 2006), interdisciplinarity (Jessen, 2014), or combinatorics (Vásquez et al., 2021) in secondary education highlights this relationship.

Research questions and method

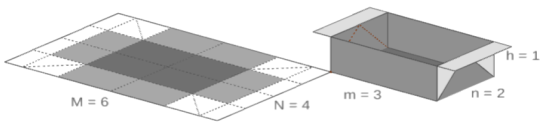
Research on modelling has revealed significant institutional limitations that hinder its integration as a regular activity in schools (e.g. Burkhardt, 2006). These constraints are linked to a predominant conception of modelling in secondary education, where it is often reduced to the mere construction or even application of specific models in predetermined situations. We start from the hypothesis that, to provide answers to the generating questions, SRPs bring forth modelling processes that are sufficiently developed to facilitate and promote the recursivity and reversibility properties of modelling. We can then formulate two research questions (RQ) addressed in this paper:

RQ1: How do recursivity and reversibility appear in the modelling processes generated by SRPs?
RQ2: How modelling process and its recursivity and reversibility properties can be shared and officialised to students along the implementation of an SRP?

Our objective is to address the first question using a specific SRP designed for 9th-grade students (aged 14–15) as a case study. We approach this study through a didactic engineering process (Artigue, 2020) and its four phases: the preliminary analysis of the didactic phenomena at stake; the *a priori* analysis of the educational proposal to be implemented to address these phenomena; the *in vivo* analysis during the implementation; and the *a posteriori* analysis to consider both the phenomenon at stake and the inquiry process implemented. In our case, the preliminary analysis starts from the results from Bolea et al. (2004) and Ruiz-Munzón (2010) interpreting algebra from a modelling

perspective and Barquero (2023) with the interpretation of recursivity and reversibility as central properties of modelling. Here, we focus on the *a priori* epistemological analysis of the proposal (presented in the following section) to highlight the recursivity and reversibility properties of an SRP, which is complemented using some elements of the *in vivo* and *a posteriori* analyses of the first SRP implementation in secondary school during the academic year 2023-24.

A priori analysis of the study and research path



The SRP starts by considering a type of traditional cake from northern Spain, the 'sobaos pasiegos', which uses a paper mould created through a simple origami technique (Figure 1). The generating question posed is Q_0: 'How can we construct the best mould among those that can be created using the same folding method?' This SRP is an adaptation of the 'cake box' case, from the one proposed by Chappaz and Michon (2003), used in research on mathematical modelling in primary education and teacher education, as presented in Barquero et al. (2024). The initial question in the *sobaos pasiegos* case is more realistic, given that in Spain, these cakes come in various sizes depending on the commercial brands that produce them. The initial system includes the cake mould and the origami technique. Here, we only consider the specific case of making folds in halves and quarters of the sheet in both dimensions, which addresses the question Q_1: How is the mould constructed?

Figure 1: *Sobaos pasiegos* in their paper mould and pattern for mould construction (our production)

From this point, we can consider different initial models: tables with different sheet sizes and the resulting moulds (measurement models, M1), as well as geometric models (M2) (see Figure 2). Working with both types of models leads to formulating and providing partial answers to questions such as: What relationships exist between the dimensions of the mould and the sheet? (Q_2); Given a specific sheet, what moulds can be constructed? (Q_3); Given a specific mould, what sheets create it? (Q_4); What sheet is needed to get a mould with a given volume? (Q_5).

In the search for an answer to question Q_0, we can consider proposals aimed at finding moulds with certain optimal properties: "with the lowest sheet cost", "with the largest volume", "the best-selling one", etc. However, difficulties arise that require measurement and geometric models to be refined or expanded. Individual numerical calculations are needed for each case, which creates challenges in finding and generalising the relationships between the dimensions of the sheet and the mould.

SHEET			MOLD			
LONGER SIDE (cm)	SHORTER SIDE (cm)	AREA (cm²)	LONGER SIDE OF THE BASE (cm)	SHORTER SIDE OF THE BASE (cm)	HIEIGHT (cm)	VOLUME (cm³)
7,7	6	46,20	3,85	3	1,5	17,33
8,3	5,4	44,82	4,15	2,7	1,35	15,13
10,2	7	71,40	5,1	3,5	1,75	31,24
13,1	6,1	79,91	*It is not possible because the flap exceeds the height of the mold.*			
7,2	7,2	51,84	*It is not possible because there is no flap.*			

Figure 2: Example of measurement (M1) and geometric models (M2) (authors' production)

Therefore, it seems reasonable to represent these dimensions and their relationships using algebraic expressions, progressing towards an *algebraic model* (M3) considering N and M as the shorter and longer sides of the sheet respectively, n and m as those of the mould's base, and h the height of the mould. We thus obtain generic answers to the posed questions. For example:

Q_2: *What relationships are there between the dimensions of the mould and the sheet?*

The sheet must satisfy $N < M < 2N$ (it cannot be a square $M = N$ to ensure there is a flap, and $M < 2N$ to ensure the flap does not exceed the height).

From sheet to mould: $h = ¼\ N$ $m = ½\ M$ $n = ½\ N$ (that is to say, $h = n/2$)

From mould to sheet: $M = 2m$ $N = 2n$

Q_3: *Given a sheet, what moulds can be constructed?*

From the previous relationships, we get the length of the flap $p = ¼\ (M - N)$

Q_4: *Given a mould, what sheets can create it?*

Assuming $m > n$, the mould must have $h = ½n$ and, to ensure that the flap exceeds the height, $M < 2N$ (or $m < 2n$). Therefore, if $m < 2n$ and $h = ½n$, we obtain a sheet with $N = 2n$ and $M = 2m$.

The algebraic model can lead to an evolution in the previously posed questions, raising new relevant ones, such as: How do small variations in the sheet dimensions affect the volume and height? (Q_6); What sheets with a given area lead to a mould with the highest volume? (Q_7); Which of the moulds with a given volume have the smallest sheet area? (Q_8). These questions are difficult to address within the algebraic model, as it does not facilitate an easy or detailed analysis of the covariation between variables. However, these questions created the possibility of evolving M3 towards a new model, a functional model (M4), which could be more efficient in relating the dimensions and the sheet area to the dimensions and volume of the mould. For instance, by considering the volume of the mould as a two-variable function $V(M, N) = m{\cdot}n{\cdot}h = ¼N{\cdot}½M{\cdot}½N = (1/16)N^2M$, it is possible to analyse how small variations in the dimensions of sheets influence the volume using different graphs of $V(M)$ or $V(N)$ for given values of N and M respectively. Moreover, given a sheet surface area $A = M{\cdot}N$, the volume can be expressed as a single-variable function $V(N) = A{\cdot}N/16$, enabling the determination of the optimal sheet dimensions to maximize the volume for a fixed surface area.

Classroom implementation and *in vivo* analysis

The SRP implementation took place as a classroom activity in May 2024, involving five groups of 9th-grade students, each with around 25 students, at a school in the metropolitan area of Barcelona where mathematics is taught using a traditional methodology (individual work, board presentations followed by exercises, etc.). Twenty minutes, in the first session, were used to explain the new work dynamics (new student-teacher roles and evaluation criteria for the activity) and to organise the working groups. The SRP was then carried out over seven sessions of 75 minutes each, with five sessions dedicated to the inquiry process and two to preparing a final individual report and taking a test, both of which were evaluative. The standard format for an inquiry session consisted of 10-15 minutes of reviewing the work done so far and discussing the issues to be addressed in the session, 40 minutes of free inquiry teamwork, 15 minutes for presenting the inquiry results and solved questions with a discussion of new questions to be addressed, and, finally, five minutes for writing a session diary. During the sessions, a video on the mould's construction was used along with

recommendations for making moulds and taking measurements. No additional instructions were provided by teachers. The experience was carried out by three teachers non-researchers in their regular mathematics class. Another teacher, the first author of the paper, acted as an observer in one of the classrooms. The *a posteriori* analysis was developed by the observer and two more researchers (all the authors) based on the analysis of students' productions: weekly collected group reports and individual students' diaries collected at the end of the implementation

The generating question was proposed by a pastry company andarrived to the class through an email from the company's CEO. After presenting the generating question, it quickly became agreed that the question to address was "What is the best mould for the company?" The students started working with the initial system, which consists of the cake, its mould, and the origami construction. They attempted to create moulds with different dimensions. During this process, questions about moulds based on the size of the sheet began to emerge. For instance, most students tried to create the mould with a square sheet and discovered that it was not possible as the associated mould did not have flaps. To better understand the relationships between sheets and moulds, they used measurement and geometric models, which coexisted during all the inquiry process (Figure 3).

Figure 3: Examples of the students' work using measurement and geometrical models

At this point, students only considered certain types of moulds (those that met the identified relationships). Then, questions appeared about the sheet properties that lead to the best mould. Several ideas emerged and were developed through the SRP, about the possibility for the company to reduce costs or sell more. Two main lines of inquiry emerged: some groups focused on finding "What mould sells the most?" (searching for dimensions that are more manageable or more appealing to consumers), while others aimed to minimise the mould's cost by using less paper while providing the same volume of cake, that is, "search the sheet dimensions giving a mould of a specific volume". From now on, we will focus on this second line of inquiry.

Throughout this process, students worked with measurement and geometric models, but some students felt the need to generalise the detected relationships using algebraic models. This generalisation seemed to provide a more global understanding of the variables chosen and their relationships, moving from a local level of reasoning about covariation (elements of *one* sheet and *its* mould) to a more general level (variation in the relationships among moulds). In this step towards a more general approach, facilitated by the construction of algebraic models, questions arose about how the height or volume changes as the dimensions of the sheet vary. When students discovered that volume changes even when the sheet's area remains constant, they raised questions including several variables (or variables and parameters): "How does the volume vary for different sheet dimensions that keep the area constant?" and "What is the minimum sheet area required for a specific volume?"

Finally, students conducted a one-by-one case study where they calculated the volume of the moulds constructed from different sheets with the same area but different dimensions. Students did not formally introduce functions or functional models. They tend to continue using the previous ones, comparing the measures or giving different values to the variables of the algebraic expressions. Through this study, students discovered that "the maximum volume is when the sheet's short side and long side are as close as possible" and that "the flaps should be just the right size so the mould can be easily handled." They then propose a reasoned answer to Q_0 of the type: "We concluded the ideal dimensions for us: a sheet of 18 cm x 14 cm. In our opinion, this size will create ideal moulds because the sides are very similar but not identical. This design maximises the volume of the cake while reducing overall costs and ensuring the presence of flaps for mould stability." Finally, students ended up constructing this "best" mould.

A posteriori analysis about recursivity and reversibility

Our investigation aims to highlight the recursivity and reversibility modelling properties and their potential utility in creating questions that help to progress in the modelling process. The recursivity is clearly reflected during the development of the SRP: starting from an initial system S_0 (the cake and the mould construction model that allows answering Q_1), question Q_2 arises regarding the understanding of the relationships between the sheet and the mould to identify the moulds that can be constructed. The measurement and geometric models M_1 and M_2 are used to deduce "one-to-one" relationships between each sheet and its mould. The need to gain a broader understanding of these relationships to obtain general answers through relationships among different moulds and their respective sheets (Q_3 , Q_4 and Q_5) leads to the initial system $S_0 \leftrightarrow M_1 / M_2$ evolving into a new system S_1. The new system calls for a new (algebraic) model M_3 that provides a more general perspective and understanding of the sheet-mould relationship. At this point, the new system S_2 formed by $S_1 \leftrightarrow M_3$ allows addressing questions about volume optimization (Q_6, Q_7 and Q_8), leading to the starting point of a functional model M_4 that helps consider relationships as functions to be optimised. Figure 4 shows the hypothetical development of the inquiry through the consideration of a sequence of models and systems, together with the questions generated.

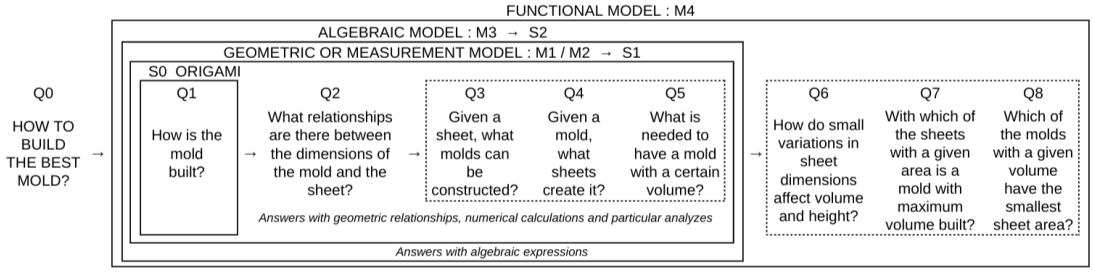


Figure 4: Diagram of the modelling process highlighting its recursivity (authors' production)

The characteristic of reversibility appears consistently in the process of validating the found answers. For example, to provide the final answer, some properties are deduced from the initial system ("the sheet must be close to a square shape to optimise the volume, but not exactly square to ensure the flaps"), but then the length of the flaps and the dimensions of the mould and sheet must be calculated using measurement and algebraic models. Subsequently, the initial system for constructing the mould

is transformed into the model used to build the final mould solution.

$$M_4 \leftrightarrow S_2 \;\rightarrow\; M_1 / M_2 / M_3 \leftrightarrow S_2 \;\rightarrow\; M_3 \leftrightarrow S_3 \;\rightarrow\; M_0 \;(S_0)$$

Functional — *Flaps and proportions* — *Calculations* — *Origami*

On the other hand, we also detect reversibility in the modelling processes as a solving strategy to elaborate answers to the questions that arise. For instance, when addressing the question of how the cake volume changes with small variations in the dimensions of the sheets, which arises when exploring the functional model, students observed that, rather than using a functional model directly, they could reverse the role of system and model to the previously known models (measurement and geometric or algebraic) to propose an empirical answer.

Discussion and conclusion

The analysis presented not only illustrates the characteristics of recursivity and reversibility in action but also highlights them among the fundamental components of the modelling process (questions, systems, models, tools for model validation, etc.). These components need to have a clear and defined status during the development of the SRP to let teachers and students comment on the evolution of the inquiry process. This implies the need to establish a precise terminology to refer to these elements, which are rarely found in the school culture. For example, the *a priori* analysis emphasises the importance of identifying key variables to consider: the sheets' dimensions, the mould, and free or fixed parameters in the sheets or moulds, among others. It also underscores the need to introduce new terms to name and institutionalise the *intermediate models* generated during the modelling process, such as: “origami model,” “geometric and measurement models,” “algebraic model,” or “functional model.” In this regard, this study contributes to anticipating the necessary terminology to be shared and institutionalised with teachers, and then, in their turn, with students in the classroom. Thus, our research tries to intervene in the phenomenon that Wozniak (2012) characterised as the spontaneous “silence” or “mutism” surrounding modelling in the classroom, providing teachers and students with elements to talk about, describe, comment on, explain, and justify modelling processes.

What remains as a future line of research is the in-depth analysis of the relationships between algebraic and functional models, as well as the role of covariation in the models evolution. It is important to note how each model implicitly incorporates the concept of covariation between quantities, a concept that evolves in its treatment depending on what each model enables to do. This might lead to a better understanding of how covariation is interpreted concerning the recursive and reversion process of delimiting and working in and with systems and models.

Students' use of benchmarks in the process of solving Fermi problems

Marlena Meyer[1] and Gilbert Greefrath[1]

[1]University of Münster, Germany; marlena.meyer@uni-muenster.de

In this paper, 9 secondary school students aged eleven to twelve years were observed working individually on two Fermi problems to investigate how students use benchmarks in different activities of solving Fermi problems. Specific focus was dedicated to identifying the sub-activities of processing Fermi problems where benchmarks were used. One of the Fermi problems the students worked on required the estimation of lengths, the other the estimation of weights. The data was analysed using qualitative text analysis. The findings indicate students use benchmarks when working on Fermi problems especially to estimate missing quantities and to validate made estimates.

Keywords: Fermi problems, benchmarks, estimation.

Introduction

In our everyday life, estimation skills are a relevant ability to deal flexibly with quantities (Hoth & Fricke, 2022). For example, during the corona pandemic, it was important for our health to keep a distance of 1.50 m and to estimate this distance (Hoth & Fricke, 2022). To determine missing quantities by estimation, the to-be-estimated object can be compared with another object, about which prior knowledge already exists (use of benchmarks) (Hildreth, 1983). When working on Fermi problems, missing data must be determined by realistic estimates (Ärlebäck, 2009). Thus, benchmarks can be used when working on Fermi problems. In this paper, we present a qualitative study in which the use of benchmarks in students' processing of Fermi problems is examined in more detail. As Fermi problems are suitable for initiating modelling activities in school (e.g. Ärlebäck & Albarracín, 2019), this study focuses on Fermi problems at early secondary school levels.

Theoretical Background

Fermi problems

Fermi problems are named after the physicist Enrico Fermi, who was known for answering seemingly impossible questions with reasonable accuracy (Efthimiou & Llewellyn, 2007). A typical example of such a question is the following: "How many piano tuners are there in the city of Chicago?" (Efthimiou & Llewellyn, 2007, p. 253).

Fermi problems are described as open estimation problems with a real-world connection (Ärlebäck, 2009; Greefrath & Frenken, 2021). They are non-standard problems where it is required to make assumptions and estimate quantities (Ärlebäck, 2009). Furthermore Fermi problems can be characterized as underdetermined, open tasks (Greefrath & Frenken, 2021). Since Fermi problems are characterized by the absence of data and the need to make reasonable estimates, the main focus of Fermi problems is the acquisition of data by estimation (Ärlebäck, 2009; Greefrath & Frenken, 2021). Thus, Fermi problems have a relation to estimation problems (Albarracín & Gorgorió, 2014). At the same time, Fermi problems are described as a special type of mathematical modelling tasks (Greefrath & Frenken, 2021). That's why Fermi problems are mentioned in both the context of estimation and the context of mathematical modelling (Ärlebäck, 2009). Fermi problems are suitable

to introduce mathematical modelling to students (Ärlebäck, 2009; Ärlebäck & Albarracín, 2019; Sriraman & Lesh, 2006). This is also emphasized by the fact that Fermi problems are accessible for all students, they can be solved at different educational levels and can be of different complexity (Ärlebäck, 2009; Ferrando & Albarracín, 2021). Furthermore students do not need pre-mathematical knowledge to work on Fermi problems (Ärlebäck & Bergsten, 2010). At the same time, further research indicates that there are differences in performance on Fermi problems based on prior knowledge (Segura et al., 2024).

Fermi problems can be solved by splitting the problem into smaller sub-problems, so that these problems can be solved by estimating and thus the main problem can be solved (Albarracín & Gorgorió, 2014). For example, the question about the number of piano tuners in Chicago can be broken up into questions about the total number of pianos in Chicago, the average number of piano tunings a tuner can complete in a year, and so forth (Efthimiou & Llewellyn, 2007). According to Greefrath & Frenken (2021) Fermi problems can be described in a more general sense as open tasks that are based on a small amount of information, or even just a picture and a question. This study encompasses such tasks.

Ärlebäck (2009) describes different activities students engage in when working on Fermi problems: *Reading*, *Making model*, *Estimating*, *Calculating*, *Validating*, *Writing*. These activities can be visualised in a graphical representation of the solving process, called *MAD framework* (Ärlebäck, 2009). *Writing* means reading and understanding the task. *Making model* involves simplifying and structuring the task and mathematizing. *Estimating* describes the activity of making quantitative estimates. *Calculating* means doing maths like performing calculations or rewriting equations. *Writing* is the process of summarizing the findings and results and writing up the solution. *Validating* encompasses interpreting, verifying and validating results as well as calculations and the model itself related to the real-life context of the problem (Ärlebäck, 2009; Ärlebäck & Albarracín, 2019). As multiple estimates are needed, there exists no exact answer to Fermi problems (Ärlebäck, 2009; Sowder, 1992). For this particular reason, estimates should be validated (e.g. Segura & Ferrando, 2023). This way, students can be encouraged to critical thinking and discussing variations in estimates (Sriraman & Lesh, 2006). Previous studies have found, among other things, that students validate real results when solving mathematical modelling problems by comparing them to the situation model including real-world experiences or directly to the real model (Czocher, 2018). Other previously research has shown that students validate their results or estimates by using personal extra-mathematical knowledge and experiences from outside schools (Ärlebäck, 2009; Ärlebäck & Bergsten, 2010). Further studies have found, among other things, that pre-service teachers make errors when working on Fermi problems that are related to (missing) estimation skills (Segura & Ferrando, 2021). For example, it has been found that pre-service teachers build incorrect initial models due to inadequate mental representations of benchmarks, or that estimates are made that are incompatible with the real situation (as the mathematical result is not interpreted in the real situation) and this is not validated.

Estimating and benchmarks

Since the estimation of quantities is an essential activity in the process of solving Fermi problems, we will explain the estimation of quantities in more detail. As estimating is defined as the process of determining a measurement without using measuring tools, estimating can be described as a mental process, as contrasted to measuring, which is a physical activity (Bright, 1976). In order to estimate quantities, the object to be estimated can be compared mentally with known objects (Hildreth, 1983). This way, benchmarks can be used as tools. Benchmarks are mental representatives of a certain magnitude that can be used for estimation (Hildreth, 1983; Joram, 2003; Joram et al., 2005). Thus, to determine a measurement, the to-be-estimated object can be compared mentally with an object whose measurement is known by imagining a benchmark (Joram et al., 2005). For example, the height of a person can serve as a benchmark for length and can be used to estimate the size of a room (Joram, 2003).

Research questions

Due to the fact that Fermi problems are characterized by the absence of data and the necessity of estimating quantities, it is conceivable that the use of benchmarks is of great importance in the process of solving Fermi problem. This leads to the following research question of how students use benchmarks for lengths and benchmarks for weights during the process of solving Fermi problems.

In this paper, we focus on the activities engaged in the process of solving Fermi problems to investigate where benchmarks are used in this process. Thus, the following research question arises:

- In which sub-activities of the process of solving Fermi problems do students use benchmarks for lengths and benchmarks for weights?

Method

To answer this research question, we investigated solving processes of nine secondary school students (7 female, 2 male). All in all, we investigated 18 solving processes. The students were between eleven and twelve years old and had good or very good grades in mathematics. Each student worked

Figure 1: Task "thumb"

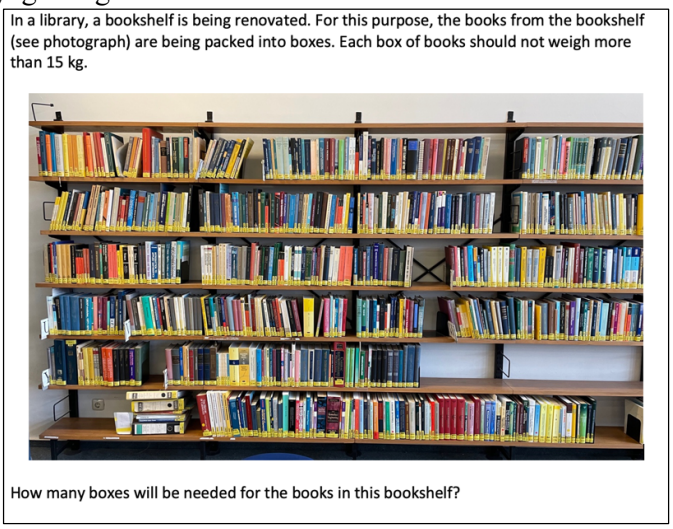

Figure 2: Task "bookshelf"

separately on two Fermi problems outside of regular school lessons. One of the Fermi problems was about estimating lengths (the task "thumb") and the other Fermi problem was about estimating weights (the task "bookshelf"). In both problems it was necessary to work with a given photo. For example, when processing the task "thumb" (Figure 1), the height of the thumb statue, the length of a person's thumb and the height of a person or the person in the photo must be determined. The students were videotaped while working on the Fermi problems. At the beginning the students were instructed to think aloud and practiced this by solving a sudoku before they received the first task. After working on both Fermi problems, the students were interviewed about their solving process. For example, they were asked how they determined their estimates.

The data was analysed with the qualitative text analysis (Kuckartz, 2014). The videos were transcripted and excerpts of the interviews that are relevant for the research question were integrated to the transcripts. The transcripts were subdivided into coding units (each line of the transcript represents one coding unit) and each coding unit was coded with one of the activities students engage in when solving a Fermi problem (Ärlebäck, 2009). In addition, a category was created for the use of benchmarks. This means in addition to the activities, the text passages where benchmarks were used, for example by naming and referring to a benchmark, were also coded. The coding schemes for the activities (in abridged version) is presented in table 1.

Table 1: Coding scheme for the activities when working on Fermi problems (based on Ärlebäck, 2009).

Category	Definition
Reading	Reading and understanding the problem.
Making model	Structuring the task, Simplifying and making assumptions that concern the situation, mathematizing. Also making implicit estimates, for example those that establish a relationship between two quantities.
Estimating	Making estimates of quantitative nature. (Estimates of numerical values.)
Calculating	Doing maths, e.g. performing calculations, also working with the calculator.
Validating	Interpreting, verifying and validating results, calculations, the model itself. Also Re-estimates.
Writing	Summarizing the findings and the results, writing up the solution, entering the result in the answer sentence.
Other	Activities that are not associated with a category but nevertheless relate to the editing process, e.g. statements on the difficulty of the task.

In cases, in which several activities take place at the same time, the activity that is in the main focus has been coded. The data was coded by the first author and a second coder was trained. About 50 % were coded by the second coder and the intercoder reliability for the Fermi activities was $\kappa = .90$, which can be interpreted as almost perfect (Landis & Koch, 1977). No coding units were specified for coding the benchmarks and each coder independently identified in which activities benchmarks

were used. In the case of independently identified coding units, it is more useful to report a percentage agreement rather than Cohen's kappa. The percentage agreement for the benchmarks was 95,65 %.

Findings

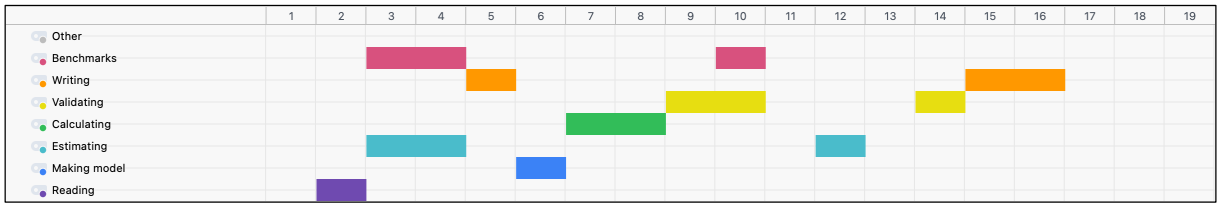

Figure 3: Modelling activity diagram of the process of solving the task "thumb" by Max

To visualize the solving processes of the Fermi problems, we used the modelling activity diagram (MAD framework) based on Ärlebäck (2009). In contrast to Ärlebäck (2009), we decided to represent the activities in the modelling activity diagram using lines from the transcripts. Figure 3 shows an example of a modelling activity diagram. The numbers 1-19 in the header of the diagram represent the line numbers of the transcript. Empty columns are statements made by the interviewer (e.g. at the end asking if the student has finished) or irrelevant statements (e.g. about switching on the calculator). As you can see in figure 3, the student used benchmarks in different activities. On the one hand, he used benchmarks during the activity of *Estimating*, on the other hand he used benchmarks during the activity of *Validating*. In the modelling activity diagrams of other solving processes of other students and the other Fermi problem we can see that many students used benchmarks during the activity of *Estimating*. Overall, benchmarks were used during the activity of *Estimating* in 9 out of the 18 solving processes (6 for the task "thumb", 3 for the shelf "bookshelf"). There is also one solving process where a student used a benchmark during the activity of *Making model* (for the task "thumb"). The student in the aforementioned example is the only individual who used a benchmark during the activity of *Validating*. In other activities than *Making model*, *Estimating* and *Validating*, no use of benchmarks was found in this study. Benchmarks were not used by every student and not in every task, in 8 out of 18 solving processes no benchmarks were used (2 cases in the task "thumb", 6 cases in the task "bookshelf"). In general, benchmarks were used frequently, but more often in the task "thumb" than in the task "bookshelf".

During the activity of Estimating, the students used benchmarks to estimate missing quantities that are needed to solve the problem. An example of using benchmarks for length during the activity of *Estimating* is presented in the following transcript excerpt of the task "thumb":

Sophia: I think the woman is […] a metre 60 […].
Interviewer: How did you find out how tall the woman is?
Sophia: I imagined […] how tall my mum is. Um, and then I compared whether the woman was similar, taller or shorter.

Another example of using benchmarks for weights during the activity of *Estimating* is shown in the following transcript excerpt of the task "bookshelf":

Sophia: 50 grams one book.
Interviewer: How did you find out how heavy a book is?
Sophia: I looked at how much a packet of flour weighs, I think it weighs a kilo, um, and then because I often read books in the evening, I estimated how much a book

weighs, and then I thought um, maybe 50 grams, because all but two or three of the books here aren't that thick.

The activity of *Making model* also includes making implicit estimates that establish a relationship between two quantities. For this, a student also used a benchmark, as the following transcript excerpt of the task "thumb" shows:

Lara: So the thumb has to be bigger than this door here, because the door, that is, it's over 2 metres, because a door like this is 2 metres at most.

A Benchmark were also used for validation to validate made assumptions and estimates. The following transcript excerpt of the task "thumb" is an example of a students' use of benchmarks during the activity of *Validating*:

Max: But if the thumb is 2.50 metres. Then I estimate approximately that the woman is between 1,70 and 1,80 metre (re-estimates the height of the woman). That should be appropriate. There's a door at the back (points at the door in the photo) (…) and doors are normally 2.5 metres tall. Then I would say that the thumb and the door have the same height.

The benchmark that Max used to validate the estimate for the height of the thumb statue is different than the one he used when estimating at the beginning of the problem solving process.

Discussion

The presented study shows that, in general, students made use of benchmarks when working on Fermi problems. Benchmarks were only used in the activities of *Making model*, *Estimating* and *Validating*. Therefore, the discussion focusses on these three activities. They were mainly used during the activity of *Estimating*. Since the estimation of quantities can be described as a mental comparison between the to-be-estimated object and known objects (Hildreth, 1983), it is to be expected that students, if they make use of benchmarks when working on Fermi problems, do so mainly during the activity of *Estimating*. That benchmarks were used for estimation is in line with the results of other studies, in which pre-service teachers used benchmarks for estimation when solving Fermi problems but did not have an adequate mental representation of them (Segura & Ferrando, 2021). As benchmarks can be individual, for example when own body parts serve as benchmarks, (Bright, 1976; Joram, 2003), it can be assumed from the findings of our study that students not only use personal extra-mathematical knowledge and experiences from outside school to make an estimate, as other studies have shown (e.g. Ärlebäck, 2009), but also use benchmarks to make an estimate.

In this study, benchmarks were also used during the activity of *Validating*. Other studies have shown that validating is necessary when working on Fermi problems to prevent the use of unrealistic estimates in the solution (Segura & Ferrando, 2021). As the results of this study indicate, benchmarks might support this process. In our present study, students used benchmarks, which they have not used for estimation in the solving process before, to validate previously made estimates. This may point to an additional aspect of validation processes in terms of students verifying their assumptions and estimates by the use of benchmarks. These findings are in line with prior research (e.g. Ärlebäck & Bergsten, 2010) and extend the description of validation activities in the process of solving mathematical modelling problems in other studies (e.g. Czocher, 2018). To summarize, we can say that students use benchmarks in the activities of *Making model*, *Estimating* and *Validating*. It is

conceivable that benchmarks can support students to make estimates (implicit and estimates of numerical values) and to verify made estimates.

The presented study has some limitations that we would like to address. The use of benchmarks could not be identified in every solving process. However, this does not imply that no benchmarks were used in these processes. It is possible that the students simply did not mention them or were unable to name them, although they were instructed to think aloud and were asked how they estimated quantities. However, it would have been possible to encourage the students to validate their assumptions and estimates more specifically during the interview.

Outlook

Regarding the findings of this study, further research is planned. On the one hand, the benchmarks for lengths and the benchmarks for weights used by the students in this study will be analysed in more detail to classify them. In addition, students' procedures and strategies to estimate quantities when solving Fermi problems will be investigated. To investigate in more detail how students use benchmarks for lengths and benchmarks for weights during the process of solving Fermi problems, we will also examine how realistic the made estimates are. Furthermore, a quantitative study is planned. This study will investigate the knowledge of benchmarks about the quantities length and weight of secondary school students as well as the relation of this benchmark knowledge and the Fermi solving process. Moreover, in this planned quantitative study we will also analyse whether assumptions and estimates are more realistic when benchmarks are used when working on Fermi problems. Additionally, the findings of the study presented in this paper raise the question, whether benchmarks are frequently used in validation. This represents another further future research project.

Didactic transposition constraints on modelling at upper secondary level: Comparing France and Norway

Elsa Puchaczewski[1], Marianna Bosch[2] and Heidi Strømskag[1]

[1]Norwegian University of Science and Technology, Trondheim; elsa.puchaczewski@ntnu.no
[2]University of Barcelona, Spain

This study explores the didactic transposition constraints on teaching mathematical modelling at the upper secondary level in France and Norway, focusing on curriculum and textbook content. Grounded in the anthropological theory of the didactic, the research examines how modelling is conceptualised and implemented in both countries' educational systems. By analysing textbooks, the study identifies variations in how modelling tasks are proposed and how students engage in the modelling process. The French textbook mainly focuses on algebraic tasks, while the Norwegian textbook emphasises computer-based regression analysis. The research also highlights challenges such as the lack of recursive modelling and limited use of parameters, restricting students' opportunities to explore the iterative nature of modelling. The study provides insights into modelling education in both contexts and suggests areas for further development.

Keywords: Didactic transposition, mathematical models, model–system dialectic, praxeology, textbook content.

Introduction

The integration of mathematical modelling in the new upper secondary French curriculum and the reinforcement of modelling as one of six core elements in the new Norwegian curriculum mark a significant shift in mathematics education in these countries. This prompts a new process of didactic transposition (Chevallard, 1991), which refers to how scholarly knowledge is transformed into knowledge to be taught. The resulting transformation involves creating new types of textbook tasks and instructional strategies to incorporate modelling into the teaching repertoire. Generally, in the context of mathematical modelling, didactic transposition faces unique challenges due to the lack of a well-established scholarly consensus and terminology on modelling knowledge (Puchaczewski et al., 2024). Consequently, each country's curriculum develops its own definition and approach to modelling, leading to potential variations in how modelling is taught and understood across different educational systems. The studies briefly summarised below shed light on the situation of mathematical modelling in textbooks at the upper secondary level in some European countries.

Zwaneveld et al. (2017) reveal that the two most frequently used Dutch mathematics textbooks seldom include genuine mathematical modelling. The tasks analysed rarely require students to engage in characteristic modelling activities, such as conceptualising, mathematising, solving, interpreting, verifying, validating, iterating, communicating, and reflecting. Moreover, the majority of modelling tasks in these textbooks lacks appropriate modelling purposes, for instance, explanation, prediction, decision-making, or optimisation. Kröger (2019) examines the alignment of textbook content on modelling with national curriculum goals in Germany and Sweden, finding that textbooks mainly focus on applying and manipulating mathematical formulas within closed systems. This approach fails to meet curricular goals that prioritise applying mathematics to open-ended, real-world

problems. In a similar vein, Berget (2022) uncovers a critical gap in the Norwegian educational system between the theoretical goals set by the national curriculum in force from 2006 to 2020 and the modelling tasks implemented in textbooks and examinations under that curriculum. The tasks analysed tend to emphasise calculation and application of known formulas rather than the creative process of developing and validating models that are new to the students. This situation mirrors the one found in Denmark by Jessen and Kjeldsen (2021).

This study aims to explore and compare the conception and implementation of modelling in the current upper secondary mathematics curricula and textbooks of France and Norway. We examine what aspects of modelling are present or neglected in these educational frameworks and instructional materials. Furthermore, we study what types of modelling tasks and techniques to solve them are proposed in textbooks, along with the explanations and justifications they provide. By analysing curricular guidelines and textbooks, we seek to uncover the prevailing conceptions of modelling and the new responsibilities assigned to teachers and students in both educational systems in the discipline of mathematics. The study of its presence in other school disciplines is beyond the scope of this study. This study provides insights into the didactic transposition constraints on modelling at the upper secondary level in these frameworks, and the comparison between the two countries helps identifying those constraints. The research question we have addressed is:

> What didactic transposition constraints related to modelling at upper secondary level in France and Norway can be inferred from current curricular guidelines and mathematics textbooks?

Theoretical framework: Didactic transposition and mathematical modelling

This study, conducted within the Anthropological Theory of the Didactic (ATD, Chevallard, 2019), draws on the theory of *didactic transposition* (Chevallard & Bosch, 2020), which examines how knowledge is transformed from the scholarly institution where it is created to the educational institution where it is taught and studied (referred to as *external* didactic transposition). Within these systems, knowledge objects—like modelling—are organised around specific types of tasks and techniques (i.e., *praxis* elements), and descriptive discourses and theories (i.e., *logos* elements), collectively termed *praxeologies*. These praxeologies evolve across different institutional systems, where they are generated, reinterpreted, applied, and reshaped. This transformation often fragments and reorganises the original knowledge to adapt to the new institutional conditions and constraints.

The focus of this study is on the *results* of didactic transposition processes in the context of mathematical modelling. We consider two dimensions of modelling. The first is the *epistemological* dimension, which pertains to the dialectic of systems and models and serves as our reference epistemological framework. Grounded in Chevallard's (1989) theorisation, it identifies two primary entities: a system (intramathematical or extramathematical) and a corresponding mathematical model designed to address a question or questions about this system. The modelling process is described in three stages: *defining the system* by identifying its relevant aspects and parameters, *constructing the model* by establishing relationships among these parameters, and *working on the model* to answer the posed questions and generate new insights about the system under study. Two key attributes of mathematical modelling are highlighted (Chevallard, 1989). *Reversibility* involves reversing the relationship between a system and its model, enabling the system to be interpreted as a model of its

own model. *Recursivity* frames modelling as a recursive process, where an existing model can be remodelled at higher levels with more advanced mathematical tools. For example, an initial exponential growth model may develop into a logistic growth model to capture additional dynamics in an ecological system.

The second dimension of modelling is the *ecological*, which relates to how institutional conditions, such as curricular frameworks, teacher preparation and available resources, either enable or constrain the integration of mathematical modelling into educational contexts (Barquero, 2023).

Methods

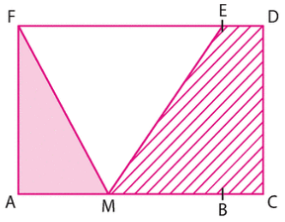
This study employed praxeological analyses, examining the content of mathematical modelling in mathematics textbooks from France and Norway. Curriculum guidelines from the two countries served as a reference, highlighting the importance of mathematical modelling. The selected textbooks are *Maths 2de* (Gringoz et al., 2023) for Year 10 in France, and *Matematikk 1T* (Borge et al., 2020) for Year 11 in Norway. Note that Year 10 in France (*2de*) corresponds to Year 11 in the Norwegian educational system. These textbooks were chosen as representative examples from a broader sample of textbooks due to their frequent use in their respective countries.

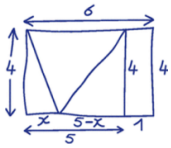
Using the ATD modelling framework, *thematic analyses* were carried out on the textbooks to identify: the types of tasks related to modelling, the systems treated, the construction of models, the work on models, and the presence or absence of recursive modelling. *Maths 2de* was analysed for tasks labelled "Modelling a situation," while *Matematikk 1T* was examined for its dedicated chapter "Modelling."[1] Building on the individual analyses of the textbooks, a comparative analysis of didactic transposition processes in modelling, informed by Puchaczewski et al. (2024), was carried out to examine how each educational system portrays mathematical modelling in textbooks.

Examination of the knowledge to be taught through textbooks

In the French curriculum introduced in 2019, modelling is one of six competencies to be developed, along with researching, representing, reasoning, computing, and communicating (Ministère de l'Éducation nationale et de la Jeunesse, 2019—hereafter MENJ, 2019). Modelling is mentioned in relation to some algebraic notions such as "variables, algebraic expressions, equations or inequations" or "multiple, divisor, even number, odd number, prime number, vectors as a modelling tool for physics, real functions and sequences for continuous and discrete phenomena" (MENJ, 2019, p. 7). Modelling also appears in probabilities, where the curriculum mentions "theoretical models of reference" and construction of models from frequencies, as ways of modelling randomness. To sum up, modelling is not a well-defined category in the French curriculum. It appears as part of the praxeologies to be taught but is partitioned by the type of models to be used—algebra, geometry, analysis, or probability.

Mathematical modelling has been part of the Norwegian upper secondary level curriculum since 1994. In the new curriculum for Years 1–13 (Directorate for Education and Training, 2020—hereafter





[1] Excerpts from the French and Norwegian documents are translated by the authors.

DET, 2020), it remains central as one of six core elements: "Modelling and applications," alongside "Exploration and problem solving," "Reasoning and argumentation," "Representation and communication," "Abstraction and generalisation," and "Mathematical fields of knowledge." The overarching description of modelling," consistent across Years 1–13, emphasises real-world relevance and critical engagement (DET, 2020, pp. 2–3):

> A model in mathematics is a description of reality using mathematical language. The pupils shall gain insight into how mathematical models are used to describe everyday life, working life and society in general. Modelling in mathematics means creating such models. It also means to critically evaluate whether the models are valid and what limitations the models have, evaluate the models in view of the original situations, and evaluate whether they can be used in other situations.

The French case

When analysing *Maths 2de* (Gringoz et al., 2023), we can see that modelling is explicitly mentioned, through the action of modelling, its process, or its product: "Modelling: Describing a concrete situation using mathematical knowledge, for example, writing an equation or a function for studying the given situation" (*Maths 2de*, 2023, p. 380). In this textbook, modelling praxeologies are specifically developed in tasks labelled as "Modelling a situation," which is introduced by a specimen (Figure 1) with indications about the technique (named "reflexes"), a commented solution describing the solving process in multiple steps echoing the reflexes, and a suggested answer closer to what a student should write.

<table>
<tr><td colspan="2">I learn how to model a situation with a placeholder [indéterminée in French]</td></tr>
<tr><td>Reflex 1–Identify the placeholder and its nature</td><td>Reflex 2–Translate the task using the placeholder</td></tr>
<tr><td colspan="2">Problem statement
ACDF is a rectangle such that AC = 6 and AF = 4.
B is on [AC] and E is on [FD] such that CB = 1 and DE = 1.
M is an arbitrary point on the segment [AB].
Morgan wants to find out at what distance from point A he should place M so that the shaded area is greater than or equal to the area of triangle AMF.
What inequality must he set up and solve to answer this problem?

</td></tr>
<tr><td>Commented solution

Step 1: I identify that I need to find the possible values of the distance between A and M.
The placeholder is therefore the distance AM, which I will denote as x. These possible values are the "unknowns." (Reflex 1)
Step 2: I look for the formulas "in terms of x" for the two areas mentioned in the problem statement. (Reflex 2)
Draft: Area (AMF) = Base × Height = $\frac{4 \cdot x}{2}$.
Area (MCDE) = Area (BCDE) + Area (MBE)</td><td>Written answer
I set x = AM.
Thus, the Area (AMF) is calculated as:
Area (AMF) = $\frac{AM \times AF}{2} = \frac{4 \cdot x}{2} = 2x.$
And the Area (MCDE) is calculated as:
Area (MCDE) = Area (BCDE) + Area (MBE) =
$4 \cdot 1 + \frac{(5-x) \cdot 4}{2} = 14 - 2x.$
The inequality that Morgan must set up is therefore: $14 - 2x \geq 2x$</td></tr>
</table>

Figure 1: "Model a situation with a placeholder." Example reproduced from Gringoz et al. (2023)

About the task in Figure 1, we note that, first, the system is mathematical, rooted in physical geometry, where distances are used to formulate an inequality. The parameters are the lengths and

areas of the system and those who do not have a fixed value can easily be expressed in relation to those with fixed value and the target length called "x". The model created, an inequality, comes from a subtraction of two areas expressed this way. Solving this inequality, which is not asked in the task, provides the conditions for the placement of the point M in the geometrical system so that the shaded area is greater than or equal to the area of the triangle AMF: $2x \leq 14 - 2x$ has solution $0 \leq x \leq 3.5$.

Studying the inequality would allow to make inferences about the geometrical configuration, such as how changes in x (moving M along AB) affect the geometrical system. For instance, the boundary case $x = 0$ corresponds to the vanishment of the triangle AMF as M coincides with A. There is no invitation to any recursive modelling, even though the potential exists for considering a functional model or to replace the fixed values of the lengths AC and AF with parameters, to study the variation of the studied areas with the variation of the shape of the rectangle.

The Norwegian case

In *Matematikk 1T* (Borge et al., 2020), modelling is presented as a standalone chapter, divided into three sections. The first section, "Mathematical models," establishes connections between models and formulas, as well as between models and functions, linking them to real-world systems. A dedicated subsection within this section addresses parameters, distinguishing them from variables. Parameters are described as fixed, though potentially unknown values, unless data are used to determine them. The second section, "Regression analysis," outlines the making of a function from data with computer assisted regression analysis, introduced as a "method we can use to build models" by "finding a function that best fits a given dataset." Some comments are made by the authors regarding the choice of the model, either based on its "simplicity" (evaluated from the number of parameters), or its connection to known laws governing the system (which can be given by "experts" of the situation to be modelled). The third section, "Modelling in practice," addresses key considerations for selecting and refining models. It discusses aspects such as balancing simplicity with accuracy when choosing a mathematical function and the treatment of "deviating points" that diverge from the general trend.

One of the worked-out demonstrations in the third section examines the relationship between a car's speed and its braking distance, providing a detailed view of the iterative process of refining models. The authors provide data linking these two quantities (see Table 1).

Table 1: Speed vs braking distance (taken from Borge et al., 2020, p. 289)

Speed (km/h)	10	20	30	40	50
Braking distance (m)	0.5	2.0	4.5	8.0	13

The authors then construct models: they first place points representing the data in a coordinate system and approximate them with a linear function, represented graphically as a straight line. They then choose to fit the data with a second-degree function instead, ensuring a better fit to the datapoints. The authors note, however, that "this model gives a [non-zero] braking distance even when the car is stationary, since $f(0) = 0.3$" (Borge et al., 2020, p. 290), prompting them to refine the model again by using a power function. With this third model, they estimate the braking distance of a car at a speed of 80 km/h. Notably, the authors suggest further refinements by adding new parameters, such as the

road dryness or the type of tyres used. Nevertheless, this recursive modelling initiative is not developed further.

Building on the description in the presented example, we recognise the system as being rooted in a mechanical context, providing a dataset that links speed and braking distance for specific values. However, the absence of physical laws in the modelling process, such as those related to friction, represents a significant limitation, as it prevents generating fundamental insights into the system itself. Instead, the regression models are restricted to predicting braking distances within the range of the given data. Moreover, other parameters, such as road surface conditions, are not mentioned, further limiting the dataset's ability to capture more complex conditions inherent in the system.

Some reversibility is present, as the physical system guides model adjustments for boundary cases. Recursivity is also evident when provisional models, influenced by the physical system (e.g., data point positions on graphs), are iteratively refined to create more accurate models.

Discussion and conclusion

When comparing the textbooks of France and Norway, some specificities and commonalities become visible. These observations will be discussed in relation to our reference epistemological model. In both cases, the *modelling process* appears in the textbooks as a special kind of mathematical activity limited to some specific cases or types of tasks. Similarly, *the system to be modelled* is almost always given as a delimited entity, with its elements (quantities or dimensions) either pre-identified, or straightforward to determine. The system is rarely modified or enlarged to evaluate the scope of the model or to enhance its applicability. The *types of models* proposed to be built are also limited. In the French textbook, models consist of algebraic expressions treated as equations, inequalities, or functions. Only one model is typically considered in each case, with little discussion on its relevance to the system and other possible alternatives. By contrast, in the Norwegian textbook, models are predominantly functions derived through regression analysis. In these cases, the textbook encourages the consideration of multiple possible models and selecting the one that either best fits the data or most closely reflects the underlying system. Moreover, some tasks rely on other methods than regression: for instance, solving equations algebraically in the case of determining the equation of a curve passing through given points, or approximating the volume of an object using geometric formulas for composite shapes. The *work on the model* is limited: in the French case, it is largely taken for granted and not discussed, while in the Norwegian case, the model is primarily used to compute function values at specific points. Concerning *reversibility* and *recursivity*, these processes are absent in the French textbook, while the Norwegian textbook implicitly fosters recursivity through tasks that involve refining models, frequently by incorporating a new parameter, as seen in tasks on cooling processes and pulse development following physical exertion.

Our results connect with two established didactic phenomena concerning the ecology of modelling at the secondary school level, along with a curricular constraint identified in this study. The first phenomenon, examined by Strømskag and Chevallard (2022), is the lack of utilising parameters in modelling with algebraic expressions. Parameters, when present, are often assigned numerical values prematurely, which reduces opportunities for symbolic manipulation. This practice obstructs key iterative processes such as model revision (recursivity) and the transformation of systems through

model manipulation (reversibility). In addition to this, the removal of differential equations from the Norwegian upper secondary curriculum in 2020 introduces a significant didactic transposition constraint. Differential equations are crucial for describing and understanding intrinsic laws in dynamic systems, making their exclusion a substantial limitation on modelling practices. This omission likely explains the lack of models based on fundamental principles and the prevalence of modelling processes based on regression analysis. While effective for data fitting, regression does little to foster comprehensive insights into the systems being modelled. It is worth noting the apparent contradiction in introducing modelling as a core element of the curriculum while simultaneously omitting differential equations, a fundamental tool for mathematical modelling.

Finally, the second didactic phenomenon concerns the absence of an explicit and elaborated *logos* of modelling praxeologies (Barquero et al., 2024). In the cases studied, modelling is largely limited to *praxis*: in the French context, two "reflexes" dominate, closely tied to algebraic modelling, while in the Norwegian context, the justification of model choices remains highly specific to individual modelling tasks, lacking generalisation or connection to a broader framework. This limitation poses challenges for teachers and students, as they lack the necessary vocabulary and conceptual tools to articulate, manage, and further develop modelling processes.

We conclude with two observations. First, we note the slowness of the didactic transposition process and the difficulty of modifying the traditional mathematical organisations in secondary school, strongly rooted in the paradigm of visiting works (Chevallard, 2019). In this context, the earlier introduction of modelling in Norway (1994) compared to France (2009) helps explain the more developed presence of modelling in the Norwegian textbook. Second, fully integrating modelling into the knowledge to be taught requires more than introducing new types of tasks. It requires a profound transformation of the mathematical organisations to be taught and a reimagining of the role of mathematics in addressing both extramathematical and intramathematical open questions.

Modelling in the learning of the definite integral for civil engineering

Mariela Elizabeth Ramírez-Inca[1] and Hugo Rogelio Mejía-Velasco[1]

[1]Centre for Research and Advanced Studies (Cinvestav), Mexico; mariela.ramirez@cinvestav.mx

In this paper, we show one part of a much broader research focused on designing a modelling sequence to promote the understanding of the definite integral (DI) from the perspective of models and modelling (MMP) through activities that involve accumulation processes. We present part of the design and how it is intended to be implemented with a group of civil engineering students taking the Integral Calculus course. The sequence's design aims to address issues related to the learning of the DI, its interpretation, and its use in specialised courses, particularly in solving problems closely related to the workplace. Furthermore, we review some of the design principles proposed within the MMP and share our reflections on how they might be adapted and used as a guide for designing activities aimed at specific groups of higher education or university students.

Keywords: Definite integral, modelling, civil engineering, teaching and learning.

Why is the definite integral difficult for engineering students to interpret?

We agree with Bressoud et al. (2016) that the teaching and learning process of calculus often focuses on procedural, with an emphasis on the calculation of antiderivatives, while ignoring the meaning of the DI as an accumulation process. Moreover, the teaching is focused on strictly formal aspects, but do students really understand through formal approaches? And is it enough for them to identify the DI in different contexts beyond the calculation of the area under a curve? Empirical studies (Orton, 1983; Kouropatov & Dreyfus, 2014; Serhan, 2015) reveal that although students master integration techniques and algorithmic calculations, they struggle to solve problems in non-mathematical contexts that require the use of the DI. Furthermore, presenting the DI solely as the area may limit students' understanding associated to this concept. To address this, Attorps et al. (2013) and Greefrath et al. (2021) suggest exploring the DI in various contexts that involve accumulation processes.

González-Martin and Hernandes (2018) observed a discrepancy between the mathematics curriculum and the specialisation courses' curriculum. For example, when we examine the integral calculus courses for civil engineers, one of the applications of the DI is the calculation of the centroid of a plane region. But why and for what purpose does a civil engineer need to know how to calculate the centroid of a plane region or a body? By reviewing a Strength of Materials course, we found that calculating the centroid is essential in the design and construction of beams, as it is necessary to obtain the shear force and bending moment diagrams of a beam.

González-Martin (2021) proposes a didactic transposition for of bridging the gap between calculus courses and the specialisation subjects for engineering students. Even though we do not use the concept of didactic transposition, in our proposal we select a specific type of beams of the bridges to contextualise the situation from a MMP (Lesh & Doerr, 2003). Specifically, through the principles of activity design we address the research question: How can we design a modelling sequence that enables civil engineering students to develop an understanding sufficient to recognise, interpret, and apply the concept of the definite integral in various contexts?

The MMP in the teaching and learning process

If the objective is related to the teaching and learning of a particular concept, with a focus from a contextual perspective, where models are understood as systems of elements, relationships, operations, and rules that are useful for describing, explaining, or predicting the behaviour of other systems, and modelling as a set of activities that involve students in the development, understanding, modification, and intentional use of one or more models to interpret a particular context, then, the MMP provides a coherent and systematic framework, allows to reflect on numerous aspects that can support teaching and learning processes through the use of contexts in modelling activities (Ärlebäck et al., 2013; Ärlebäck 2017) and it is characterised by the design of a sequence of models and modelling activities, beginning with Model Eliciting Activities (MEAs), followed by one or more Model Exploration Activities (MXAs) and/or Model Adaptation Activities (MAAs) (Lesh & Doerr, 2003). MEAs are activities characterised by a problematic situation that prompts students to manipulate, predict, construct, describe, and explain a model based on their prior knowledge of a situation. These activities should encourage an iterative process in which students express and represent their initial ideas and thinking about the explicit and implicit characteristics of a problem (Ärlebäck & Doerr, 2017; Türker-Biber et al., 2022). However, since one MEA is not sufficient to achieve the expected learning objectives and students require multiple opportunities to explore and use their mathematical constructions in different contexts, it is suggested to follow the MEAs with the implementation of one or more MXAs, followed by one or more MAAs (Doerr, 2016). MXAs consist of sub-activities that involve different representations using different digital tools, animations, and powerful notation systems, allowing students to manipulate, test, explore, and modify the models that emerged from the MEA. MAAs, on the other hand, are characterised by being designed in such a way that they allow students to extend and apply the models that emerged from the MEAs and were refined in the MXAs to other contexts with similar structures to the initial. It is important to note that MEAs and MAAs differ from the routine mathematical problems commonly found in textbooks and should be designed according to the six principles of the design (Lesh et al., 2003).

Design principles of the MEAs and MAAs

According to Lesh et al. (2000), the main criterion for evaluating and validating the effectiveness of modelling activities is that when students engage with these activities, they reveal significant conceptual models from a mathematical standpoint and powerful ones from a practical perspective. To assess the fulfilment of this criterion, it is suggested that designers of modelling activities ask themselves a series of questions framed in the design principles. However, since the MMP began with a focus on primary level mathematical education, and our activities are designed for higher education, we add questions to the questions suggested by Lesh et al. (2000) for each principle. In the following paragraph, we detail each principle and the reflective questions we suggest.

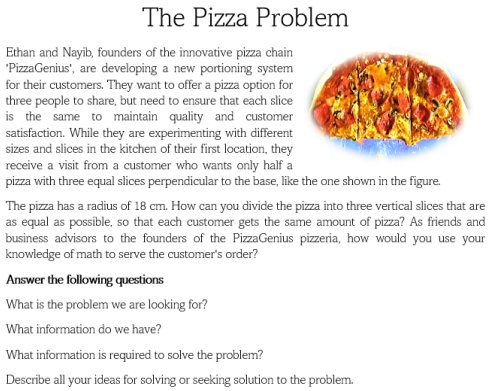
Model Construction Principle: To check compliance of this principle, the MMP suggests questioning whether the proposed activity for students promotes the need to develop a model to interpret data, objectives, and explore possible solution processes. We consider that it is pertinent to ask: Among the possible solution processes, is there the emergence of models related to, close to, or necessary for studying a particular concept? Is it possible to identify the type of system the students are being

challenged to construct? And can the system focus on a significant mathematical construct? *Reality Principle:* We recognize that one person's reality may not be the same as another's. However, when focusing on a specific university course, we revisit the idea of proposing problems that align with the group's interests and experiences (Lesh et al., 2000). Therefore, we asked the following questions: Could this really happen in a situation close to real life? Is the context of the situation close to the reality of the university student? Is the context or situation relevant to the students' professional career as an engineer? Does the proposed problem or situation allow students to explore different perspectives and solutions that encourage debate and discussion? And does the situation provide opportunities for students to reflect on their own experiences and knowledge and how they relate to the proposed situation? *Self-Evaluation Principle:* It is proposed that designers question whether the activity provides students with the opportunity to assess the validity of the possible model alternatives that emerge, whether these models require refinement in different modelling cycles, and whether the context of the problem allows students to identify whether the proposed problem has been resolved or not. We also suggest reflecting on the question: Does the assessment process enable students to recognise the need to delve deeper into one or more mathematical models to evaluate the effectiveness of the solutions found? (It is likely that this principle can be fully verified once work with the MXAs is underway.) *Documentation Principle:* Designers are advised to consider whether the activity prompts students to explicitly reveal their thinking about the situation, including data, goals, and possible solution paths. It is particularly important that the process provides an "audit trail" that allows examination of the types of systems and patterns the students are considering. We consider that it is pertinent to ask: Is the problem situation clear and sufficient for students to describe types of conceptual systems related to the mathematical object in focus? And does the problem context stimulate and encourage students to externalise their thinking, whether through qualitative, quantitative, and/or symbolic descriptions or graphical representations? We believe that when the focus is on learning, documenting arguments and reflections is important so that during discussions, ideas can be externalised, modified, and refined concerning the concept being understood. It is also likely that this principle can be fully verified only after working with the MXAs. *Reusability/Generalisability Principle*: The idea here is to reflect about the next question, is the model reusable, modifiable, and/or transferable to other situations? We consider it necessary to verify that the proposed situation directs and encourages the student to explicitly deepen the mathematical models that conceptualise and reinterpret a concept in other situations. *Effective and/or Simple Simplicity Principle:* To validate this principle, it is suggested to consider how the model was developed rather than the model itself. That is, whether the ideas from the process leading to the generalisation of the model are applicable in other contexts.

Method and proposal design

Evidence from pilot studies showed that a single MEA is not sufficient to refine students' ways of thinking (citation from articles in press). These findings led us to design MXAs and the MAA. The pilot studies also helped identify modelling cycles and determine the need for a generalisation process, as well as the level of intervention required by the researcher or teacher during the development of the MXAs.

Our proposal is designed for civil engineering students taking the course on integral calculus. Specifically, we seek to address two key issues: the difficulties students face when solving extra-mathematical problems involving DI and the disconnect between integral calculus content and specialised subjects. To tackle this issue, we designed a modelling sequence consisting of two MEAs (MEA1 and MEA2), two MXAs (MXA1 and MXA2), and one MAA. The sequence begins with MEA1, which aims to elicit student ideas on approximation, accumulation, and area through a problem that involves an unconventional way of cutting half a pizza into three equal parts. Next, MXA1 involves the use of a GeoGebra applet to facilitate the graphical and dynamic representation of area approximation via Riemann sums. The aim of MXA1 is for students to explore and refine their initial ideas, while also appreciating and applying conceptual tools related to Riemann sums and limits, which lead them to view the DI not merely as the area under a curve but as accumulation.



Following MXA1, we propose MEA2, which shifts the problem context to one closely related to the workplace of civil engineering, involving the design and construction of beams. The objective of MEA2 is for students to see the DI as the centre of mass of a load, while the aim of MXA2 is for them to use additional conceptual and digital tools to refine and expand the models that emerged in MEA2, viewing the DI as the accumulation of load that a beam can support and as a moment with respect to an axis. Finally, the aim of MAA is for students to apply this new way of thinking about the DI as a useful tool for calculating shear force and bending moment in beams with trapezoidal loads (accumulation of forces and moments).

In the following, we briefly describe and explain the design of each activity, which was developed and adjusted based on previous pilot studies (Ramírez-Inca & Mejía, in press) that verified the adherence to the aforementioned principles.

MEA 1 and MXA1: Pizza problem

With MEA1 we introduce the pizza problem (Figure 1), which is not related to their future workplace but is connected to their everyday life (*reality principle*). In Mexico City, a pizzeria offers pizzas with innovative shapes and sizes. We chose this context to motivate students to develop ideas and notions related to area approximation (*model construction principle*). When we pose the question, “How can you divide the pizza into three vertical slices that are as equal as possible, so that each customer gets the same amount of pizza?”, we aim for students to reflect on what is accumulating and what is varying, depending on the number of equal pizza slices. Since the restriction is to make perpendicular slices with equal areas, self-assessment *(self-evaluation principle*) can be performed by verifying that the areas are equal.

In Figure 1, it is observed that the activity includes a set of questions aimed at helping students describe and explain their ideas and conceptual systems directed at solving the problem, following the *documentation principle*. We believe that these questions, along with MXA1, guide students to delve into the mathematical models that emerge and reuse them for another similarly structured situation, adhering to the *generalisation principle*. Regarding the *simplicity principle*, although the problem situation requires considerable reflection and data interpretation, we consider that the problem is straightforward and involves integral calculus elements that students are expected to have already studied.

The Pizza Problem

Ethan and Nayib, founders of the innovative pizza chain 'PizzaGenius', are developing a new portioning system for their customers. They want to offer a pizza option for three people to share, but need to ensure that each slice is the same to maintain quality and customer satisfaction. While they are experimenting with different sizes and slices in the kitchen of their first location, they receive a visit from a customer who wants only half a pizza with three equal slices perpendicular to the base, like the one shown in the figure.

The pizza has a radius of 18 cm. How can you divide the pizza into three vertical slices that are as equal as possible, so that each customer gets the same amount of pizza? As friends and business advisors to the founders of the PizzaGenius pizzeria, how would you use your knowledge of math to serve the customer's order?

Answer the following questions

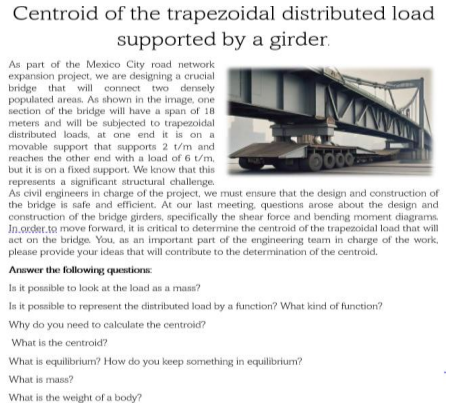
What is the problem we are looking for?

What information do we have?

What information is required to solve the problem?

Describe all your ideas for solving or seeking solution to the problem.

Figure 1: MEA 1. The Pizza problem



MXA1 involves questioning the models proposed by the students and building upon those ideas that facilitate an "optimal" solution to the problem. Specifically, a GeoGebra applet that allows the translation of problem information into a dynamic geometric representation of area accumulation through Riemann sums. In this dynamic environment, students can manipulate problem parameters while exploring, testing, and refining their conjectures. Additionally, students are asked to organise the new information into a tabular representation, which, through team and plenary discussions, will involve new mathematical knowledge to answer the question: How can they divide half of the pizza into three proposed portions as equally as possible to ensure each customer receives the same amount of pizza?

MEA 2 and MXA2: Centroid of the trapezoid-shaped distributed load supported by a beam

MEA 2 was designed based on a context close to the workplace of a civil engineer, following the *principle of reality*. Gere and Barry (2013) and Hibbeler (2011) explain that the resultant force on a body is equivalent to the area under a curve of the distributed load and acts through the centroid of that area, highlighting the importance of integration in solving engineering problems. As reported by González-Martín et al. (2021), although they recognise the use and significance of integration, in their practical examples they consider it an alternative solution and detail the primary solution as processes involving free-body diagrams and equilibrium equations. Detailed analysis of specific cases, such as the use and significance of integration in the design and construction of beams, shows that its application is straightforward and can achieve the same reasoning, provided the concept of integration is understood.

For the design and construction of bridges, which include the design and construction of beams, shear force and moment diagrams are used. One way to obtain these is through the graphical method, using equilibrium conditions to find the equations and values for shear force and bending moment. Depending on the type of load the beam supports, the first step is to simplify the loads by finding the total area and treating it as a single load applied at the centroid of that area. In this sense, MEA 2 (Figure 2) aims to facilitate the emergence and documentation of concepts related to physical principles and their application for determining the centroid (*principles of model construction and documentation*). Given that the situation involves concepts from other sciences, it is clear that the emerging models will require various cycles of modelling (*principle of self-evaluation*) and challenge

students to deepen and reinterpret a particular mathematical concept in different situations and reuse the idea with which the model is intended to be developed (*principles of generalisation and simple prototype*). This is likely to be fully achieved through an exploratory activity. Therefore, MXA 2 provides students with a set of conceptual and digital tools (Phet simulator) along with a guide of questions aimed at promoting reflection on what is being accumulated (areas, forces, moments).

Centroid of the trapezoidal distributed load supported by a girder.

As part of the Mexico City road network expansion project, we are designing a crucial bridge that will connect two densely populated areas. As shown in the image, one section of the bridge will have a span of 18 meters and will be subjected to trapezoidal distributed loads, at one end it is on a movable support that supports 2 t/m and reaches the other end with a load of 6 t/m, but it is on a fixed support. We know that this represents a significant structural challenge.

As civil engineers in charge of the project, we must ensure that the design and construction of the bridge is safe and efficient. At our last meeting, questions arose about the design and construction of the bridge girders, specifically the shear force and bending moment diagrams. In order to move forward, it is critical to determine the centroid of the trapezoidal load that will act on the bridge. You, as an important part of the engineering team in charge of the work, please provide your ideas that will contribute to the determination of the centroid.

Answer the following questions:

Is it possible to look at the load as a mass?

Is it possible to represent the distributed load by a function? What kind of function?

Why do you need to calculate the centroid?

What is the centroid?

What is equilibrium? How do you keep something in equilibrium?

What is mass?

What is the weight of a body?

Figure 2: MEA 2. The centroid of the trapezoidal distributed load

MAA: shear stress and bending moment of a beam carrying a distributed load

Following MXA 2, we propose MAA (Figure 3). Although its context appears similar to that of MEA2, it presents a different issue, adhering to the *reality principle*. This activity requires students to use and refine the models and ideas developed in previous activities. The proposed questions guide students to reflect on and describe their ideas about using integration (*construction and documentation principles*) to create shear force and bending moment diagrams for a beam, ensuring coherence in their graphs (*self-evaluation principle*). In this case, the accumulation involves shear force and bending moment (*generalisation principle*). Furthermore, this reflection can be extended to other structures or engineering problems involving physical concepts and treated as accumulation processes (*principle of simple prototype*).

Shear stress and bending moment in a beam having distributed loads with trapezoidal shape.

As part of the Mexico City road expansion project, we are designing a crucial bridge that will connect two densely populated areas. As shown in the image, one section of the bridge will have a span of 18 meters and will be subjected to trapezoidal distributed loads, at one end it is on a movable support that supports 2 t/m and reaches to the other end with a load of 6 t/m, but it is on a fixed support. We know that this represents a significant structural challenge. As civil engineers in charge of the project, we must ensure that the design and construction of the bridge is safe and efficient. At our last meeting, questions were raised about the design and construction of the bridge girders, specifically the shear force and bending moment diagrams. They already analyzed the moment, point load and trapezoidal load centroid. Now, what is required is that you, as part of the design-build engineering team, determine the shear and bending moment equations that need to be known to construct the respective diagrams.

We are approaching the delivery date of the work and you, as part of the design engineering team, should present your ideas and solutions to the problem.

Figure 3: MAA. Shear stress and bending moment in a beam

Considerations

Based on the analysis of the pilot results and an interview with one of the authors of this theoretical approach, (R. Lesh, personal communication, 12th March 2024), it was considered necessary to

modify and define a warm-up activity that encourages students to reflect on and discuss ideas involving concepts of approximation, variation, and accumulation. Most importantly, it should promote students' ability to engage in modelling activities.

We believe that implementing this sequence in introductory civil engineering courses will foster a better understanding of DI. Through accumulation processes, the aim is to reconstruct and identify the concept of the centroid and recognise distributed loads as a single point load. As Greefrath et al. (2021) point out, this helps to identify that many engineering concepts, like physical concepts, can be understood and reconstructed through accumulation processes.

It should be noted that we are still working on identifying the levels of understanding of the definite integral (ID) that can be achieved through the implementation of the modelling sequence by civil engineering students, and these will be refined in upcoming implementations of the sequence.

In-service teachers' scaffolding practices based on diagnosing modelling challenges during instruction

Liron Schwartz-Aviad[1], and Zehavit Kohen[2]

[1]Technion, Israel Institute of Technology, Israel; sliron@campus.technion.ac.il

[2]Technion, Israel Institute of Technology, Israel; zehavitk@technion.ac.il

This study focuses on the theoretical relationship between teachers' diagnostic and instructional competencies essential for effective modelling instruction. We explored teachers' scaffolding practices as a key component of their instructional competence, aimed at supporting students, based on their diagnostic competence in identifying modelling challenges. Data from nine observed modelling lessons conducted by teachers during real-time modelling instruction were analyzed. The findings reveal five well-defined themes of scaffolding practices teachers employ to support students in overcoming identified modelling challenges across various modelling phases, while promoting independent student learning. These valuable insights empower the linkage between teachers' diagnostic and instructional competencies and suggest practical recommendations to enhance their practices in modelling instruction.

Keywords: Scaffolding practices, Mathematical modelling instruction, Instructional competence, Diagnostic competence.

Introduction

The significance of mathematical modelling (MM) in mathematics education has seen a consistent rise in recent decades (Kaiser, 2020). The MM process implicates translations between the real-world and mathematics (Blum, 2015; Borromeo Ferri, 2018; Kaiser, 2020) and consists of several phases that form a modelling cycle. This process is cognitively demanding, requiring both mathematical and extra mathematical knowledge not commonly used in regular math lessons, thus presenting cognitive challenges in each step of the process (Wess et al., 2021; Galbraith & Stillman, 2006). Teachers play a crucial role in guiding their students through this complex process (Borromeo Ferri, 2018), which necessitates possessing the essential competencies required for effective modelling instruction (Borromeo Ferri & Blum, 2010).

This study focuses on two key competencies, examining their demonstration in the practical work of modelling instruction in class. The first is the *diagnostic* competence which involves identifying students' challenges in each phase of the modelling cycle, and the second is the *instructional* competence which entails employing appropriate practices to engage students in the MM process, often relying on accurate diagnoses (Borromeo Ferri, 2018; Stender & Kaiser, 2015). Despite their interdependence, scant research exists on teachers' instructional competence that directly stems from diagnostic competence. So far, studies have mainly examined either teachers' diagnostic and instructional competencies as separate entities (e.g., Siller et al., 2023), or the development of pre-service teachers' diagnostic and instructional competencies during teacher training (Wess et al., 2021). Limited exploration exists on in-service teachers' instructional competence, grounded in their diagnostic competence during real-time modelling instruction, particularly across the distinct

challenges of each modelling phase. Scaffolding has become a prominent approach in investigating teachers' instructional practices in educational research over recent decades (Van de Pol et al., 2010), especially in MM research (Schukajlow et al., 2015; Stender & Kaiser, 2015). It comprises providing temporary support to help learners solve tasks independently, aiming to minimize teacher intervention when knowledge or skills are lacking. The current study adopts this approach to investigate teachers' application of scaffolding practices, as part of their instructional competence, resulting from diagnosing modelling challenges during real-time modelling instruction. Building upon previous research that explored the various modelling challenges teachers identify within each phase (Schwartz-Aviad & Kohen, 2023), this study delves into the scaffolding practices teachers use to support students in overcoming these challenges, considering each distinct phase of the MM process.

Theoretical background

The diagnostic and instructional competencies of teachers during modelling instruction

MM is commonly depicted as a cyclical process involving back-and-forth transitions between real-world and mathematical domains (Blum, 2015; Borromeo Ferri, 2018; Kaiser, 2020). Kaiser and Stender's modelling cycle (2013) outlines five major consecutive phases: 1) *Understand simplify*; 2) *Mathematise*; 3) *Mathematical work*; 4) *Interpret*; and 5) *Validate.* To effectively engage students through the MM process and its phases, teachers should possess appropriate competencies, which were identified by Borromeo Ferri and Blum (2010) as: (1) *Theoretical* competence which encompasses knowledge of modelling cycles, aims, and perspectives, (2) *Task-related* competence that includes solving and cognitive analyzing MM tasks, (3) *Diagnostic* competence that addresses the recognition of students' difficulties and mistakes within each modelling phase, and (4) *Instructional* competence which refers to planning and executing modelling lessons, by using appropriate interventions. We address Diagnostic and Instructional (DI) competencies as a unified entity, given their theoretical interconnection (Borromeo Ferri, 2018), encompassing teachers' ability to identify challenges in the MM process within each phase and employ appropriate scaffolding practices to support students in overcoming those challenges. A previous study (Schwartz-Aviad & Kohen ,2023) explored teachers' diagnostic competence, by utilizing Wess and colleagues' framework (2021) for difficulties in the MM process to detect teachers' identification of challenges within each modelling phase. This framework outlines potential challenges in each modelling phase based on studies that have explored students' struggles and challenges in the MM process (e.g., Galbraith & Stillman, 2006). Building on that framework, this study aims to link the challenges teachers detect within each modelling phase with the scaffolding practices they employ to support students in overcoming these challenges.

Scaffolding as theoretical basis for teachers' instructional competence

Scaffolding refers to providing temporary support to help learners solve tasks independently, while minimizing teacher intervention, referring to three main characteristics: 1) *contingency*, which involves the adaptative support to the student's current learning status; 2) *fading*, which includes the gradual decrease of support; and 3) *transfer of responsibility*, which encompasses shifting learning responsibility to the student (Van de Pol et al., 2010). During modelling instruction, teachers should provide adaptive interventions tailored to each student's learning needs to foster independent

engagement in MM. These interventions, while not all explicitly stated, encompass all scaffolding characteristics and are seen as a realization of the scaffolding concept (Stender & Kaiser, 2015). While studies have explored teachers' scaffolding in MM (Schukajlow et al., 2015), including pre-service teachers' activities to promote students' independent learning (Stender & Kaiser, 2015) and MM-oriented practices (Siller et al., 2023), a research gap exists regarding scaffolding practices derived from teachers' diagnostic competence in identifying modelling challenges. This study addresses this gap by examining teachers' scaffolding practices that promote independent student learning during modelling instruction, focusing on challenges specific to each modelling phase.

Research goal and question

Our main goal is to examine the demonstration of in-service teachers' DI competencies, namely their instructional competence, that is based on their diagnostic competence in identifying students' modelling challenges, within the setting of real-time modelling instruction. Specifically, we pertain to answer the following question: What scaffolding practices do teachers use for different modelling phases to assist students in overcoming modelling challenges?

Methods

This study was part of a Professional Development (PD) initiative designed to equip lower-secondary school mathematics teachers with competencies needed for effective modelling instruction. The program spanned 30 academic hours throughout one academic year, emphasizing the essential professional competencies for modelling instruction (Borromeo Ferri & Blum, 2010). It combined theoretical learning through six synchronous online meetings with practical classroom implementations of MM tasks in three asynchronous meetings (Fig. 1).

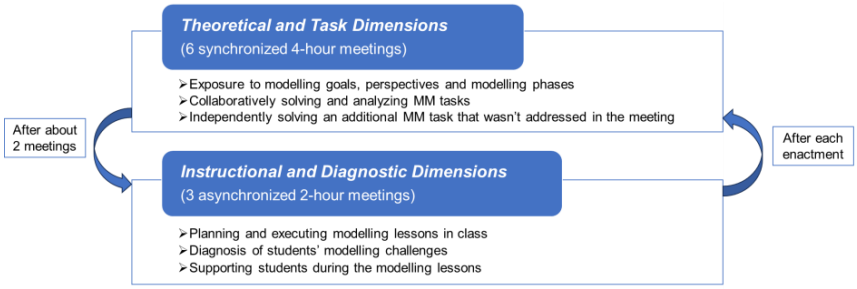

Figure 1: The PD program structure

Throughout the PD program, the teachers were exposed to six MM tasks and were asked to select at least one to implement in their classrooms, according to their preferences. Notably, teachers were not briefed on our conceptualization of the DI competencies. These tasks, rooted in scientific-engineering contexts drawn from authentic tech-related applications (Kohen & Orenstein, 2021), challenge students by requiring extensive scientific-engineering knowledge not typically included in mathematics lessons (Kaiser & Stender, 2013). Thus, students in this study were not required to fully validate their mathematical results, such as improving the model. Further, the execution of MM tasks in formal lessons in this study featured a blend of plenary sessions for real-world context elaboration and model development, group work or teacher-led guidance for mathematical procedures, and plenary sessions for result interpretation.

The study enlisted five Israeli mathematics teachers from lower-secondary schools (8th and 9th grades) who took part in the PD program. Participants comprised four women named Emma, Lea, Lucy, and Rachel and one-man John (pseudo), selected for their readiness to be observed while conducting MM tasks in class. The teachers had no prior knowledge of MM. Research tools included nine observations on teachers' enactments of MM tasks in their respective classes (Table 1).

Table 1: Summary of the MM tasks that were implemented by the teachers

Teachers	MM tasks implemented in class[1]
Emma	YouTube
Lea	YouTube
	Autonomous car
	A Signal from Satellite
John	YouTube
	Google website browser
Lucy	Mobileye (two lessons)
Rachel	Image Resolution

[1] The full tasks can be found at https://mted.technion.ac.il/i-mat-tasks-english/

To thoroughly analyse the challenges that teachers identify within each modelling phase and their corresponding scaffolding practices, we recorded and transcribed each lesson. The first author, an expert in MM, conducted the observations during 90-minute math lessons, focusing closely on teacher-student interactions from a whole class instruction perspective. Building upon our previous study examining teachers' diagnostic competence in identifying modelling challenges (Schwartz-Aviad & Kohen, 2023), this study focuses on their instructional competence that explicitly relies on their diagnostic competence. Using qualitative content analysis (Hsieh & Shannon, 2005), we identified key themes of practices teachers used to address challenges in modelling instruction, focusing on those that promote independent student learning.

Findings

We detected five themes of scaffolding practices, each addressing a specific challenge within a particular modelling phase outlined by Kaiser and Stender (2013) (Fig. 2).

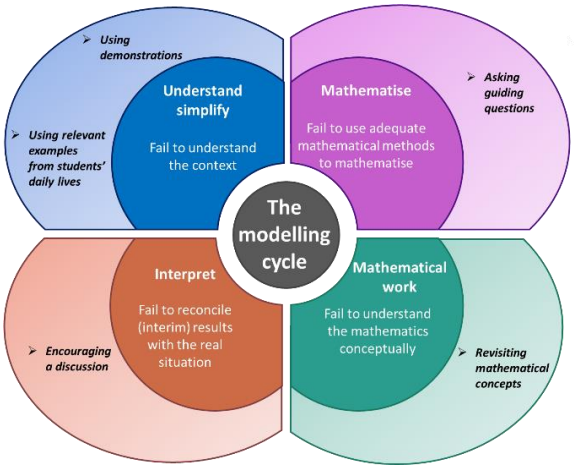

Figure 2: The themes of scaffolding practices, with relation to the modelling challenges within the various modelling phases

In the figure, the inner cycle demonstrates a modelling challenge within each modelling phase that was found to be addressed by a specific scaffolding practice, while the outer cycle depicts the corresponding scaffolding practices identified. In the following, we describe the identified themes according to the different modelling phases.

1. Using demonstrations to base understanding of the real-world context

This theme implicates teachers using various demonstrations to support students establish understanding of real-world concepts to address the challenge of *fail to understand the real-world context*. For instance, the YouTube task addresses video streaming issues, focusing on two indicators while watching a video: the viewing bar (data viewed) and the loading bar (data downloaded). After explaining these terms, Emma noticed students struggling to understand that the viewing bar moves faster than the loading bar, as one student asked, "I do not understand which bar moves faster?". To address this challenge, she used a demonstration with two volunteer students. Emma asked them to stand in front of the class and represent the viewing and loading bars to help students visualize the difference in their movement speeds and the point where they meet. She purposefully chose Eli and Amir, to represent the red viewing bar and grey loading bar, respectively, because they were wearing red and grey shirts. She explained: “Eli represents the red viewing bar, and Amir will be the loading bar. Who is going first? Amir goes first, and then they meet... Why do they meet? Who moves faster? [providing students with time to think and answer before directly answering], Eli." Emma then positioned the students next to each other and instructed them to start walking straight: “Amir, start walking [Amir walks straight], now Eli... stop [they both stop walking]. Who is walking for a longer time? [prompting students to think without specifying the answer directly], Amir [the loading bar takes more time].”

2. Using relevant examples from students’ daily lives to base understanding of the real-world context

This theme comprises teachers providing relevant examples from students' daily lives to support them understand real-world concepts, after identifying the challenge of *fail to understand the real-world context*. For example, John noticed a student struggling to grasp why different movies have varying loading speeds in the YouTube task:

Student Abby: Why does each movie have its own speed?
Teacher John: I'll give you an example. When I was a child, I watched a cartoon called Marko (the Heart) that was simple and quick to load because it had less data. But if you take a Pixar or Marvel movie, which has high quality and more data to download... [encourages the student to draw conclusions independently]
Student Abby: Every second, more data is downloaded because there are more frames, and more frames in each second.
Teacher John: Exactly...

3. Asking guiding questions to select and use an appropriate mathematical model

This theme involves teachers asking guiding questions to support students in selecting an appropriate mathematical model to solve the MM task, after identifying the challenge of *fail to use adequate mathematical methods to mathematise*. For instance, during Lucy's instruction, students struggled to choose using triangle similarities to measure the distance between the two vehicles in the Mobileye

task. Thus, Lucy asked guiding questions to prompt students to think about triangle similarities without directly telling them:

Student Alex: There's some kind of formula between triangles, since the camera captures at a wide angle, so it seems to me that it should work just fine.
Teacher Lucy: What formula between triangles?... what did you mean? [asking guiding questions without answering directly]
Student Alex: I don't remember what it's called. The camera captures from such a wide angle...

Even after the students figured out using triangle similarities, they struggled with its application, and Lucy continued asking guiding questions while maintaining minimal support:

Teacher Lucy: Do we have a connection between the triangle we know, the triangle ECD, and the larger triangle ABC on the vehicle in front of us? What is the connection between these triangles?
Student Jack: It is triangle similarities.
Teacher Lucy: Nice! How?
Student Jack: You have the sides and angles that are equal.
Teacher Lucy: Wait, slowly. What about the sides?
Student Jack: Here you have the angles that are equal...
Teacher Lucy: There are the vertex angles, and what else?
Student Jack: They share common sides.
Teacher Lucy: Common sides? I don't see that. The triangles are connected only at the vertex... EA is not a side in a triangle; it's more than a side... Come, help us think. You said the triangles are similar; now I ask how [prompting students to think].

4. Revisiting mathematical concepts to support their understanding

This theme encompasses teachers revisiting mathematical concepts necessary for the solution to address the challenge of *fail to understand the mathematics conceptually*. For instance, during the Image Resolution task, Rachel intentionally wrote an incorrect Pythagorean Theorem equation on the board and asked students one by one if they thought it was correct, engaging them in identifying the mistake themselves before reinforcing the correct concept. When they did not detect the mistake, she revisited the concept of the Pythagorean Theorem equation to support their understanding: “All 9X should be squared, and all 16X should be squared. I'm not just dwelling on this because it's a very, very common mistake, we forget that each of the factors is squared” (writing on the board the correct equation: $(16X)^2+(9X)^2= (50)^2$).

5. Encouraging a discussion to support understanding of how to reconcile results with the real situation

This theme refers to teachers initiating a class discussion to address a challenge of *fail to reconcile (interim) results with the real situation*. This discussion focuses on the solution process of the MM task, helping students understand how to align their results with real-world contexts. For instance, after achieving a graph representing the loading and viewing bars of YouTube, Emma detected a student who did not understand the meaning of the red line in relation to the real situation. To address the challenge, she facilitated a classroom discussion about the topic to encourage students to think independently through the problem:

Student Mia: Is it possible to continue the red graph so that it is above the grey one?
Teacher Emma: If the red line continued indefinitely, where do you think it would stop? Come show us. I want everyone to listen to the question and please try to answer.

Mia asks if it is possible to continue the red graph so that it is above the grey one [facilitating a classroom discussion to prompt students to think].
Student Zoe: Yes, but you need to wait for the grey line to load
Teacher Emma: Will there be a meeting point here, and will it continue?
Student Zoe: Not now.
Teacher Emma: What do you mean?
Student Zoe: The loading requires time.
Teacher Emma: More delay time is needed so that the grey line will not continue in this way. Because if more delay time is needed, we need more data, right?

Discussion

The findings reveal five major scaffolding practices employed by in-service teachers during real-time instruction, designed to address specific challenges within each modelling phase and promote independent student learning. These practices align with the theoretical scaffolding characteristics of *contingency*, *fading* and *transfer of responsibility* (Van de Pol et al., 2010). *Contingency* is evident through the tailored approach, with each practice addressing a specific student challenge in a distinct modelling phase. *Fading* and *transfer of responsibility* are apparent as teachers gradually reduce support and shift learning responsibility to students as challenges are resolved.

This study underscores the dynamic interplay between teachers' diagnostic and instructional competencies, where each scaffolding practice directly targets a specific modelling challenge. Theoretically, it suggests that DI competencies form a unified set of skills essential for effective modelling instruction, and their integration as a core component of teachers' professional competencies for modelling instruction (Borromeo Ferri & Blum, 2010). These competencies may be positioned as a critical bridge between diagnostic and instructional competence, given the unique expertise they require, encompassing instructional practices explicitly grounded in diagnosing students' modelling challenges while fostering independent learning in MM.

Further research is warranted to assess the effectiveness of these scaffolding practices on enhancing teachers' DI competencies and promoting student independence and engagement in MM. Future studies may explore the role of scaffolding tools and practices in MM (Schukajlow et al., 2015; Siller, et al., 2023; Stender, & Kaiser, 2015) in advancing teachers' DI competencies. Practical recommendations include designing PD programs that simultaneously address both aspects of teachers' DI competencies, thereby enhancing teachers' practices and their professional competencies for modelling instruction.

Mathematical modelling as part of a general education in mathematics classrooms - challenge for teachers, responsibility for researchers

Hans-Stefan Siller[1] and Katrin Vorhölter[2]

[1] Julius-Maximilians-Universität Würzburg, Germany, hans-stefan.siller@uni-wuerzburg.de

[2]TU Braunschweig, Germany

Mathematical modelling is an essential component of the mathematics curriculum in many countries. Intensive research and discussion, also within the TWG Application and Modelling at CERME, have led to well-founded theoretical conceptualisations and frameworks as well as empirical results. However, our world is subject to constant change. It is therefore essential to regularly review the extent to which the formulated goals and perspectives as well as research projects of mathematical modelling (still) meet the requirements of general education or whether they need to be reinterpreted and implemented. Finally, it must be questioned how modelling problems should be designed on this basis. In this article, we put forward hypotheses that we hope will stimulate discussion.

Keywords: Mathematical modelling, general education, aims of modelling, problem situations

Introduction

The challenges of today's world are becoming increasingly complex, and the ability to understand the underlying processes is becoming increasingly dependent on a command of knowledge and skills. A significant proportion of the proposed explanations and derived measures for these complex problems are based on mathematical models. Skovsmose therefore demanded as early as 1994 that students must understand the relevance, but also the limits of mathematics for corresponding situations. However, Greer and Verschaffel (2007, p. 223) highlight that "people uncritically consume the products of mathematical modelling, without having any understanding of the models used, the assumptions on which they are based, or the general concept of modelling itself.". Thus, educated citizens must be able to understand, interpret and evaluate information in order to remain informed and reflective, ultimately contributing to a balanced, just society (Maaß et al., 2019; Vos, 2024).

Irrespective of whether the focus is on understanding stochastic processes when utilising large-language models, forecasting the trajectory of epidemics or the evolution of climate patterns: Each of the models employed is inherently complex and requires differentiated approaches to enable an understanding of the underlying mathematical models. Our following considerations are therefore guided by the questions: (1) What criteria and requirements must be placed on contemporary mathematical modelling in schools? (2) To what extent must the findings, concepts and requirements of recent years be (re)interpreted so that mathematical modelling can contribute to general education?

In this contribution, the term 'general education' is understood in the sense defined by Heymann (1996), who emphasises the importance of education that goes beyond specialist knowledge and promotes comprehensive personal development. He considers general education to be an education that enables individuals to think critically, acquire knowledge independently and act responsibly in a democratic and culturally diverse environment. It aims to turn people into responsible citizens who are able to deal with complex social and ethical issues. This includes the promotion of personal

characteristics and skills such as the strengthening of the student's self and the instruction in critical reasoning, which are related to life preparation, as well as skills that serve the coexistence and orientation in society such as world orientation, the development of a willingness to take responsibility and the practice of understanding and cooperation. Thus, this holistic approach to general education is not merely a transfer of knowledge; rather, it enables students to think and act independently and to navigate a complex world. Furthermore, it is compatible with the concept of higher general education as outlined by Fischer (2001) at the upper secondary level.

The following sections are not structured like a classic research paper. Rather, the first three chapters set out the aims of mathematical modelling, divided into modelling as a method and modelling as a personal capability, with each chapter ending with hypotheses that we believe are worth discussing. We then go into two aspects in greater depth, the aspect of modelling problems and the aspect of models, which we also conclude with hypotheses. The article ends with questions that (at least from the authors point of view) we as a research community should ask ourselves if we want mathematical modelling to contribute to general education today.

Aims of mathematical modelling at school

The aims associated with mathematical modelling have been established in several ways. In general, the formulation of aims can be divided into several levels. On the one hand, mathematical methods and concepts are employed to facilitate a deeper comprehension and mastery of present or future real-world scenarios (Blum, 2015) or at least "to understand central aspects of their world in a better way" (Kaiser, 2020, p. 554) while on the other hand the application references serve "to develop general mathematical competences" (Blum, 2015, p. 81) and "fostering and enhancing the motivation and attitude of learners towards mathematics and mathematics teaching" (Kaiser, 2020, p. 554). While aims of the first type see mathematical modelling as a method, objectives of the second type see mathematical modelling as a personal skill.

Both types of objectives have in common that, although they are formulated for the education of students, the achievement of these aims is targeted at the application of mathematics outside the educational context, i.e. in everyday private, professional and social life. However, the pressing questions of our time are complex and cannot be answered by a single person but require interdisciplinary cooperation (as exemplarily can be seen in expert committees). Subject teaching should therefore give students the opportunity to learn how different disciplines can contribute to finding solutions to global and local challenges of an economic, social and environmental nature (Coles et al., 2024). To this end, it is necessary to examine the extent to which known criteria for mathematical modelling problems need to be reinterpreted so that they also meet the requirement that students learn to question and assess the quality of models.

Mathematical modelling as a method

Mathematical modelling as a method can range from the direct application of known standard models to the independent development of complex models (Siller et al., 2015). At all stages, however, mathematical modelling should focus on developing a simplified description of the extra-

mathematical world within the mathematical world, working within the mathematical model, and then interpreting and validating the results thus obtained in the extra-mathematical world.

An example of the use of a standard model is the well-known application task 'fire brigade' (e.g. Kanefke & Schukajlow, 2022). Students are asked to determine the maximum height from which people can be rescued using a fire engine. Depending on the task, the required information must be read from a text or a table, estimated or researched. The Pythagorean theorem must be used as a standard mathematical model, considering the height at which the ladder is mounted. The use of standard models is essential for dealing with interdisciplinary problems (Goos et al., 2023) but is often not sufficient. It is therefore necessary for students to learn how complex, relevant problems can be solved using mathematical modelling. This can be achieved, for example, by tackling interdisciplinary problems such as the human impact on climate change. (Just et al., 2023). Among other things, students need to mathematically analyse the relationship between different data sets using regression analysis.

For a general education, one of the aims of mathematical modelling at school must be to enable students to understand, at least to some extent, models and the resulting solutions to contemporary problems, to understand and evaluate the measures derived from them and, if necessary, to develop well-founded solutions and measures themselves. This begins with the application of standard models and ends with the independent development of complex models.

***Hypothesis* 1:** *The entire spectrum of modelling problems should be covered at school. While dealing with standard models primarily serves as direct preparation for everyday life, dealing with complex models is also necessary for the development of social responsibility.*

Mathematical modelling as a personal capability

If mathematical modelling is seen as a personal capability, the area of modelling capabilities is affected. In most countries, the acquisition of modelling capabilities is formulated as an objective in school curricula (Kaiser, 2020). However, with regard to the public understanding of mathematical modelling (PUMM), Vos (2024, p. 96) claims: “In schools, the aspects that are highlighted in PUMM may often remain underexposed, whereas aspects often emphasised in modelling education, namely modelling competencies, were apparently absent in PUMM.”

If one applies the definition of competence by Weinert (2001), which many of the relevant definitions of modelling competence do, it consists not only of the capabilities necessary to move from one step of a modelling process to the next (the so-called modelling sub-competencies), but also of a corresponding attitude and metacognitive competencies (Kaiser, 2020; Maaß, 2006).

Current research focuses mainly on the acquisition of (individual) sub-competencies. This often involves isolating a single sub-step of a modelling problem (e.g. making assumptions, e.g. Segura & Ferrando (2023) or in the context of Fermi tasks e.g. Ärlebäck, Sevinc, et al. (2023)). From a research methodology perspective, this can be well justified, as sub-competencies are more reliable to collect and assess than a global modelling competence (Hankeln & Greefrath, 2021). However, Vos (2013) questions the extent to which these sub-competencies measure modelling capabilities in a valid way.

Brand (2014) showed that promoting individual sub-competencies in the sense of atomistic promotion can be more effective than promoting all sub-competencies simultaneously in the sense of holistic promotion. However, it should be noted that, on the one hand, sub-competencies themself are not sufficient to successfully tackle complex modelling problems. It should also be noted that Brand's intervention problems only focused on individual sub-competencies, whereas students were asked to work on complete tasks.

Hypothesis 2: *When promoting modelling capability, a holistic perspective should be adopted to have an affective effect on the learners as well as to develop the learners' cognitive capabilities comprehensively, where the cognitive skills do not consist only of the sub-competencies. This can serve both personality development and the creation of cultural identity by perceiving modelling as a cultural activity.*

Criteria for problem situations

Blomhøj and Kjeldsen (2006) have already presented criteria for good modelling problems for, some of which we believe are particularly relevant if modelling is to contribute to general education: The problem situation must be comprehensible to the students. Together with the fact that students should be able to understand models and the resulting solutions to contemporary problems at least to some extent, to understand and evaluate the measures derived from them and, if necessary, to develop well-founded solutions and measures themselves, this is an indispensable criterion, which at the same time means that the problem must have a connection to the reality of the students. If this is not the case, they will not be able to identify relevant factors and form appropriate models. This means that tasks should be authentic or contain authentic data, where authenticity means that the problem situation is not artificial but is relevant in certain situations outside the school context. For students to perceive mathematical modelling not only as part of the classroom but also as a method outside of school, it is necessary in this context that they can contribute their own experiences and research and use original data. By tackling problems that are either controversially discussed or presented in society, or that initially seem inaccessible to mathematical concepts, students can also learn that the modelling method is suitable for forming and defending well-founded opinions. At the same time, they can experience the dependence of results on the assumptions made and the models developed and thus learn to critically evaluate given models. They do not necessarily have to develop models themselves but can be given different models for a specific problem situation. Finally, Blomhøj and Kjeldsen also stress the need to become familiar with standard models.

This need exists particularly in a social context, as Siller et al. (accepted) emphasise. To this end, they focus on the *capabilities* needed to link the evaluation of media claims through the analysis of large data sets, identifying the skills needed for current and future civic life.

Hypothesis 3: *Students must be given the opportunity to contribute their own experiences and to work with original data that is controversially discussed and presented in a social context. Thus, they can learn to form well-founded opinions with the help of mathematical modelling and to argue for them.*

Quality of models

Dealing with real-life issues in mathematics education makes it possible to take up current problems relevant to the target group and integrate them into mathematics education. Many of these problems are characterised by the fact that they cannot be answered from only one discipline without ignoring important aspects. Questions from the STEM subjects are increasingly popular (Siller et al., 2023), as are questions related to sustainability (Ärlebäck, Carreira, et al., 2023).

A central component of the mathematical modelling of such problems is the application or utilisation of models. Models cannot be considered good or bad per se, but their quality must always be assessed in the light of the objective. Ortlieb et al (2013) identify three criteria for models based on Hertz's explanations. One of these criteria is correctness, which is given if it is consistent with known facts. He points out that correctness always depends on time, as knowledge expands and depends on the subject. Secondly, a model must be internally consistent, which he describes as permissible. The third criterion is the usefulness of the model, which means that the model does not contain parts that are superfluous to the problem being addressed. It is important that a model is as simple as possible and as complicated as necessary to represent the area of reality under consideration, which in turn is related to the purpose for which the model is being built.

An example is the modelling of the development of the corona pandemic and related situations, such as various containment measures, using the concept of exponential growth. This is not sophisticated mathematics at all, but the use of basic procedures that are deliberately chosen to describe, explain or predict situations (Siller et al., 2022; Vasquez et al., 2023).

Hypothesis 4: *For students to experience the consequences of mathematical modelling, it is essential to check the correctness, consistency and usefulness of given models and to question their own modelling as an exercise in critical thinking and the development of a sense of responsibility.*

Discussion points - responsibility of our research community

The extent to which, and the conditions under which, mathematical modelling can contribute to general education have been demonstrated in this article. Consequently, we as researchers must ask ourselves:

- How and to what extent can we, through our research, teaching and communicating science, help to ensure that mathematical modelling contributes to general education - or are we just researching it as an end in itself?
- How can mathematical modelling be used to address current issues and challenges, e.g. in the context of sustainable development and socio-ecological approaches?
- What changes are needed using AI, in particular large language models (e.g. ChatGPT), for example to formulate meaningful tasks?

So far, this paper has only touched the topic of assessment, whether in the context of performance assessment or research studies. However, it is imperative that we fulfil our responsibilities in this regard. The way modelling capabilities are evaluated in large-scale studies, such as PISA, or in national examinations, the tasks that are presented for this purpose, or in teacher training or

publications, exerts a significant influence on the implementation of mathematical modelling in schools and its perception in society. It is therefore imperative to adopt a critical stance.

- How do we measure modelling capabilities? Or to put it another way: What aspect of modelling capabilities do we measure, and do we always do so with this restriction?
- Is it simply the easiest way to meet certain methodological criteria, or does it also make sense in terms of content? What are the alternatives?

In this sense, Vos (2013, p. 488), makes the following request with regard to the measurement of capabilities in schools: "... we do not need to throw out the baby with the bathwater and abolish project-based or portfolio assessment: these formats have a high validity in relation to the creative aspects of modelling; research may assist in improving these formats with respect to test reliability".

- To what extent do the tasks we use in studies meet the criteria
- Is the relevance of the problem situation really given?

The objective of this paper is to contribute to the ongoing discourse on mathematical modelling by addressing current requirements. To this end, the hypotheses and questions presented are intended to stimulate a critical and constructive approach to addressing current and future challenges in mathematical modelling in research and teaching.

The evanescence of mathematical models and modelling in the teaching of combinatorics

Susana Vásquez[1,2], Berta Barquero[1] and Marianna Bosch[1]

[1]Universitat de Barcelona, Faculty of Education, Barcelona, Spain; susanavasquez@ub.edu
[2]Col·legi Natzaret, Esplugues, Spain

This paper explores the role of combinatorics under a mathematical modelling approach through the lens of the anthropological theory of the didactic. We analyse three educational approaches to combinatorics, two from classical textbooks and one from a proposal of a study and research path about padlocks and security. This research considers two didactic phenomena in the teaching of combinatorics: the prevalence of applicationism and the evanescence of modelling. It explores the role that intermediate models can play in enriching the modelling process and overcoming significant constraints in learning combinatorics. Through the analysis of different teaching proposals, our research highlights the importance of fostering inquiry-based learning environments where students actively engage with the recursive and reversible nature of mathematical modelling and models.

Keywords: Mathematical modelling, combinatorics, anthropological theory of the didactic, dialectics of systems and models, study and research paths.

Introduction

Combinatorics is a fundamental branch of mathematics that some researchers consider essential for developing key mathematical skills such as problem-solving, formal reasoning, abstract thinking, conjecturing or generalizing. Kapur (1970) and English (2005) emphasize the importance of including combinatorics in mathematics curricula, where its connection to areas such as probability and statistics is highlighted. Lockwood (2013) points out that research in combinatorial education is limited and has not sufficiently explored how students conceptualise counting problems. Often, the teaching of combinatorics is reduced to memorizing formulas and considering standardized counting situations (Batanero et al., 1997), which limits a deep understanding of the underlying concepts.

In this paper, based on the anthropological theory of the didactic (ATD), we examine teaching proposals in combinatorics for secondary education and their interpretation through mathematical modelling. ATD identifies two pedagogical paradigms (Chevallard, 2015). The 'paradigm of visiting works' involves a unidirectional process where teachers present structured knowledge for students to learn and reproduce, often leading to 'monumentalism', where knowledge is valued as an end in itself. The application of this knowledge, if introduced, occurs in artificial contexts, described as 'applicationism' (Barquero et al., 2013). Conversely, the 'paradigm of questioning the world' shifts the focus to the study of questions through collective investigations, where knowledge is introduced as a tool for inquiry. Chevallard (2015) proposes study and research paths (SRPs) to support the transition between the two paradigms. SRPs are instructional formats that start with the consideration of open questions to be addressed collectively by the group of students guided by the teachers, where the search and study of pieces of knowledge is conditioned to their need for the inquiry.

Our starting point is an SRP generated by the question of padlocks' security, aiming to explore combinatorics through real-world scenarios and implemented in Spanish secondary schools since 2019 (Vásquez et al., 2021). Two phenomena are linked to this SRP. First, the dominance of 'applicationism' in current secondary mathematics education, where models (combinatorial formulas) are introduced before their application. Second, the 'evanescence' of modelling activities (Wozniak, 2012) and the difficulty to work with intermediate models that do not have a clear mathematical status even if they play a determinant role in the approach of combinatorics problems.

Theoretical framework and methods

Mathematical modelling in the Anthropological Theory of the Didactic

ATD presents a perspective of mathematical modelling that places it at the centre of mathematical activity. From this vision, doing mathematics involves creating, transforming, interpreting and developing mathematical models. Mathematical modelling activities are described as processes of reconstruction and articulation of mathematical organisations of increasing complexity, generated in response to problematic questions (Barquero, 2023). The modelling process involves the following stages (Figure 1): first, the delimitation of a system S_0, which implies defining the initial piece of reality to be modelled after a question Q_0 is raised. The second stage corresponds to the construction of a model M_1 linked to a mathematical organisation supposed to help produce knowledge about the system. The next stage involves working within the model, where mathematical tools of the model organisation are used to obtain results a produce an answer A_1 to Q_0. Finally, the results obtained in the model are interpreted in relation to the original system, which can generate new questions Q_1, a new delimitation of the system, S_1 (now including S_0, M_1 and A_1), and a recursive modelling process.

A central element of the modelling process lies in the roles played by models and systems. The system refers to the object of study in the modelling process, which can be either intra-mathematical or extra-mathematical. The aspects of the system to be studied depend on the question initially addressed. Meanwhile, the model is built based on a knowledge organisation that represents the system and generate knowledge about it. Being a model or a system is not a property but a function that can be sometimes assumed by the same types of entities.

A crucial aspect in this perspective is the constant questioning of the model's adequacy to the system. This involves evaluating the model's ability to answer the posed questions, identifying its limitations, and, if necessary, redefining the system, adjusting the model or building new models that better fit the system (Barquero, 2009). The ATD emphasizes the importance of intra-mathematical modelling, that is, the modelling of systems that are intrinsically mathematical. This type of modelling has been a fundamental driver in the historical development of mathematics and enables the consideration of modelling processes where a sequence of models is involved. Intermediate models emerge during these processes, serving as bridges between different mathematical organisations.

As explained by Barquero (2023), modelling processes are *recursive* and *reversible*. Recursivity refers to the process where a model becomes the system for further modelling, allowing for successive refinements. This involves creating 'models of models' and redefining progressively the system being studied, integrating previous models and knowledge generated by models (see Figure 1). Reversibility

corresponds to the ability to invert the relationship between a system and its model, where the system can serve as a model of its previously considered model.

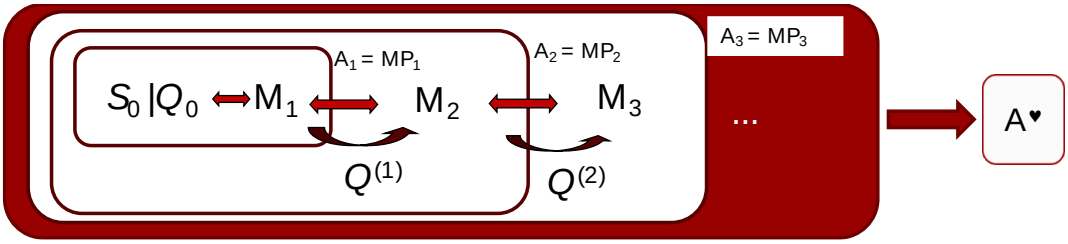

Figure 1: Diagram of the modelling process in the ATD (Barquero, 2023)

Methods

Our research follows the different phases of didactic engineering (DE) as research methodology (Artigue, 2020). The first phase focuses on a *preliminary analysis* of the didactic phenomena we have detected concerning combinatorics: the prevalence of applicationism (Barquero et al., 2013) and the evanescence of modelling praxeologies (Wozniak, 2012) in the teaching and learning of combinatorics. At this stage, we chose two textbooks to analyse their proposals. Following the work of Juberó (2022), we analysed a textbook with a classical introduction to combinatorics (Salvador & Molero, 2022) and a textbook that proposes starting from situations and generates a classification of combinatorics problems and formulas based on sequences of codes as intermediate models (Bosch et al., 1997). The second phase consists of the *a priori* analysis of a teaching proposal that aims to overcome the above-mentioned phenomena. In our case, it is concretised by the design of a study and research path (SRP) about padlocks' security. We started from the design and experiences conducted by Vásquez et al. (2021), where a full description of the SRP about padlocks is provided, followed by two cycles of implementation. From this implementation, the DE continues with the *in vivo* and *a posteriori* analysis of the SRP, which provides empirical data to contrast the initial designs of the SRP and sheds light on the didactic phenomena at stake.

To analyse the inquiry processes followed during the implementation of the SRP, we used the *dialectics of systems and models* to describe, analyse and understand the different tensions and decisions that arise in the modelling processes (Barquero, 2023). We focus on identifying the key elements in a modelling process and their evolution, in particular: the systems, the questions raised, and the models considered, as well as their relationships. With these elements, we describe the potential modelling process deduced from the didactic proposals, and how they integrate the recursive and reversive properties of modelling. We can finally state our research questions with a dual objective:

RQ1: What traits of the dialectics between systems and models characterise different proposals for the teaching of combinatorics at secondary school education?

RQ2: What conditions are established, and what constraints are anticipated, from the different proposals for the teaching combinatorics under a modelling perspective?

Analysis of the modelling process in different proposals

The textbook *Marea Verde* (Salvador & Molero, 2022), analysed by Juberó (2022), exemplifies the dominant mathematical organisation in Spanish secondary education for counting problems, focusing on permutations, variations, and combinations. Proposed strategies include tree diagrams and sequence lists, used to introduce the algebraic formula that correspond to each type of problem. Juberó (2022) highlights several limitations, such as insufficient guidance on selecting methods and a lack of theoretical discourse to interpret the results. The types of tasks proposed are repetitive and closed, with no focus on identifying variables or validating techniques. Combinatorics is taught as an application of pre-defined formulas to fixed problems, omitting key phases of the modelling process. Instead of constructing models, the textbook presents combinatorial formulas directly (M_0 to solve pre-set problems (S_0), reflecting a reduced form of applicationism (Figure 2). This approach treats models as static tools, preventing their evolution or the exploration of alternatives, limiting deeper understanding of their construction and broader applicability.

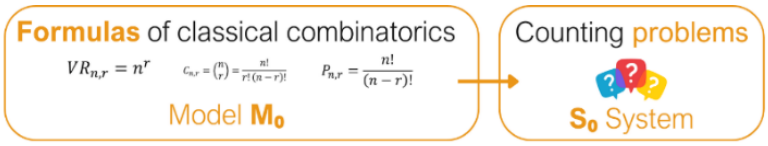

Figure 2: Diagram of the modelling process in the "Marea Verde" textbook

The *Almadraba* textbook (Bosch et al., 1997) offers a different approach, starting with situation-types such as football pools (variations with repetition), posters on a wall (variations without repetition), and prize allocations (combinations). The situations are approached through a modelling process in four phases: translation of the problem statement using a sequence of symbols, qualitative and quantitative analysis of the groups of symbols to see if the order is important or repetitions are allowed, and the generation of a general formula for each case. The book also classifies problems into simple and complex, using a classification algorithm. Juberó (2022) identified the groups of symbols as an intermediate model aiding the identification of permutations, variations, or combinations, with exploratory questions guiding the development of the techniques. However, the approach lacks technique diversity, reverse problems and explicit discussions about the interpretation or justification of the results. Unlike the earlier case, models are developed after studying initial systems (S_0), with exploratory questions facilitating the production of a first model (M_1) using a classification algorithm. Initial situations are categorised, leading to a second model (M_2) structured around symbol sequences (Q_1*: What sequence does the problem admit?*). The sequences obtained form a new system (S_2) addressed by question Q_2*: How can we obtain the total number of possible sequences?* which would lead to a final model, M_3, of numerical formulas (Figure 3).

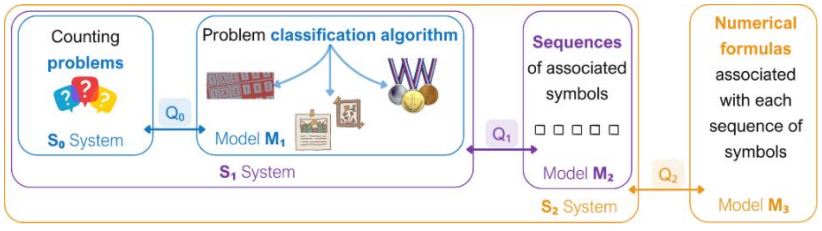

Figure 3: Diagram of the modelling process in the textbook *Almadraba*

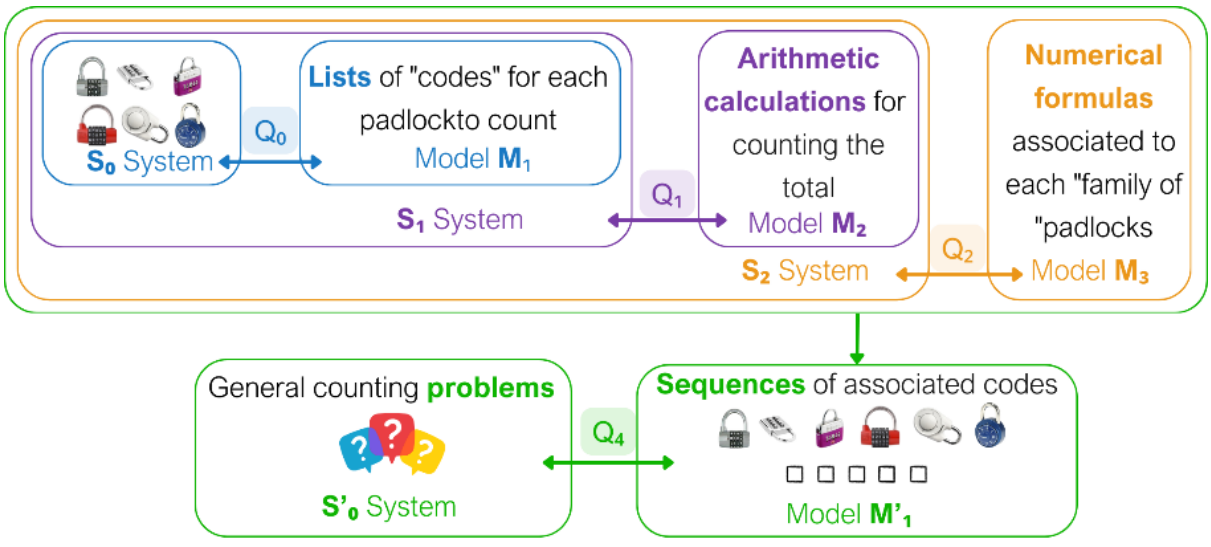
In this case, the modelling process is identifiable, with key elements such as systems, models, and questions recurring, at each step as more complex models emerge from studying "types of" counting situations. However, both teaching proposals omit crucial steps in the modelling process, such as model validation or the exploration of opener questions or systems. Their focus remains confined to pre-determined controlled counting situations aligned with combinatorial arrangements.

The third proposal consists of the SRP about padlocks, widely analysed in Vásquez et al. (2021). The initial system presented (S_0) is a set of different padlocks and a generating question (Q_0) about which of the padlocks is the most secure. This initial system is accessible to the students, they can handle the padlocks, experimentally generate lists of codes or passwords, and propose different models to list and count the total number of codes for each padlock. In the first phases of the SRP, initial models M_1 used to be proposed, involving models based on generating lists (with or without structure). For example, students used spreadsheets to make counting more feasible. Quickly a new question Q_1 emerged about *how many codes each padlock does support.* This first model reveals many limitations, especially in validating the result (How can we know if a combination is missing?). The students usually take these initial lists (simulated by the first models) and analysed them. At this step, the set of padlocks and model M_1 constituted a new system S_1 to be again modelled. Then, new models (M_2) can appear, which are more advanced and involve more comprehensive strategies, such as models based on arithmetic calculations to count the total number of codes. This process can be followed by presenting Q_2*: Can we determine the number of codes for new padlocks or those with known information? Is there any possible classification of padlocks, according to the way to count their total number of codes?* The arithmetic calculation models (M_2), along with their corresponding padlocks that comes to be modelled in previous stages, constituted the system S_2 to be studied. Along with the new information, students investigated the validity of the previous models, thereby finding a model M_3 consisting of numerical formulas (pre-algebraic in some cases) associated with each family of padlocks (Figure 4). It is worth noting that M_1 and M_2 act as intermediate models, which are crucial to explain and justify the more advanced models M_3 consisting of numerical formulas.



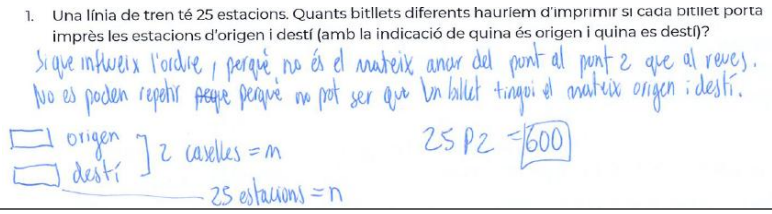


Figure 4: Diagram of the modelling process in the padlock's SRP

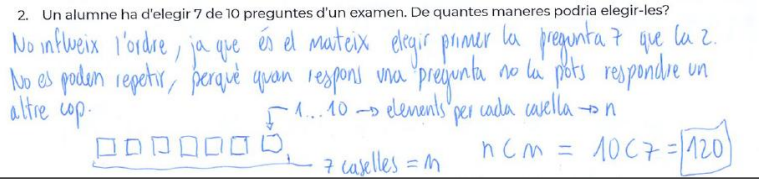

The recursive potential arises when the SRP is expanded to study other (more traditional) counting situations and introduce new questions, such as Q_4*: How can general counting problems be solved?* In this new context, the implementation shows that the padlocks (initial system, S_0) are then used by the students as models to represent sequences of codes, which helps model other counting problems using the previous intermediate models.

Results from the implementation of the SRP about padlocks

Vásquez et al. (2021) analyse students' work to show the various stages of the modelling process shortly described in the previous section. In that study, the upper part of the diagram in Figure 4 is extensively described, but little is said about the latter part about solving general counting problems. The evolution of the SRP implementation within the didactic engineering cycle shows an interesting result to this respect. In the analysis of the first two implementations, when coming to solve general counting situations, students started considering the padlocks to build the initial models. However, this use of the padlocks as intermediate models did not last, and students quickly reverted to applying formulas, without linking them to their previous work and falling, once again, into a more applicationist approach. This may have occurred because too much emphasis was placed on the formulas by the teachers, without relating them to the modelling process. One of the participating teachers described it as "some students see it as two different activities: first, we investigate the padlock problem; but then they forget and go back to using the classical combinatorial algorithm to solve the problems". In the last implementations of the SRP, teachers placed more emphasis on solving problems by always using padlocks as a tool to justify the choice of the resolution method, thus highlighting the role of padlocks as intermediate models. With these last modifications, when the students had to solve general counting problems, they first created a box diagram that represents a padlock adapted to the counting situation and analysed the main variables associated to it: cells, elements in each cell, influenced by the order (or not), repetition of the elements (or not) (Figure 5).

A train line has 25 stations. How many different tickets should we print if each ticket has the origin and destination stations printed on it?
Student: The order does matter, because going from point 1 to 2 is not the same as going from 2 to 1. They cannot be repeated because it cannot be that a ticket has the same origin as destination. (2 cells = m; 25 stations = n)

How many ways can a student choose 7 out of 10 exam questions?
Student: The order does not matter, as it's the same to choose question 7 first as it is to choose question 2. They cannot be repeated, because once you answer a question, you cannot answer it again. (10 elements per cell = n. 7 cells = m)

Figure 5: Example of student's productions

Conclusions

Concerning the analysis of the three proposals on combinatorics, we can conclude that the dialectics between systems and models evolves increasingly throughout the three proposals. In the first case (*Marea Verde*), which corresponds to the most spread teaching strategy in Spanish textbooks, there is an almost direct assignment of the corresponding formulas to the counting situations under study. In terms of the dialectic between systems and models, the formulas come first (acting as systems), and the different counting problems are considered to illustrate the type of situations that correspond to the formulas (thus acting as models). The role is reversed: situations are models of the different combinatorics formulas. In the second case (*Almadraba*), the situation is similar but an intermediate model in terms of groups of symbols and sequences is introduced between the situations and the formulas. This enables more flexibility in the study of counting situations and opens the possibility to address "complex situations" that do not directly align to an established formula (permutation, variation or combination). Finally, the SRP about padlocks initiates a more open inquiry process, which is then used as a model to address a variety of (simple) counting situation. In this case, padlocks serve as intermediate models. However, this role needs to be explicitly reinforced by the teaching strategy.

Regarding the conditions identified from a modelling perspective in the latest implementations of the SRP concerning padlocks, we have emphasized the necessity of providing a clear status to the intermediate models (M1, M2 and the types of padlocks themselves), especially to address the evanescence of the modelling process. In this respect, teachers play a central role, as it is fundamental that they assign and share words about the models, systems and the entire modelling process with their students. That is, it is necessary to develop a didactic (and mathematical) *logos* to describe the modelling process, with its main elements, including recursivity and reversibility. Otherwise, activities related to modelling will end up disappearing to the detriment of the institutionally recognised combinatorics formulas. This is the research line we are developing at present. Explicitly naming and assigning a mathematical status to the system-model dialectic can provide teachers with an epistemological tool to manage the modelling processes that emerge from inquiry processes. It will also help teachers provide new names for the concrete systems and models that are considered during the process. New mathematical developments are needed to overcome the limitations derived from the applicationism and the evanescence of intermediate models.

Pre-service teachers' judgments of students' solutions to open modeling problems: How important is it to make assumptions?

Katharina Wiehe[1], Catharina Beckschulte[1] and Stanislaw Schukajlow[1]

[1]University of Münster, Germany; kwiehe@uni-muenster.de

An important type of mathematical problems are open modelling problems. However, it is a lack of insights into teachers' judgements of students' solutions to open modelling problems. The research question was: Which aspects of the students' solutions do the pre-service teachers emphasise. Twenty pre-service teachers engaged in solving four problems, assessed 14 students' solutions to these problems, and provided justifications for their judgements. A content analysis of the pre-service teachers' justifications identified positive and negative emphases while judging students' solutions. The findings suggest that pre-service teachers emphasised numerical and realistic assumptions positively, while they emphasised unrealistic and missing assumptions negatively. This study contributes to the theory of assessment of open modelling problems by showing what aspects of students' solutions matter when assessing mathematical modelling.

Keywords: Open modelling problems, teacher education, diagnostic competence, judgements, openness.

Introduction

Open problems are important in mathematics education, especially as open modelling problems. Modelling problems are characterised by their connection to real-world contexts and require complex transformation processes between reality and mathematics (Niss & Blum, 2020). A defining characteristic of open modelling problems is that some information needed to solve the problem is lacking. As a result, problem solvers have to make assumptions to account for these missing information. Both students and (pre-service) teachers often struggle with open modelling problems (Stylianides & Stylianides, 2023). Students need to master task-specific requirements while solving open modelling problems and needed to be taught how to solve open modelling problems (Schukajlow et al., 2023). For teaching those problems, (pre-service) teachers should be capable of judging students' performance on open modelling problems (Greefrath et al., 2022). One difficulty in judging students' solutions to open modelling problems is the possibility of multiple solutions and results (Borromeo Ferri, 2022), which makes objective judgements difficult. Diagnostic activities of teachers are a main task of their profession and should take into account the openness of modelling problems. Nevertheless, there is a lack of empirical studies on the judgement of students' solutions to open modelling problems. As part of the DOModA project (Diagnose von Schülerlösungen zu Offenen Modellierungsaufgaben, Diagnostic Competencies of Student Solutions on Open Modelling Problems), we conducted an interview study to fill this research gap. In this study, we analyse which aspects of students' solutions to open modelling problems pre-service teachers positively or negatively emphasized while judging these.

Theoretical background

Open modelling problems

One of the goals of mathematics education is to develop modelling skills (Blum, 2015), for example by working on open modelling problems where crucial information is missing and complex transitions between reality and mathematics are required. In our study, we utilised such problems, where solution-relevant information is missing from the problem statement and it is necessary to make assumptions about it. The improvement of teachers' abilities to deal with open modelling problems must be a focus of attention, as prior research indicated difficulties of students with dealing with openness (Ärlebäck, 2009). Recent research suggested a framework outlining the typical requirements for dealing with open modelling problems (Schukajlow et al., 2023): (1) perceive the missing information, (2) identify the unknown quantities that are needed to solve the problem, (3) make (realistic) assumptions about the unknown quantities and (4) including the (realistic) assumption in the mathematical model. Without recognising the openness, students may approach open problems like closed ones, focusing only on provided numerical data and potentially reaching unrealistic solutions (Galbraith & Stillman, 2001). Identifying the unknown quantities is an important part of solving open modelling problems (Hankeln, 2020). Making numerical assumptions can be challenging, as it often leads to barriers in problem-solving, either due to ignoring realistic considerations or lacking the knowledge to make assumptions (Galbraith & Stillman, 2001). These assumptions must be integrated into the mathematical model, a step some students struggle with even after making the necessary assumptions (Schukajlow et al., 2023). Assumptions are categorised into situational and numerical types (Krawitz et al., 2022), with the latter involving challenging realistic reasoning and extra-mathematical knowledge. Situational assumptions pertain to assumptions about the circumstances, while numerical assumptions involve assumptions about missing values (Chang et al., 2020). Students often face difficulties with estimation skills, resulting in inaccurate estimates (Krawitz et al., 2022). Moreover, assumptions can be evaluated based on their reference to reality, with research indicating that students infrequently make realistic assumptions when solving open modelling problems (Krawitz et al., 2022). The step of making realistic assumptions is essential for achieving a good solution to a problem, as unrealistic assumptions or their absence can lead to unrealistic results throughout the modelling process (Chang et al., 2020).

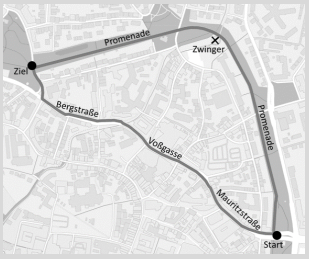
Diagnostic activities

In our study, we define diagnostic activities as the gathering and interpreting of information related to learning conditions, processes, or outcomes, often through evaluating students' written work (Leuders et al., 2018, p. 4). Diagnostic dispositions encompass the knowledge, skills, motivation, and beliefs of the individuals making judgements (Blömeke et al., 2015; Leuders et al., 2018), and are crucial for effective diagnostic thinking. Teachers often use their own solutions and knowledge to identify students' difficulties (Ostermann, 2018; Philipp & Gobeli-Egloff, 2022). Identifying strengths and weaknesses in students' work is considered the first crucial step in the diagnostic process (Philipp & Gobeli-Egloff, 2022).

The judgement of student solutions in the context of modelling problems is challenging and complex (Blum, 2015; Greefrath & Vorhölter, 2016). Open modelling problems allow multiple correct

solutions, require a combination of several sub-competencies and the modelling process must be evaluated too (Borromeo Ferri, 2022). A potential assessment scheme suggests valuing working mathematically and documentation (Maaß, 2007). One fundamental problem in assessment is how to judge simple, error-free solutions versus complex solutions with minor errors (Borromeo Ferri, 2022). Prior research on in-service teachers revealed different reasons for the judgment of student solutions to an open modelling problem. For example, some teachers see assumptions as necessary for judgement, but they underline that the focus of judgements always dependent on the content and goals of the lesson (Borromeo Ferri, 2022). According to Cai et al. (2022) teachers emphasize strongly positive aspects of students' solutions while giving feedback .

Research question



The research question of this paper is: Which aspects of the students' solutions do the pre-service teachers emphasise a) positively and b) negatively while judging students' solutions to open modelling problems?

Methods

Twenty master's students in mathematics education volunteered for this research (13 females, average age 23.35 years). Fourteen were enrolled in the educational program for secondary school teaching and six in the educational program for lower-secondary school teaching.

Promenade

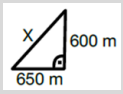
Max is riding his bicycle to school. On his way back home, he is considering whether he should take the route through the bustling city center of Münster, via Mauritzstraße, Voßgasse, and Bergstraße, or if he should bypass the city center by taking the bicycle path along the promenade. To do so, he would have to ride along the promenade for 650 meters until he reaches the historic Zwinger, and then continue for another 600 meters along the promenade.

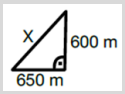
Which route do you recommend to Max so that he can get home earlier?

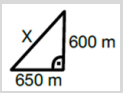
Figure 1: Open modelling problem Promenade

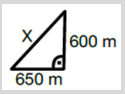
We designed an interview-based study to explore how pre-service teachers judge student solutions to open modelling problems, drawing on both theoretical frameworks and empirical evidence. Different modelling problems were addressed in the interviews lasting 60 to 90 minutes, divided into problem-solving and judgement phases. One example is the Promenade problem (see Figure 1), which could be solved by using Pythagorean theorem by calculating the missing side of a right triangle or by using scaling drawing. Participants solved four open modelling problems (problem-solving phase) and then judged various student solutions (judgment phase), justifying their judgements. Key questions were: "What are your considerations about these students' solutions?", "How do these solutions differ from your own approach?", and "How would you judge these solutions in an examination setting?". The interviews were conducted in pairs.

The Promenade problem required students to choose the best path for Max. Students had to perceive missing information, such as Max's cycling speed, and make realistic assumptions, like assuming speeds of 18 km/h along the promenade and 11 km/h through the city centre. We designed four typical student solutions based on the theoretical framework established in a previous study (Schukajlow et al., 2023). These are shown in Figure 2. The solutions vary depending on how effectively the students meet the requirements for dealing with openness. The first solution does not include any assumptions. In the second solution, the student recognised that some information was missing, but did not make a numerical assumption. The third solution contains an unrealistic assumption. The fourth solution contains a realistic assumption.









Solution 1: Without any assumption City centre: $x = \sqrt{600^2 + 650^2} = 884{,}59\ [m]$ Promenade: $600 + 650 = 1250\ [m]$  A: The route through the city centre is shorter than the route along the promenade, so Max should choose the city centre route.	**Solution 2:** Perception of the openness (in the answer) City centre: $x = \sqrt{600^2 + 650^2} = 884{,}59\ [m]$ Promenade: $600 + 650 = 1250\ [m]$  A: The route through the city centre is shorter than the route along the promenade, and Max should choose this route. You have to consider how fast Max is riding.
Solution 3: With an unrealistic numerical assumption City centre: $x = \sqrt{600^2 + 650^2} = 884{,}59\ [m]$ Promenade: $600 + 650 = 1250\ [m]$  Assumptions about the speeds at which Max can ride each route: $v_{Promenade} = 5\ km/h,$ $v_{city\ centre} = 10\ km/h$ Let $t = s/v$ be the equation for time, where: $t_{promenade} = \frac{1{,}25km}{5\ km/h} \approx 15\ min$ $t_{city\ centre} = \frac{0{,}885km}{10\ km/h} \approx 5{,}31\ min$ A: The route through the city centre is faster.	**Solution 4:** With a realistic numerical assumption City centre: $x = \sqrt{600^2 + 650^2} = 884{,}59\ [m]$ Promenade: $600 + 650 = 1250\ [m]$  Assumptions about the speeds at which Max can ride each route: $v_{Promenade} = 18\ km/h,$ $v_{city\ centre} = 11\ km/h$ Let $t = s/v$ be the equation for time, where: $t_{promenade} = \frac{1{,}25km}{18\ km/h} \approx 4{,}17\ min$ $t_{city\ centre} = \frac{0{,}885km}{11\ km/h} \approx 4{,}83\ min$ A: The route through the promenade is faster.

Figure 2: Students' solutions of the Promenade problem offered in the study

To answer the question of which aspects of the students' solutions the pre-service teachers positively or negatively emphasised, we conducted a qualitative data analysis (Kuckartz & Rädiker, 2019). The transcripts of the interviews were coded for positive or negative emphasis in the pre-service teachers' judgements. The interviews were double-coded with an interrater-reliability of κ = .92 for positive emphases and κ = .89 for negative emphases. The minimum coding unit was one sentence. Positive emphasis was assigned to statements in which participants explicitly praised or expressed agreement with an idea, approach or solution. This code captured terms such as good, great, interesting or praiseworthy. For example, one pre-service teacher positively evaluated the modelling process of a student, stating:

Lara: Yes, I think it's good that this student has definitely thought about the fact that it's not just a maths problem, but that it's also transferred back into the real world.

Emphases were coded as negative if they referred to the statements that conveyed subjective disapproval or strong negative reactions using terms such as stupid, disastrous, or idiotic. The interview transcripts were first deductively coded to identify pre-service teachers' positive or negative emphases. Then, we identified inductively which aspects of students' solutions were emphasised positively or negatively in the judgements.

Findings

Pre-service teachers positively emphasised the *making of assumptions* in students' solutions, as they saw this as an important aspect of mathematical thinking and praised students for recognising that assumptions had been made. Pre-service teachers appreciated that students had considered the context of the problems by making assumptions. *Making numerical assumptions* was also positively emphasised, regardless of the realism of the assumption, as can be seen in this interview:

Simon: This would also be a perfect solution for me in the sense that an assumption has been made. They may not be exactly right, but at least they have thought about it and made an effort (points to a solution with a numerical assumption).

Furthermore, pre-service teachers positively emphasised *assumptions in text form*, as these did not imply setting exact values and were correctly placed within the context. In an interview, the mention of influencing factors in the text was positively emphasised and, in another interview, making rough estimates without specifying exact values was considered an acceptable and effective approach. In addition, pre-service teachers emphasised positively a *physical approach* of the Promenade problem. For example, the calculation in solutions 3 and 4 of the Promenade problem, which the pre-service teachers expected to be an essential part of any correct solution of Promenade problem ("under any circumstances"). The students' *calculation* was also positively emphasised. It was emphasised that a student solution without an assumption (solution 1) would also be a mathematical achievement because "everything was done correctly" but no assumption was made. The way in which all the student solutions were *written down* and the *use of units* was emphasised positively.

Pre-service teachers particularly emphasised *unrealistic assumptions* that ignored the context negatively, like in interview 4:

Lia: It's also great physically here with T is equal to S by V, but/but the assumption is actually total nonsense.

The pre-service teachers judged the calculation as correct and identified students' problems in interpreting their results, but also noted the *missing transfer to reality* in a negative way due to the lack of assumptions. The *lack of reasons for numerical assumptions* was also emphasised as negative. The pre-service teachers did not perceive the importance of making assumptions in the modelling problems and rated *numerical assumptions* in students' solutions negatively. They explain that "the problem did not require such a complex solution with numerical assumptions" and that solutions without any assumptions were sufficient, which was not correct. The pre-service teachers negatively emphasised solutions, in which students made *assumptions in text form*. On the one hand, because these additional statements were made without a mathematical basis and, on the other hand, because

these statements do not contain any justification. In one interview, this mention was emphasised negatively because it was not mathematically calculated or included. In addition, it is negatively emphasised that the solution perceiving the openness in the answer would be a lazy solution. *Assumptions made in the drawing* were negatively highlighted, because the drawing showed the need to make assumptions, but not the calculation.

Discussion

The pre-service teachers mainly emphasised numerical assumptions positively and showed a general appreciation for students' use of numerical assumptions in their solutions, appreciating the precision and clarity of these assumptions brought to the problem-solving process. This aligns with previous research, which highlights the importance of making numerical assumptions (Chang et al., 2020; Schukajlow et al., 2023). However, judgements of regarding unrealistic assumptions differed significantly, with some pre-service teachers believing that assumptions could be helpful when considered in context, and others believing that they should be kept strictly within realistic parameters. The missing transfer to reality was viewed negatively, emphasising the need for students to make their assumptions explicit. The assumptions in text form, was seen as positive, demonstrating the value of contextualised thinking. This indicates that pre-service teachers value context-specific reasoning (Chang et al., 2020). Assumptions in text form were both positively and negatively emphasised, reflecting different perceptions that depend on the context and plausibility of the assumptions. Following the requirements for open modelling problems, this can be interpreted as an essential step in recognising openness. On the other hand, the pre-service teachers evaluate the answers negatively due to their missing reasoning or missing mathematical considerations. Overall, numerical assumptions, along with realistic and unrealistic assumptions, received much attention from pre-service teachers. This focus indicates that pre-service teachers primarily concentrated on the quantitative aspects of students' solutions. This is in line with the assessment scheme of Maaß (2007) focussing on the calculation and documentation during the modelling processes. This highlights the necessity for the development of assessment schemes that focus on other aspects, such as situational assumptions. In contrast, assumptions represented in calculations were mainly highlighted positively, suggesting a focus of concrete numerical representations as evidence of modelling competencies.

Pre-service teachers tend to emphasise particularly positive aspects of students' solutions (Cai et al., 2022). In line with previous research, our study demonstrated that these emphases differ between pre-service teachers. Furthermore, we observed that the type of students' solutions influenced the emphases. These findings indicate that the accuracy of pre-service teachers' judgments is contingent upon the specific open modelling problems or contexts presented. A novel finding of this study is the identification of specific aspects of students' solutions that pre-service teachers emphasize in their judgments. However, further research is needed to validate these findings. One limitation of this study is that the sample consisted solely of students from a German university. Future studies should assess the judgments of pre-service teachers from diverse educational contexts and analyze the judgments of in-service teachers as well. Another limitation is that four solutions were presented with typical errors which were derived from theory and prior research. In future research, it would be beneficial to adopt a more open approach and inquire directly from students which solutions they consider

effective and how they would evaluate different aspects of these solutions. This aspect warrants further research, preferably utilising qualitative methods or mix-methods, as quantitative approaches might not capture the nuanced differences in pre-service teachers' judgements. By showing what might be important in assessing students' solutions, this study contributes to the theory of assessment of open modelling problems.

The dishwasher experience: Pre-service teachers' use of extra-mathematical knowledge while investigating societal topics

Suela Kacerja[1], Lisa Steffensen[2] and Trine Foyn[1]

[1]University of South-Eastern Norway, Norway; suela.kacerja@usn.no

[2]Western Norway Applied Sciences, Norway

Keywords: Mathematical toolkit, water consumption, mathematical modelling, extra-mathematical knowledge, pre-service teachers.

Introduction and previous research

In this poster, we present an ongoing qualitative study focusing on a toolkit for mathematical modelling (MM) of societal issues with pre-service teachers of mathematics (PTs). A toolkit is a collection of different elements, such as readings, prompts, discussion tasks, lectures, etc., related to the societal topic and its teaching (Kacerja et al., 2024). In this class, 30 PTs (4th year) were shown a video as a prompt for some general discussions and a presentation about water scarcity issues in South Africa. Then, they were given a discussion task where they could choose one or more questions about water consumption to answer in their group work for 45 minutes. Here, the focus will be on a videotaped session of one group of four Norwegian PTs working with an MM problem exploring the amount of water used when washing dishes in a dishwasher versus by hand.

Mathematical modelling is a core element in the Norwegian mathematics curriculum (Ministry of Education and Research, 2019), and reality is the source of modelling problems. Several versions of the modelling cycle describe the MM process. Borromeo Ferri (2007) emphasises the activation of extra-mathematical knowledge (EMK) when working on a real-world problem in various MM phases, while Maas et al. (2019) value collecting information as necessary in the process. In addition, Salinas-Hernandez, Kock and Pepin (2023) found that students use general resources, curriculum, social and cognitive resources for solving MM tasks. In our study, we want to explore what extra-mathematical knowledge and what resources the PTs use in MM of societal issues in the different stages of the MM process. In the following, we present some preliminary results of our analysis of data from the group work. The analysis consisted of reading the transcribed data, defining different MM stages of the extended modelling cycle (Maas et al., 2019), and then looking at the kind of resources the students used as in Salinas-Hernandez et al. (2023), and identifying the kind of extra-mathematical knowledge PTs used, according to Borromeo Ferri (2007).

Preliminary results

The PTs were only given the real situation, the issue of water consumption, and they had to pose themselves a problem to explore. Here, the EMK is the PTs' own experience; one of the four PTs had recently bought a new dishwasher, and thus, he had information and details about it. The problem was to compare the amount of water used to wash dishes in the dishwasher with the handwash. In this way, they created a simplified model or a mental representation of the situation. Moving on to the next MM stage, towards a real model, they needed to collect information (Maas et al., 2019) in terms of EMK (Borromeo Ferri, 2007). Internet resources, or general resources in terms of Salinas-

Hernandez et al. (2023), were used to collect data such as how much water a dishwashing cycle uses, or how much water per minute it runs with a full tap. Thus, time and amount of water were naturally pointed out as variables in the real model. In addition, using their experience as extra-mathematical knowledge and as a resource, the PTs agreed that the number of dishes was also a variable to be considered and whether the dishwasher ran half-full or full. These resources were used to help the process of mathematizing. When designing the mathematical models of dishwasher vs handwash to compare the amount of water, they used their experience to decide how long it takes to wash some of the different kitchen utensils by hand and the number of dishes in full vs a half dishwasher.

In the validation phase, the PTs used their experience to validate the correctness of the data and expressed awareness when using the results to look back at their own EMK about water consumption. As one of the PTs said when they found that a full tap pours 6 litres of water: "That's terribly wasteful. Does anyone who washes dishes, if they wash dishes by hand, do it [use full tap all time]?". The PTs found a difference of 50 litres more water for washing by hand for a full dishwasher, which was much more than they expected.

Our findings show that the PTs used extra-mathematical knowledge in many of the MM stages, also more than those pointed out by Borromeo Ferri (2007). Further, the main resources were their own experience, as a social resource, cognitive resources such as their previous mathematical knowledge, and the internet search as a general resource (Salinaz-Hernandez et al., 2024). Further research will focus on analysing what kind of EMK and resources the other groups of PTs used when dealing with MM of societal issues, to be able to support PTs in their MM processes better and advance the research in MM of societal issues.

Bridging mathematics and sustainability: Exploring the role of sustainability in mathematics education

Carolin Kammrad[1] and Michael Meyer[1]

[1]University of Cologne, Germany; carolin.kammrad@uni-koeln.de

Keywords: Mathematics education for sustainability, Education for sustainable development (ESD), Questionnaire, Motivation, Sustainability

Sustainable development is a global priority, as emphasized by initiatives such as the United Nations' 17 Sustainable Development Goals (SDGs). Education for sustainable development (ESD) equips individuals with the knowledge, skills and values needed to foster sustainability. However, not all subjects have integrated ESD to the same extent – a disparity reflected in a year 9 student's remark in this study: "What does this have to do with maths?"

Mathematics plays a pivotal role in addressing sustainability challenges, from climate science to social justice (e.g. Skovsmose, 2023). Sustainability provides a practical context for key mathematical competencies, particularly process-related skills (e.g., modelling) and content-related skills (e.g., functional relationships and data analysis) (Reiss et al., 2016). Mathematical modelling tasks bridge abstract concepts with real-world applications, fostering critical thinking, problem-solving, and engagement (Niss & Blum, 2020). Furthermore, such tasks not only align with ESD goals but can also enhance students' motivation and emotional engagement with mathematics (Maaß & Mischo, 2012). There is a growing body of literature on the integration of ESD in mathematics education (overview in Vásquez Ortiz et al., 2023), but this study addresses a critical gap: understanding students' readiness to engage with sustainability-related tasks in mathematics. It explores students' attitudes, motivation, and perceptions of sustainability within mathematics lessons, with a focus on developing and validating a questionnaire as a tool for further research. The research is guided by the following questions:

1. How suitable are the developed items and scales for assessing students' engagement with sustainability in mathematics education?
2. What do the preliminary results from this questionnaire reveal about students' attitudes, experiences, and perceptions of the connection between sustainability and mathematics?

Method

A mixed-methods approach was adopted, centering on the development and validation of a questionnaire to assess students' engagement with sustainability in mathematics. Items were adapted from the PISA (Mang et al., 2018) and tailored to reflect sustainability contexts within mathematics education. The questionnaire includes Likert-scale items to measure attitudes, motivation, and experiences, as well as open-ended questions to provide insights that can be reconstructed using qualitative methods. This studies sample comprised 192 students (grades 5–12) across academic and vocational secondary schools in NRW, Germany. Data collection took place between December 2023 and May 2024, with all responses anonymised. Descriptive statistics identified trends, patterns, and

anomalies, and Cronbach's alpha evaluated scale reliability. Interpretive analysis of free-text responses is ongoing to explore recurring themes and distinctive perspectives.

Results and Discussion

In addressing Research Question 1, it was found that the scales used in the questionnaire exhibited exemplary to moderate reliability (Robinson et al., 1991). Cronbach's alpha values range from .623 to .859. In addressing Research Question 2, preliminary findings highlight the following:

- Limited integration of sustainability in mathematics: While 71% of students reported encountering sustainability topics in school, only 7% agreed that these topics were addressed in their mathematics lessons.
- Correlation between motivation and sustainability perception: Students who expressed greater motivation and interest in mathematics were more likely to recognize sustainability-related aspects in their lessons.

The questionnaire provides a foundation for assessing students' readiness for these tasks. Future work will expand the sample and refine the questionnaire to aid in developing tailored sustainability-focused tasks for diverse classroom contexts.

DEDICATION

This text is dedicated to Professor Kees Hoogland. At CERME10 in Belfast (Ireland) in 2017, he was among the proposers of TWG7 "Adults learning mathematics" and he was its leader at two subsequent CERMEs. He was a very inspiring mathematics educator with a particular eye for students in the "lower" tracks and for the low numeracy among vulnerable people. Among his scientific contributions is the Common European Numeracy Framework (Hoogland et al., 2021). Despite already being very sick, he still engaged energetically in the TWG7 discussions at CERME14 in February 2025 in Bozen-Bolzano (Italy). A few months later, Kees passed away on 14 June 2025 at the age of 64.

This paper introduces the new Thematic Working Group "Mathematics for work, society and personal development: lifelong learning" (TWG7) within CERME. This research domain focuses on mathematical opportunities, challenges and vulnerabilities that people of all ages face in a wide array of contexts. After a conceptualisation of the domain, we summarise our work at the CERME14 conference. Leading themes were (1) adults learning mathematics, which included mathematics in evening schools, in prisons, and in intergenerational mathematics learning, (2) mathematical literacy and numeracy, and (3) workplace mathematics and the vocational education that prepares for this. Synthesizing the discussions during the conference, we see the richness of theoretical and methodological approaches, commonalities across the three themes and a need for developing new vocabulary. Concluding, we evaluate the work of TWG7 and identify directions for future work.

Keywords: Adults learning mathematics, mathematical literacy, numeracy, vocational mathematics education, vulnerability.

Conceptualizing the research domain of TWG7 within CERME14

The Thematic Working Group with number 7 (TWG7) within the 14th Congress of the European Society for Research in Mathematics Education (CERME) covered the research domain *Mathematics for work, society and personal development: lifelong learning*. This was the first time a TWG had

this title. In this paragraph, we will explain this research domain before summarizing and synthesizing the presentations and discussions at the conference.

Although the title of the research domain of TWG7 was new, it built on work of the TWG7 *Adults learning mathematics* at earlier CERMEs. With the ambition to grow as a research community, it was decided to express the research domain of TWG7 in terms of purposes of mathematics rather than defining the research domain by a target group of learners. Obviously, the new domain still included all research on *adults learning mathematics*, as expressed by *mathematics for personal development* and by *life-long learning* in the new title. The appended terms *mathematics for society* expressed that TWG7 now also explicitly included research on mathematical capabilities needed for participating successfully as citizen in society (also known as *mathematical literacy* and *numeracy*). Finally, the terms *mathematics for work* explicated that TWG7 now also embraced research on *vocational mathematics education* and *workplace mathematics*.

The title change of TWG7 reflects a trend in mathematics education research, in which research foci, perspectives and themes gradually evolve (Inglis & Foster, 2018). Yet, putting different themes together may also lead to confusion and incoherence. Therefore, we (the co-leaders of TWG7) felt a need to discuss the research domain *Mathematics for work, society and personal development: lifelong learning*. We asked ourselves: what characterizes the research domain, what are its boundaries, and what are commonalities across themes? For instance, based on Gal et al. (2020), we agreed that the target group of TWG7 could by and large be connected to *precarity* of life situations (e.g., lacking predictability, job security, material or psychological welfare) and *vulnerability* in using and learning mathematics.

As part of our discussions, we looked at recently published research that may not have fitted the "old TWG7", yet would fit the new. An example was Chapman's (2022) case study of a 9-year-old girl in a voluntary, week-long knitting summer camp, in which she suddenly realises that she needs fractions and proportions for her knitting design. This study would fit the domain of TWG7 being about *mathematics for (hobby) work and personal development.* This study taught us that TWG7 can potentially include youngsters, and that mathematical activities can surface informally and unexpectedly within non-mathematical activities (e.g., knitting). Another example was Sundtjønn (2021), who describes mathematics classrooms with 16-year-old students in vocational education (hair dressing, technical production, etc.). This study would fit TWG7 being about *mathematics for work.* It taught us that vocational mathematics education can be (traditional, pure) mathematics education with few connections to the vocational future of students, albeit offered within vocational education institutions. A third example was from Kalman and Solares (2018), who portray how near-illiterate industrial workers cope with low salaries and their purchases and debts. This study would fit TWG7 being about *mathematics for society*. It taught us that near-innumerate people have complex numeracy strategies, that participants in the research need not be *students* or *learners,* but can be *people* without intention to *learn* mathematics, but still can *use, do, fear,* or *avoid* mathematics. Based on these discussions, we described the research domain of TWG7 as follows in the call-for-papers:

> The domain of *Mathematics for work, society and personal development: lifelong learning* studies the breadth and depth of mathematical challenges that people of all ages face in a wide array of

contexts. These contexts can be at home, in workplaces, in vocational education, in adult education (e.g., evening classes and prison education), in leisure activities, when coping with digital technology and media, and so forth. Throughout their lives, people encounter mathematical challenges for a variety of reasons, such as making informed decisions regarding personal finance and health, quality control in workplaces, or debates on global issues. The challenges can lead to vulnerability, frustrations, or avoidance, but also to finding ways of overcoming barriers. TWG7 concerns mathematical literacy, numeracy, critical mathematics education, using mathematics productively and reflectively in different environments, mathematics in and for work, large-scale surveys about mathematics for work and society (e.g., Programme for the International Assessment of Adult Competencies, PIAAC), and teaching and learning mathematics with adult learners (e.g., curriculum, pedagogy, and didactics).

TWG7 at CERME14 in 2025 in Bolzano (Italy) attracted 23 submissions: 17 papers and 6 posters. After a thorough peer-review process, seven papers were rejected. The resulting rejection rate of 30% was somewhat higher than that of other TWGs. TWG7 was attended by 19 participants coming from Germany (1), Italy (5), Netherlands (3), Norway (3), Sweden (3), Spain (1), and UK (3).

Below, we summarise the research presented and discussed within TWG7 at the CERME14 conference. The leading themes were: (1) *adults learning mathematics*, which includes mathematics in evening schools, in intergenerational family learning, and in prisons, (2) *mathematical literacy* and *numeracy*, and (3) *vocational mathematics education* and *workplace mathematics*.

Leading theme: Adults learning mathematics

Within adult mathematics education, many learners are vulnerable, have experienced discouragement, anxiety, failure, or even dropping out (Gal et al., 2020). Classrooms in adult mathematics education are characterised by age-, language-, culture-, and pre-knowledge-diversity. Reasons to enrol are the lack of learning opportunities during their youth, in particular women who have been historically excluded from educational pursuits due to gender-based caretaking responsibilities. Adults register for mathematics classes, among others, because of the wish to assist children with homework, or to acquire a diploma that opens access to career changes. However, there generally is a substantial turnover in adult classes, since disturbances caused by financial, family- or work-related issues may disrupt studies. However, adults' success in learning mathematics positively impacts not just their own lives, but also their family's well-being.

To this research, *Stacey* added a survey on adults' *anxiety* and *self-efficacy* in relation to their success in obtaining a formal mathematics diploma, the mathematics General Certificate in Secondary Education (GCSE). The results showed that males were just as anxious as females. Older learners were less anxious, had greater self-efficacy, and were more likely to pass than younger adults. Also, those whose first language was not English were more likely to pass than native English speakers.

The study by *Syyeda et al.* departed from the fact that many citizens, in particular in disadvantaged communities, are unaware of free mathematics courses offered in their vicinity. To reach out to immigrant women, they conducted an Action Research, in which they organized workshops with fun mathematical activities for children and their mother (or caretaker). At the end of the workshop,

information was provided to participants about courses at the local adult education college. Interviews confirmed a want for information, an eagerness to enrol, and the positive impact of *intergenerational learning* (or *family learning*) on empowering adults.

The research theme *adults learning mathematics* also includes research on mathematics education in prisons. Within this regulated environment, adult learners are vulnerable, miss their families and their agency, experience depression, and so forth (Ahl, 2020). Just like "regular" adult education, groups show age-, language-, culture-, and pre-knowledge-diversity, but the learning processes are also affected by the variety in lengths of stay (awaiting trial, having short- or long-term sentences), the lack of internet, and the presence of guards. Also, mathematical tasks with real life contexts (e.g., buying a mobile phone) connect to life in freedom, and hence can be frustrating and hurtful. Within TWG7, three studies were presented about the teaching and learning of mathematics in Italian prisons.

Both *Mennuni et al.* and *Regola et al.* presented results from the first phases of an Educational Design Research for mathematics education in Italian prisons, based on various data collections among mathematics teachers working there. *Mennuni et al.* analysed these regarding the intertwinement of learners' motivation, the class-group composition, and possibilities for personalization of the teaching. For instance, the high turnover of learners asked for personalization, and the small classes enabled this. Learners' background variety both hindered and enriched learning processes, and teachers witnessed that pure mathematical problems could make learners temporarily forget their worries or negativity. *Regola et al.* formulated design requirements and proposals, which included, among others, that activities should be exclusively based on pen-and-paper and *imagination*, due to a lack of internet, rulers, compasses, calculators, and so forth. Also, activities needed to cater for the fluctuating group of learners, have a low entry level to be accessible to many, yet also offer challenges to more advanced learners.

Galli et al. conducted an Action Research, in which a mathematics workshop was carried out, evaluated, refined and carried out again. Participants were adult men (18–30-year-old) awaiting trial. They analysed the classroom setting, the implementation of the planning, learners' attitudes and difficulties, and technical-logistical issues. Time management was complex due to learners coming late or walking out for a smoke. The workshops consisted of three parts: an engaging start, a core problem, and a take-away problem (to chew on after the workshop), which was very well-received. Participants engaged actively, testified of feelings of empowerment, and said that the mathematics offered an "escape from the vicious circle of everyday thoughts".

In the TWG7-discussions, we observed that classrooms in adult mathematics education differ in many ways from those in compulsory education. For instance, adults have a long and complex history of mathematics learning and their participation in classes is not obligatory, but driven by motives that can be personal or social. Nevertheless, adult mathematics classes are marked by substantial turnover, which brings challenges to mathematics teachers. We observed that the teacher competences needed in adult mathematics education are largely unaddressed in teacher education. Supplemental modules in teacher education may include the design of mathematics lessons tailored to adult learners' backgrounds, needs and interests, and strategies to flexibly adapt lessons when participation fluctuates. Regarding mathematics education in prisons, teachers need competences to design lessons

that do not require "forbidden" tools, that avoid reminiscing of life in freedom, and that provide "food for thought" for the hours after lessons. We also observed the methodological dominance of intervention studies such as Educational Design Research and Action Research, which testified of a need for research-based teaching approaches tailored to the learning of mathematics by adults.

Leading theme: Mathematical literacy and numeracy

The research theme *mathematical literacy and numeracy* focuses on the mathematical capabilities needed by citizens for participating successfully in society, which some researchers indicate as *mathematical literacy* and others as *numeracy*. Although the two terms differ in their definition, we use these interchangeably according to how presenting researchers used them. According to Gal et al. (2020), many adults with low numeracy are *vulnerable* in our data-driven society, in which citizens must make important decisions regarding health, finances, schooling, and so forth, based on quantitative information. Generally, numeracy levels impact adults' employability, well-being, health, and self-reliance, and also impacts macro-level factors in society.

Since social workers need to use quantitative information to assist their clients, *Mulder et al.* conducted a study on numeracy in social work education. They reviewed curricula in social work programs and administered a survey among students and found that financial and digital literacy were included in social work education, but not numeracy, yet all stakeholders recognized its importance.

Bor-de Vries et al. introduced a methodological study of 17 different research instruments to measure numeracy. The analysis turned out to be more complex than expected and results are still pending.

Hoogland and Díez-Palomar presented preliminary results from the latest international comparative study on adults' numeracy, the Programme for the International Assessment of Adult Competencies (PIAAC), which includes 31 countries and 160 000 adults. The assessment was carried out through tablet-based, door-to-door interviews. The overall results indicate, by and large, increasing skill inequities between and within countries, as well as between genders.

Díez-Palomar and Hoogland studied how *people in the street* understand the term numeracy. They conducted a survey among Spanish adults using an open-item questionnaire. Most participants perceived numeracy to be "about numbers", "performing basic calculations" or "mathematics for beginners". The difference between mathematics and numeracy was explained as the first being advanced and the latter being basic. Apparently, mathematics was associated with "school-like" things, whereas numeracy was not associated to using mathematics and mathematics reasoning for solving problems in everyday life. This research result means that many citizens, and likely also politicians and educational leaders, will be similarly ignorant that the meaning of numeracy is connected to solving real-life problems in order to participate successfully in society.

Bolstad studied theoretically three well-known conceptual frameworks for mathematical literacy by analysing underlying purposes, contexts, outcomes, and practices of mathematical literacy in these. Her results reveal that none of the frameworks captured the distinction between the social practices in which mathematical literacy is needed, and the social practice in which it is learnt. Hence, frameworks for mathematical literacy should consider both formal and informal learning, and also

the practices of teachers and their norms in providing learners with agency, time, and also with real-life challenges that learners care about and want to solve.

In the TWG7-discussions, we observed how the research theme *mathematical literacy and numeracy* overlapped with the theme *adults learning mathematics*, if only because the competences needed for *mathematical literacy* and *numeracy* are expected from adults. Nevertheless, *mathematical literacy and numeracy* is not confined to adults, but needs also fostering with younger learners. Another clear overlap of the themes *mathematical literacy and numeracy* and *adults learning mathematics* is their call for research on the typical teacher competences needed for teaching mathematical literacy, numeracy, adults learning mathematics, and mathematics in prisons.

Leading theme: Vocational mathematics education and workplace mathematics

In many countries, students at a certain age are separated into theoretical and practical streams based on "academic results", students' preferences, and a complex layer of socio-economic, ethnic and other factors (Dupriez et al., 2008). This separation is at the end of grade 4 (e.g., Germany), around age 13 (e.g., Netherlands, England), or around age 16 (e.g., Nordic countries, Italy, Spain). The mathematics curricula in practical streams can be similar or slimmer than in theoretical streams (Italy, Spain, England), they can focus more on future vocations (e.g., Germany), on mathematical literacy (South Africa), or can be a hybrid (Netherlands, Nordic countries). These environments for mathematics education are indicated as *vocational mathematics education*, whilst this term also includes *mathematics for the workplace* training to employees offered by industries (FitzSimons, 2014).

Within this research theme, *Sundtjønn* studied 16-year-old students in education for Technical Production, and their reactions to a paper-based mathematics task on calculating the volume of a moped cylinder. Using Wenger's (1998) theory of communities of practice, she classified the students as *legitimate peripheral participants* in their future vocation. Also, she conceptualized a new verb, *to authenticate,* for the process of assessing whether or not aspects in the task existed in real-life. While working on the task, students used their out-of-school knowledge to assert the given information in the task and the question as authentic, but not the formula-based solution method. Mathematics teachers in vocational education are recommended to recognize and use students' vocational expertise for task solutions, since this raises their motivation to engage with mathematics.

Knutson used tasks on construction work and geometry to interview vocational teachers and mathematics teachers at vocational schools and compare their perception of *educationally significant vocational mathematics knowing*. She derived six categories, which revealed whether and how a teacher foregrounded mathematics or the vocation: procedural memorization, context-bound grasp, conceptual comprehension, vocational-mathematical connection, vocational-mathematical fusion, and mathematics as component in vocational "bildung". For instance, the category "vocational-mathematical fusion" entailed that mathematics was perceived as essential, but insufficient for solving vocational problems, which by their nature cannot be solved without vocational knowledge. The study illuminates complexities in integrating mathematical and vocational knowledge, but also the wide variety in perceptions on mathematics held by teachers in vocational education.

Dalby studied the communities of mathematics teachers at 16 vocational colleges in a 2-year long change project, and like *Sundtjønn*, she used Wenger's (1999) theory of communities of practice. Traditionally, the mathematics teachers operated in isolation within the institutions, which led to divides between mathematics teaching and the mathematical competencies needed in vocational programmes. Through meetings, visiting each other's classrooms and recognizing commonalities, interdepartmental communities emerged that shared responsibilities for developing students' mathematics skills through better connected approaches to teaching mathematics. Simultaneously, the professional identities of mathematics teachers changed, with more emphasis on the educational context and less on the mathematics.

Muhrman and Frejd carried out a survey with learners (n=234) at two schools to statistically compare two teaching conditions of mathematics learning in vocational education and the effects on learner motivation. One condition was textbook-based mathematics learning in traditional settings, and the other was "subject-integrated teaching" with co-teaching by a mathematics teacher and a vocational teacher within a workplace environment. The results showed that students in the latter condition had a significantly higher motivation to engage in learning, more sense of the usefulness of mathematics, and felt better prepared for their professional future.

Another study on co-teaching in vocational education is from *Fiorentino and Montone*, who studied students' experiences in a classroom-based intervention, in which a mathematics teacher and a teacher of Fashion and Design collaborated and learnt from each other's worlds. Using the Theory of Semiotic Mediation (Bartolini Bussi &Mariotti, 2008), the researchers introduced the term *boundary artefact* for vocational objects that can serve the learning of mathematics, such as sewing patterns used in fashion design. They observed very positive reactions from students, who saw usefulness in mathematics and one exclaimed that this helped her see connections between fractions and ratios.

In the TWG7-discussions, we noted the improvements in students' motivation through the creation of "mathematical relatedness" in vocational mathematics lessons. Many students in vocational education have experienced disappointments when learning mathematics, and the TWG7 research showed that this potentially can be curbed when they come to see that mathematics can be useful in their future workplaces and also when they can use their vocational competences in mathematics tasks. We also noted that Wenger's (1999) theory of communities of practice was a two-edged sword in this research, assisting in the analysis of students as already having a vocational identity (in *Sundtjønn's* study), and in the analysis of the isolation of mathematics teachers and subsequent integration into the school community of vocational teachers (in *Dalby's* study).

Cutting across the leading themes and looking forward

In looking back at TWG7-papers, we see that several papers cut across themes. The study by *Mulder et al.* was about *numeracy* within the education of social workers. This study was about learning to use quantitative information in a vocation and therefore, also fitted the themes *mathematics for work* and *vocational mathematics education*. Similarly, the study by *Syyeda et al.* fitted *adults learning mathematics*, being about mathematics learning by female adults with an immigrant background. This study also fitted the theme *mathematical literacy and numeracy,* since it aimed at empowering participants with life skills. This thematic overlap of TWG7-papers revealed cross-overs between

research themes. It showed that the research domain *Mathematics for work, society, and personal development – lifelong learning* was not thematically fragmented, but interconnected.

Another thematic interconnection, in this case between *mathematical literacy* and *workplace mathematics,* came from *Frejd and Vos*. They theorized how citizens and workers interact with advanced mathematics (e.g., calculus), even if they never studied it. Their new concept, the *mathematical co-productivity chain*, describes how mathematical work by professional mathematicians is simplified, transformed and visualized into schedules and diagrams for use by citizens and workers. When using these, the behaviour of citizens and workers is monitored and sent back to the mathematicians for further improvement of the underlying mathematics. Hence, the mathematical co-productivity goes back-and-forth. Their society-based analysis revealed commonalities in workplace mathematics and mathematical literacy.

Frejd and Vos' new concept was just one example illustrating a need within TWG7 for new research vocabulary. Likewise, *Sundtjønn* conceptualized the verb *to authenticate*, *Knutson* defined what teachers perceived as *educationally significant vocational mathematics knowing*, and *Fiorentino and Montone* coined the new term *Boundary Artefact*. This scientific need for new concepts was appended by a need for a better popular understanding of two terms important within TWG7, namely *mathematical literacy* and *numeracy* (see *Díez-Palomar & Hoogland*), which additionally lack satisfactory translations in some languages (e.g., Spanish, German, Scandinavian languages). This urge to develop suitable concepts and vocabulary point at a future scientific agenda for TWG7.

Regarding theoretical frameworks, we noted a rich variety, but also a call by *Bolstad* for practice-based frameworks that differentiate between the "learning environment" and the "using environment". We noted that the first does not necessarily needs to be an educational institution, and eventually, the two can be the same environment. Additionally, the work in TWG7 had a surprising methodological variety, with an international large-scale survey (*Hoogland and Díez-Palomar*), various surveys (*Díez-Palomar and Hoogland, Knutson, Muhrman and Frejd*, *Stacey*), a long-term organisation study (*Dalby*), a curriculum study (*Mulder et al.*), a methodological study (*Bor-de Vries et al.*), several classroom-based intervention studies (*Fiorentino and Montone, Galli et al.*, *Mennuni et al.*, *Regola et al.*, *Sundtjønn, Syyeda et al.*), and two theoretical studies (*Bolstad, Frejd and Vos*). This variety in grain size in research methods, together with the earlier mentioned urge to develop concepts, vocabulary and frameworks, indicate that the research in TWG7 has ambitions and growth potential. Moreover, across all themes there was a call for research and development of specialised teacher education modules that cater for the teaching to *lifelong* learners and users of *mathematics for work, society, and personal development*.

Acknowledgment

We thank Beth Kelly for her important contributions to preparing for TWG7 at CERME14.

Mathematical literacy – What is missing?

Oda Heidi Bolstad

University of Agder, Kristiansand, Norway; bolstado@hivolda.no

In this theoretical paper, I discuss three different conceptualisations of mathematical literacy (ML): the five perspectives of ML proposed by Jablonka, the numeracy model proposed by Goos et al., and the PISA Assessment and analytical framework. After a short summary of each, I compare different aspects included in the three conceptualisations and discuss their commonalities and differences. The three conceptualisations can be related to different phases of education and teaching. However, none of the conceptualisations concern teachers' classroom practice and classroom norms. I argue that a framework for fostering learners' ML could involve aspects related to teacher practice and the social practice of the learners.

Keywords: Mathematical literacy, numeracy, numeracy model, PISA framework.

Introduction

We live in an increasingly data-driven society, in which mathematics plays an important role. Numbers and quantities are everywhere: in medical reports, describing political trends, providing financial advice, and advocating social policy. Also, governmental services present information to the public using mathematical ideas and devices. One recent example is the outbreak of the COVID-19 pandemic in early 2020. Health authorities provided information to the public about the spread of the pandemic in mathematical terms, such as various types of graphs, tables, and concepts, and mathematical modelling was used as a basis for prediction of the virus' transmission speed. Consequently, competences in mathematical communication, mathematical representation, mathematical symbols and formalism, mathematical modelling, and mathematical reasoning were needed to interpret the information provided (Aguilar & Castaneda, 2021). The COVID-19 pandemic is only one example of events contributing to the growing understanding that underdeveloped mathematical competences limit an individual's prospects in terms of health conditions, career opportunities, social well-being, financial security, and political participation. Considerations have been made as to what constitutes the mathematical demands, skills and knowledges needed to work within modern society. The term *mathematical literacy (ML)* denotes the competence to deal with the mathematically related aspects of engaging in society with independence and agency.

It is an educational goal to educate citizens so they can use mathematics to pose and solve problems and, hence, act in society and to further develop their understanding of the world (Hansen & Hana, 2015). Several policy documents and research papers provide definitions, models, and frameworks comprising aspects of ML. The different models and frameworks vary in their level of detail and comprehensiveness and in terms of which group of learners they concern. For instance, the Common European Numeracy Framework (Hoogland et al., 2020) and the PIAAC framework (OECD, 2021) concern adult learners. In this theoretical paper, I discuss three of the most widely cited contributions concerning learners in comprehensive school: the five perspectives on ML proposed by Jablonka (2003), the numeracy model proposed by Goos and colleagues (Goos et al., 2014), and the PISA Assessment and analytical framework (OECD, 2023). I use *conceptualisations* as an umbrella term when referring to Jablonka's (2003) five perspectives of ML, Goos et al.'s (2014) numeracy model,

and the PISA framework (OECD, 2023). I start by briefly summarising the three conceptualisations. Further, I compare them to reveal their commonalities and differences. Finally, I discuss whether there is something missing in the three conceptualisations of ML and what this might be.

Jablonka's (2003) five perspectives on ML

Jablonka (2003) uses the term mathematically literate to refer to a mathematically educated and well-informed individual. She discusses five different, and sometimes conflicting, perspectives on ML which are related to the different ways in which the relationship between mathematics, culture, and curriculum is conceived:

- ML for developing human capital: the ability to analyse, reason, and communicate ideas and results by posing and solving mathematical problems related to individual and social problems
- ML for cultural identity: the use of informal mathematical knowledge involved in cultural practices and artifacts. This also includes practices used in the workplace. Hence, it includes competences that are not developed in school settings
- ML for social change: the use of mathematics in pursuing social and political change.
- ML for environmental awareness: the use of mathematics to analyse, reason, and communicate ideas and results related to environmental problems
- ML for evaluating mathematics: the ability to evaluate the use of mathematical applications and to be critical in terms of its objectivity and its limitations

According to Jablonka (2003), the perspectives vary with the values and rationales of the stakeholders who promote them. She argues that it is impossible to conceptualise ML without promoting a particular social practice.

Goos et al.'s (2014) numeracy model

According to Geiger et al. (2015, p. 611), ML "is the capacity to make effective use of mathematics in contexts related to personal life, the workplace, and in exercising civil responsibilities." Goos et al. (2014) developed the numeracy model as a tool for teachers to plan for, and reflect upon, effective teaching and learning practice with a focus on ML. This conceptualisation of ML incorporates four dimensions that are embedded in a critical orientation to using mathematics (Geiger et al., 2015; Goos et al., 2014):

- contexts: the ability to use mathematics in various contexts in everyday life, work life, and citizenship
- mathematical knowledge: mathematical concepts, skills, problem solving strategies, and estimation capacities
- tools: the use of material, representational and digital tools to mediate and shape thinking
- dispositions: confidence and willingness to use mathematics in engaging with real-life tasks, and the flexible and adaptive use of mathematical knowledge
- critical orientation: using mathematical information to make decisions and judgements, support arguments, and challenge arguments or positions

Goos et al.'s (2014) numeracy model has been used in several research and development projects.

OECD's (2023) PISA 2022 Assessment and analytical framework

In the PISA 2022 Assessment and analytical framework is defined as

> an individual's capacity to reason mathematically and to formulate, employ, and interpret mathematics to solve problems in a variety of real-world contexts. It includes concepts, procedures, facts and tools to describe, explain and predict phenomena. It assists individuals to know the role that mathematics plays in the world and to make the well-founded judgements and decisions needed by constructive, engaged and reflective 21st Century citizens. (OECD, 2023, p. 22).

In this conceptualisation, ML takes place in the context of a challenge or problem that arises in the real world and comprises four categories:

- contexts: personal, occupational, societal, scientific
- 21st century skills: critical thinking, creativity, research and inquiry, self-direction, initiative and persistence, information use, systems thinking, communication, reflection
- mathematical reasoning and problem-solving processes: mathematical reasoning, formulating, employing, interpreting and evaluating
- mathematical content knowledge: quantity, uncertainty and data, change and relationships, space and shape

Comparing the three conceptualisations of ML

In this section, I compare the three conceptualisations of ML. I start by looking at the purposes for which the conceptualisations were developed. Next, I compare the three conceptualisations, focusing on whether, and in what way, the following aspects are included: contexts, mathematical content knowledge and skills, tool use, personal attributes, outcomes (what ML enables one to do).

Jablonka's five perspectives of ML concern societal and political issues beyond formal education. They serve as discussion points to display how it is not possible to conceptualise ML without promoting a particular social practice. Jablonka is not preoccupied with the types of subject knowledge and competences involved in ML or the teaching of these. Rather, her five perspectives concern various ways ML can be used in life outside the classroom. Hence, the purpose of Jablonka's five perspectives of ML is critique, of both society and mathematics, which is something citizens should be able to do. By contrast, Goos et al.'s numeracy model was developed as a response to educational policies in Australia, where ML is considered a general competence to be developed across school subjects. In this context, the development of ML was considered the mathematics teachers' responsibility. The model serves as a tool to support teachers, particularly teachers of other subjects than mathematics, to meet the curricular requirements to teach ML across the curriculum. It aims to capture different aspects involved in ML in a structured way so that teachers can easily use it when designing or evaluating ML tasks. In this way, the purpose of Goos et al.'s numeracy model is education and school, and it is explicitly directed toward teachers' practical work. The third conceptualisation, the PISA framework, aims to assess the extent to which 15-year-old pupils have acquired the knowledge and skills that are essential for full participation in modern societies. Therefore, it is developed to guide the structure and content of the ML assessment. PISA impacts curricula and policy in the participating countries (OECD, 2023), which has also been an explicit aim (OECD, 2004). The purpose of the PISA ML framework is, thus, to assess pupils' outcome of

schooling and to impact school policy. In this way, the three conceptualisations are developed for quite different purposes.

One common aspect of ML in the three conceptualisations, is that the capacity to use mathematics in real-life contexts is central. However, the way contexts are described in the three conceptualisations vary. Goos et al.'s numeracy model includes contexts from personal life, work life and citizenship. These are broad categories describing various areas of life from which mathematical situations may originate. Although the wording is slightly different, Goos et al.'s numeracy model contexts parallel the first three contexts in the PISA framework: personal, occupational, and social. Jablonka's five perspectives also concern contexts from personal, work life and citizenship. Jablonka relates using mathematics in personal, work related, or citizenship contexts to ML for developing human capital and conceptualises ML as "the ability to analyse, reason and communicate ideas and results by posing and solving mathematical problems" (p. 80). In this conceptualisation, the individual is at the centre because ML concerns the individual's ability to use mathematics to change their life prospects. This conceptualisation parallels the conceptualisation of using mathematics in context described by Goos et al. (2014) and the PISA framework (OECD, 2023). The PISA framework also includes a fourth context, scientific, which concerns the application of mathematics in the natural world, science, technology, and pure mathematics. This scientific context has no direct parallel in Goos et al.'s numeracy model, but it is related to Jablonka's perspective of ML for developing environmental awareness. In addition to developing environmental awareness, Jablonka also mentions contexts related to cultural practices, evaluating mathematics, and pursuing social change, which concern using mathematics to understand, challenge and change structures and practices in society. This conceptualisation of using mathematics in contexts does not only concern change for the individual but also a societal change.

Another central issue in ML is mathematical knowledge. Goos et al.'s numeracy model and the PISA framework both include lists of several types of mathematical knowledge needed to solve problems in real-world situations. Goos et al. list mathematical content and processes as one aspect. In the PISA framework, mathematical content knowledge and mathematical reasoning and problem-solving processes are separated. The five perspectives by Jablonka do not include such lists. In fact, Jablonka criticises the idea of universally applicable lists of knowledge and skills. She argues that "it is questionable whether mathematical skills can be separated from the social dimension of action and from the purposes and goals of the activity in which they are embedded" (p. 79) and that the description of transferable methodological or process skills "ignores the interests and values involved in posing and solving particular problems by means of mathematics" (p. 79). When considering societal and political issues and solving problems in everyday life, as described by Jablonka, the type of mathematical knowledge and skills used or needed is not a central issue. However, in school and educational policy settings, the curriculum guides the teaching content and the assessment of learning outcomes. In these settings, lists of knowledge and skills become a way to structure curriculum content and to adhere to curriculum goals. Hence, the educational perspective of Goos et al.'s numeracy model and the PISA framework may explain the inclusion of knowledge and skills lists in the two ML conceptualisations. Appreciating informal strategies and mathematical ideas involved in cultural practices is a form of mathematical knowledge that is usually included in curriculum documents, but not explicitly covered by Goos et al.'s numeracy model nor the PISA framework.

Informal mathematical knowledge relates to ML for cultural identity in Jablonka's perspectives and contributes to a social practice perspective of ML rather than an educational perspective, which is the case with Goos et al.'s numeracy model and the PISA framework.

Tool use can contribute to shape and mediate thinking in all sorts of contexts, within and outside school. Goos et al.'s numeracy model lists different types of tools: physical, representational and digital. The PISA ML framework also includes tool use but embraces the 21st century skill of computational thinking pertaining to abilities to reflect on the evolving role of computers and tools in day-to-day life, pattern recognition and decomposition, designing and using abstraction, and determining whether and which tools could be used. Jablonka does not mention tools as an aspect of ML. As with lists of knowledge and skills, I relate lists of tools to an educational perspective of ML.

A more personal attribute involved in being mathematically literate concerns valuing mathematics and holding the view that mathematics is useful. As many learners experience lack of motivation and meaning, and sometimes also anxiety, related to mathematics as a subject, curriculum documents emphasise the importance of developing positive attitudes toward mathematics (Goos et al., 2014). The view is that since ML involves using mathematics to solve problems in everyday life, a mathematically literate person is someone who considers mathematics important and useful and is willing to engage in mathematical problem solving. In Goos et al.'s numeracy model, this aspect is called dispositions. The 21st century skills in the PISA framework include creativity, self-direction, initiative, and persistence, which can be considered personal attributes involved in ML. The consideration of personal dispositions can be related to the educational perspective for which the two conceptualisations were developed. In Jablonka's conceptualisation, dispositions toward mathematics are not explicitly mentioned as an aspect of ML. Jablonka comments that although practices in everyday life and work involve mathematics, the mathematics involved is not an essential part of these practices. Therefore, positive dispositions towards mathematics are not a prerequisite for using mathematics to solve real-life problems. Rather, interest in the problem itself is important.

Being critical is an essential aspect in all three conceptualisations. In Jablonka's perspectives, ML for pursuing social change involves mathematical argumentation when contributing to debates about social equity issues. In a similar way, ML for creating environmental awareness involves using mathematics to understand and solve environmental problems, and ML for evaluating mathematical applications involves realising that the use of mathematics is not objective and has limitations. The critical aspects in Goos et al.'s numeracy model and the PISA framework relate to several of Jablonka's perspectives of ML. Goos et al.'s numeracy model is grounded in a critical orientation, emphasising that a mathematically literate person must evaluate the results obtained and recognise how mathematics is used for different purposes. In the PISA framework, the critical aspect involves using mathematics to explain and make judgements. In addition, the PISA framework includes critical thinking as one of the 21st century skills. Here, critical thinking involves making justified arguments and defending oneself from lies.

Although they were developed for different purposes and over a span of 20 years, the three conceptualisations have many aspects in common. However, there is one major difference between them related to what ML enables one to do. Goos et al.'s numeracy model and the PISA framework are focused on knowledge and understanding, reasoning mathematically, and using mathematics to solve problems and make decisions. A clear focus in Jablonka's perspectives is the importance of not

only using and understanding mathematics, but also to use mathematical knowledge and understanding to contribute to change, either in one's personal life, work life, or in society. Although one could argue that competence in solving problems and making decisions leads to change because deciding about something is usually followed by some sort of action related to that decision, acting on these competences to impact and change personal, social, work, and environmental situations for the better is not explicitly emphasised in the PISA framework and Goos et al.'s numeracy model. Also, potential conflicts that may arise when solving real-world problems are not discussed.

Table 1: Comparison of ML conceptualisations

	Five perspectives of ML (Jablonka, 2003)	The numeracy model (Goos et al., 2014)	PISA Assessment and analytical framework (OECD, 2022)
Purpose	Outcome (using mathematics in critiquing society and mathematics itself)	Education (supporting teacher practice e.g., in terms of task design)	Education (assessment, aiming to impact policy)
Contexts	Personal, work, citizenship, social, culture, environment, mathematics	Personal, work, citizenship	Personal, work, social, scientific
Mathematical knowledge and skills	Mathematical argumentation and critique	Concepts, skills, problem solving, estimation	Concepts, procedures, facts, reasoning, problem-solving, quantity, uncertainty and data, change and relationships, space and shape
Tools	Not specified	Representational, physical, digital	Not specified
Personal attributes	Not specified	Confidence, flexibility, initiative, risk	Creativity, self-direction, initiative, and persistence
Outcomes	Social and mathematical critique (understand, use, make judgements, argue)	Critical orientation (understand, use, make judgements, argue)	Critical thinking (explain, argue)
Social practice	Critiquing and changing society	Teaching	Testing

A summary of the comparison of the of the three ML conceptualisations is shown in Table 1. The summary shows that the focus of using mathematics in contexts and the grounding in the critical are the two issues in which three conceptualisations mostly align. However, while Goos et al.'s numeracy model and the PISA framework take an educational perspective mostly focusing on mathematical practices involved in ML, Jablonka focuses on social practices. According to Jablonka, engaging in solving real-life problems by means of mathematics is always situated in a social practice. This social practice perspective is not explicit in Goos et al.'s numeracy model nor the PISA framework.

Discussion and conclusions

Educational policy documents have been criticised for only providing descriptions of what ML is and what mathematically literate persons can do without any further support for teaching (Bolstad, 2020). The three conceptualisations of ML compared in this paper can be related to different parts of education. The PISA framework is comprehensive, as it aims to assess ML in a large international test. In this sense, the PISA framework can be compared to an official curriculum, with curricular aims and objectives and consequential assessments, but without guidelines for teaching. Goos et al.'s numeracy model is simpler, aiming to support teachers in conceptualising ML and planning ML teaching and task design. Therefore, Goos et al.'s numeracy model represents a teacher-intended curriculum. Jablonka's perspectives discuss what it means to be mathematically literate in different social practices and describe various ways in which ML can lead to action. These perspectives do not concern teaching specifically, but can be useful for considering the social, political, and cultural values promoted in a task or situation. Therefore, I relate Jablonka's perspectives to intended learner outcomes and how people use ML outside the classroom or learning environment. In this way, the PISA framework and Goos et al.'s numeracy model concern education and learning while Jablonka's perspectives concern the goals of education and the outcomes of learning.

The three ML conceptualisations include mathematical activities, personal attributes, and learner outcomes. Although they may support teachers to conceptualise ML and plan ML learning activities, I claim that something is still missing from discussions about conceptualisations of ML. None of the conceptualisations frame *how* individuals can *develop* ML, and how teachers can *foster* this development in the classroom. The term fostering is often used to denote teaching methods alternative to instructional teaching. Fostering ML requires more than an understanding of the concept and a set of task features. Aspects related to teacher actions, classroom norms, and the learners' social practises should also be considered. This claim is supported by Frejd et al. (2025), who showed that a combination of factors is needed to foster ML. The factors they identified, in addition to task features, were related to teacher actions and classroom norms that fostered pupil agency. Fostering ML requires classrooms governed by democratic norms providing learners with choices, time, challenge, and problems from real life that they care about and want to solve (Frejd et al., 2025). Frejd et al., thus, argue that it is not the tasks in themselves that are important. This means that even though a task is designed according to the aspects in Jablonka's five perspectives, Goos et al.'s numeracy model, or the PISA framework, the task implementation in the classroom may still adopt traditional teacher-centred practices involving traditional classroom norms and expectations focusing on the learning of mathematics. Such traditional practices and norms do not reflect the way mathematics is used by citizens to pose and solve problems which enables them to act and to further their understanding of the world.

Hence, none of the conceptualisations consider the difference between the social practice of the learning environment and the social practice where the ML is needed. A learning environment promoting the social practice of education in terms of traditional teaching and testing will not foster the use of ML in the actual social practice where ML is needed because the social practice of teaching and testing ML is different from, for example, using mathematics in societal critique. Simply setting a task in a real-world context does not educate citizens who can use mathematics to solve problems and engage in society. Fostering ML requires considerations of the learning environment and of the

social practices of the learners. Such considerations are important because different social practices have different norms, and these norms affect how people develop and use ML. A framework supporting the fostering of ML should, therefore, also include teacher practices. I argue for the need to further conceptualise ML in order that the social practice perspective in terms of teacher practices and learner practices is included. Further discussions about what such a framework could look like is encouraged. In this paper, my focus is on formal education. However, fostering ML happens in both formal and informal learning situations. A framework for fostering ML could also consider vocational and adult education, in addition to learning beyond formal education.

The shaping of mathematics teacher identities in vocational education through a whole organisational approach

Diane Dalby

University of Nottingham, UK; diane.dalby@nottingham.ac.uk

Most post-16 vocational education in England is provided by large Further Education colleges in which specialist teachers of formal mathematics courses are structurally separated from vocational staff. This leads to divisions between formal mathematics and the mathematical competencies embedded into vocational programmes. In this study, by engaging with an organisational change programme to develop a Whole College Approach (WCA) to mathematics, colleges developed new interdepartmental communities of practice with shared responsibility for the development of students' mathematics skills. Participation in these communities empowered staff to address organisational issues collaboratively and develop a more connected approach to mathematics but indications of accompanying changes in professional identities for mathematics teachers, with more emphasis on the educational context, also have implications for those working in vocational education.

Keywords: Mathematics teachers, vocational education, professional identity, communities of practice.

Introduction

In many Further Education (FE) colleges in England, specialist mathematics teachers teach formal courses leading to national examinations whilst vocational teachers are responsible for the mathematics that is embedded into their programmes. Mathematics teachers usually share workspaces with teachers of the same subject and become part of a team in which the primary focus is mathematics teaching. These teams form small communities of practice, held together by shared beliefs that shape the identities of the members (Wenger, 1999). Such communities tend to produce strong subject-focused mathematics teacher identities and can provide valuable opportunities for the professional development of teachers (Dalby & Noyes, 2022) but there are risks of stagnation or inappropriate models of practice when these teacher communities work in isolation from the broader vocational context in which they are situated.

In English post-16 education, there is a longstanding historical division between vocational education and academic subjects (Pring et al., 2009) and this separation is still evidenced within FE colleges in structures, operational processes and pedagogies (Dalby & Noyes, 2016). Although communities of mathematics teachers in these organizations are often tightly focused on subject-specific pedagogy, which is important to classroom practice, there are few opportunities to share across boundaries and develop a more holistic view of students' mathematics learning experiences.

The Whole College Approach (WCA) project sought to design and research an organisational change programme to support the development of a more connected and collaborative approach to mathematics provision, in which vocational and mathematics staff work together to address strategic, operational and pedagogical issues. The aim of this paper is to explore the question: *How does participation in collaborative interdepartmental communities of practice affect the professional*

identities of mathematics teachers? Although this was not the main purpose of the research project, the data available provide interesting evidence for discussion. Further details of the mechanisms and resources used in the WCA project can be found elsewhere[1] and a more complete report of the findings will be published separately.

Context

Most vocational education in England is provided by Further Education colleges. These are typically large and complex organizations that offer a wide range of study programmes, mostly vocational but some academic, to students aged 16 years and over. Students develop mathematics skills related to their vocational pathway in a way that is naturally embedded into their vocational learning but if they did not achieve a specified minimum standard in the General Certificate of Secondary Education (GCSE) mathematics examination taken at age 16 years in school, government policy requires them to attend additional mathematics classes and retake the GCSE mathematics examination. These classes are usually taught by mathematics specialists whilst the mathematics embedded into vocational learning is the responsibility of vocational staff.

Although some FE colleges use a more dispersed staffing structure, many have a centralised team of mathematics teachers who deliver formal courses such as GCSE mathematics to students from across the organisation. Students who are required to retake the GCSE examination would typically attend one or two mathematics sessions a week with these specialist mathematics teachers, often in rooms outside their vocational area, whilst the rest of their study programme takes place in vocational classrooms or workshops. These arrangements tend to reinforce a common perception amongst students that GCSE mathematics is an addition to their study programme with little connection to the mathematics skills they are developing in vocational sessions (Noyes & Dalby, 2020). The structural separation of mathematics teachers from vocational staff is a further barrier that means issues such as students failing to attend mathematics lessons, or exhibiting poor behaviour are difficult to address.

Theoretical perspective

There are two main theoretical areas of relevance to this paper. The first is the theoretical grounding of the WCA programme and the second concerns the interrelated concepts of professional identity and membership of a community of practice.

The WCA programme is based on a framework of theoretical concepts derived from studies of soft systems thinking, complexity and organisational behaviour. Although there are similarities to other whole organisational approaches (e.g. Coben & McCartney, 2016), differences in the aims and context meant that a bespoke theoretical framework was developed, based on five core concepts (contextual, holistic, interconnected, multidimensional, evaluative) from soft systems thinking. Significant contextual differences between colleges evidenced in previous studies (Noyes & Dalby, 2020) suggested the need to consider each college *context* carefully and develop context-sensitive change strategies (Trowler, 2005) for individual colleges. The large and complex nature of FE

[1] https://www.et-foundation.co.uk/professional-development/maths-and-english/cfem/cfem-resources-and-evidence/whole-college-approach/

colleges as organizations meant that a *holistic* approach was appropriate in which the limitations of working in complex situations was recognised (Hawkins and James, 2018). Within such an approach, it is important to understand the *interconnected* nature of the separate parts and value is placed on understanding how different functions interact (Monat and Ganon, 2015). A key element of the WCA programme was the formation of a small WCA team to lead their college intervention, which included a vocational teacher, mathematics teacher, vocational manager, mathematics manager and a senior leader. By involving staff from different levels and sections of the organisation, the aim was to allow complex interactions to be explored from different perspectives and these views then utilized to develop a *multidimensional* analysis (Checkland, 2000). The value of regular feedback when working with complex systems (Hawkins and James, 2018) was also embedded into the WCA programme through formal reviews for *evaluation* and reflection at regular intervals.

The underlying aim of the WCA was conceptualized as journey along a continuum from a position of organisational fragmentation towards coordination, and then collaboration, followed by the active participation of vocational and mathematics staff in efforts to improve students' experiences of learning mathematics. Although colleges started from different points on this continuum, the intended direction of travel was the same. Bringing staff together into purposeful interdepartmental communities and developing a collaborative way of working were considered important steps in the process. Each college commenced with their WCA team working through a set of self-assessment tasks and other materials, guided by an external expert. The dual aims of these tasks were to support the college in the analysis and planning of a college context-sensitive intervention, whilst also facilitating the development of the WCA team into a collaborative community.

The theoretical view of professional identity in this paper is grounded in a socio-cultural position where identity is shaped by social interactions and therefore constantly changing rather than stable (Holland, 2001). Individuals construct identities in their discourse that may be transient (Sfard & Prusak, 2005) but they explain their positioning at a point in time by synthesizing what they think and do into a sense of who they are (Grootenboer & Ballantyne, 2010). Identities are however shaped by social interactions and therefore the communities in which an individual lives and works are influential. The active participation of an individual in a community of practice allows a reciprocal process of membership and identity formation to take place (Wenger, 1999) in which an individual is influenced by the community and its shared beliefs but is also instrumental in shaping its values.

The professional communities that mathematics teachers belong to are important to the construction of professional identity (Wenger 1999). Although the communities that form within organisational structures may not always be active communities of practice as defined by Wenger (1999), a teaching team or department often develops the key characteristics of a domain of operation, a shared interest and commitment to each other. In a mathematics department we might typically see some individuals presenting identities that suggest they are the knowledgeable experts in the community and therefore occupy a central position, whilst others may identify themselves as peripheral members who are still developing skills (Lave & Wenger, 1991). Peripheral members would generally aspire to become more central and therefore the dominant behaviour, skills and professional identities of the 'knowledgeable experts' have a significant influence on the values and practices of others.

Apart from the departmental community, teachers may belong to other communities of practice, taking different positions within them and engaging with varying levels of commitment. The potential of additional communities of practice within a college to shape teachers' identities is the prime concern in this paper but it is also important to consider how such communities might be developed.

Research methods

The findings presented in this paper are based on research carried out during a two-year project (2021-2023) that aimed to improve the understanding, planning and implementation of whole organisational approaches for mathematics in English FE colleges. This involved the design, pilot and research of mechanisms and tools to support FE colleges with the development of a Whole College Approach to mathematics, and with the crafting of their own context-sensitive interventions to improve student engagement with, and achievement in mathematics. The research involved 16 FE colleges, which although self-selected, represented the diversity of Further Education colleges in England in terms of size and location. Each college followed the same basic WCA programme but designed their own college interventions as part of the study.

A case study approach was used, with qualitative data generated from interviews with WCA team members (27), formal written reports by colleges (34) and detailed observation notes from the termly meetings with each WCA college team. Two short surveys for WCA team members and two focus groups were carried out prior to the case studies to identify areas for exploration in the interviews. Monthly online meetings with representatives from the colleges were used to monitor progress and review emerging themes from the analysis. After an initial period, four colleges with contrasting early experiences of the WCA programme and contexts were selected to be the primary case studies.

An iterative grounded approach suitable for qualitative studies was adopted for the analysis, using emergent coding from which categories and key themes were developed. From the initial analysis, four in-depth case studies were developed, followed by further analysis to construct shorter summaries of the other 12 college cases and then a cross-case analysis. Only selected findings from key themes related to this paper are presented in the following section but other findings are discussed elsewhere (Dalby, 2024) and a more comprehensive report of the main study will be published later.

Findings

The reciprocal relationship between identity and membership of a community of practice (Wenger (1999), means there are key points of interest for this paper in two of the emergent themes from the analysis: the formation of inter-departmental communities; and mathematics teachers' identities.

Interviews and college reports showed wide agreement that the development of *an interdepartmental and multi-level WCA team* was an essential element of the programme and vital to the progress of colleges with the development of a WCA. Furthermore, there was strong evidence that developing an appropriate culture within this team was important since this enabled a holistic view of the issues to be constructed. Interview data and college reports showed how WCA team members came to recognise the value of different perspectives and realized that this allowed them to collectively construct a better-informed view of the complex mechanisms and interactions they needed to consider when planning interventions. Several WCA colleges, for example, reported that their early

discussions resulted in the conclusion that the real problem was not the one they initially thought they needed to address, and that recognising this led to more appropriately targeted interventions.

Observation notes of early WCA team discussions provided evidence of some repositioning of individual attitudes and beliefs during this process and shifts in narrative identity. For example, although some teams initially demonstrated divided views, especially between vocational and mathematics staff, their use of language changed after completing the self-assessment tasks, with increased use of "we" in their discussions rather than "us" and "them". This indicated a new shared ownership of the issues with mathematics and a change in identity that reflected recognition of a common interest in students' mathematical development. College reports evidenced agreement that the development of this shared understanding in the WCA team was important for practical reasons since it enabled them to develop more efficient collaborative approaches to operational issues, such as poor attendance at mathematics sessions, rather than trying to address these independently.

The need for more communication between mathematics and vocational staff was identified by most WCA teams as they worked through the self-assessment tasks in the early part of the programme. Different interventions were developed by colleges to facilitate more frequent interdepartmental communication such as: arranging informal meetings over lunch; designing joint mathematics events in vocational contexts; allocating a mathematics teacher to a vocational area to be a 'link' tutor; and visiting each other's lessons. Each of these served to increase communication, but also led to the development of new *interdepartmental communities of teachers* who worked collaboratively on interventions. Interviews and college reports showed how teachers gained understanding of other perspectives by engaging with these interdepartmental communities and discovered benefits from the increased communication, such as new ways of addressing operational and pedagogical issues.

Interviews and observations indicated changes in identity for teachers who participated in these interdepartmental communities. These are divided into three categories to indicate the different aspects of identity that appeared in the data. First, the *narrative identities* presented by teachers themselves provided evidence that the increased communication and better understanding of alternative views that developed within interdepartmental communities led to a softening of previously polarized positions. Mathematics teachers, for example, demonstrated more vocational awareness in their narratives and vocational teachers showed greater interest in students' progress with mathematics. This was empowering since both mathematics and vocational teachers were then less isolated in their attempts to tackle issues such as poor student behaviour or absence from mathematics lessons and could work collaboratively. Interviews with mathematics teachers suggested that they now saw themselves as part of a wider team, working in partnership with vocational teachers instead of acting independently with sole responsibility for students' progress with mathematics.

Observations and interviews also showed how the sharing of knowledge within these communities was instrumental in changes to teacher practice and their *enacted identities*. Mathematics teachers, for example, explained how they gained understanding of authentic vocational contexts that they could use in their lessons, or understood how to synchronize topics and make timely connections to the vocational programme. Vocational teachers referred to benefits such as formal or informal support from mathematics teachers to enhance their teaching of embedded mathematics, and a better

understanding of mathematics examination requirements that enabled them to support students more effectively. The development of enhanced knowledge was often linked to collaborative activities, such as visits to vocational sessions by mathematics teachers where they observed authentic uses of mathematics in context, or to instances when providing support for vocational staff during the general course introduction as simply a member of staff rather than a mathematics specialist.

There was also evidence of changes in *perceived identity* in interviews and reports, where references were made to students' perceptions rather than the teachers describing the changes explicitly themselves. For example, when vocational and mathematics teachers took part in a joint mathematics/sports event with their students that involved playing darts, remarks from students were used by staff to explain the difference in identity they experienced as a co-participant in learning activity outside the mathematics classroom, compared to their normal position as an isolated specialist subject teacher. Similar changes in students' perceptions were also noted by mathematics staff when they entered the vocational environment for other reasons, such as observing lessons or assisting with other planned activities. In some interventions mathematics teachers became actively involved in vocational sessions to the extent that they became just "teachers" to students rather than specifically "mathematics teachers". Although this shift in identity was less pronounced in other cases, there was wide evidence of participating mathematics teachers moving towards a position of being a *mathematics teacher in vocational education*, working collaboratively with vocational teachers, instead of a mathematics specialist independent from the educational context.

Discussion

In summary, the findings show how the development of interdepartmental communities with shared aims is essential to a whole organisational approach since these facilitate knowledge exchange and foster collaboration. Secondly, there is evidence that for mathematics teachers, membership of a mathematics-focused interdepartmental community leads to changes in professional identity. These changes were evidenced in their narratives (narrative identities), changes in practice (enacted identities) and in observations by others (perceived identities) but generally indicated a position of greater sensitivity to the vocational educational context and less isolation.

The benefits to students, mathematics teachers and vocational staff of developing mathematics-focused interdepartmental communities were evidenced in multiple ways. By spanning existing structures, traditional barriers between mathematics and vocational departments were broken down. Changes to practice with positive effects for students and staff emerged from collaborative working in these communities, and differences between vocational and mathematics teacher identities become less stark as each contributed to an increasingly shared ownership of mathematics provision.

A shared interest in improving students' experiences of learning mathematics led the members, over time, to a commitment to each other as they worked collaboratively to tackle the issues that emerged from their discussions. We might consider these as communities of practice since they demonstrated typical characteristics to those described by Wenger (1999) with their domain of operation defined largely by the parameters of the WCA project. It is important to note that although vocational teacher identities were not included within the scope of this paper, they were instrumental in shaping these

interdepartmental communities and so intrinsically linked to the development of mathematics teacher identities. This aspect of the interdepartmental community is worth further consideration.

Despite indications of positive effects on staff and students, the timebound nature of the study means that the sustainability of such communities and identities remains unexplored. Given the instability of identity under the influence of ongoing social interactions (Holland, 2001) and close connection to a community of practice (Wenger, 1999), the issue of sustainability is complex. However, the study provides evidence of the importance of establishing interdepartmental groups across existing organisational structures in England's FE colleges and the likelihood that these would need to be maintained to cultivate and sustain vocationally sensitive identities for mathematics teachers.

This raises questions about the extent to which it is helpful for mathematics teachers in vocational education to develop a vocational identity, and whether there is an optimal balance between this and a subject-focused professional identity. For most of the mathematics teachers in this study, their dominant identity still appeared to be closest to the subject-focused community of their mathematics department, but instances did occur where this became secondary. Positioning mathematics teachers in more than one community means their identities will be influenced by each of these to a greater or lesser extent, so both the nature of the community and level of interaction need to be considered.

Conclusions

As part of a wider study of the effects of the WCA programme, this investigation into teacher identity is only exploratory and the generalizability of the findings is therefore limited. There are, however, indications of multiple benefits to FE colleges from the formation of mathematics-focused interdepartmental communities and these are worth further examination. The shaping of teacher identities to embrace a wider view of mathematics learning than the teaching that takes place in a mathematics classroom opens opportunities for enriching lessons and demonstrating the relevance through connections to students' primary studies. Furthermore, being part of a collaborative interdepartmental community is empowering, allowing mathematics teachers access to different perspectives on the problems they encounter, and mutual support in addressing these. For the organisation, these communities bridge divisions between departments and curricula, strengthening traditional 'silo' structures through new social interactions and harmonizing contrasting sub-cultures.

The sustainability of such communities and associated changes in identity are yet to be explored, which leaves questions about whether the positive effects evidenced in the study can be maintained. However, the findings suggest that a more focused study of how membership of multiple communities of practice might be used to the advantage of both students and staff would be a useful extension to the discussion in this paper.

Discussing "Numeracy" beyond the scientific community: How adult learners define numeracy and what challenges arise from that for the coming future

Javier Díez-Palomar[1] and Kees Hoogland[2]

[1]University of Barcelona, Faculty of Education, Barcelona, Spain; jdiezpalomar@ub.edu

[2]HU University of Applied Sciences Utrecht, the Netherlands

The term "numeracy" is a term whose definition has been changing, particularly over recent decades, since it began to be used in the educational field in the middle of the last century. At an international level, there is consensus that "numeracy" refers to knowledge, dispositions, and cognitive processes (higher-order thinking skills). It also has affective implications, which influence learning. However, no studies investigate how adult learners, who are the end-users of any educational action, define numeracy. In this paper, we address this research gap and investigate its challenges.

Keywords: Numeracy, Adult Basic Education, Adults Learning Mathematics.

Introduction

We inhabit an increasingly interconnected world where "intelligent" devices progressively occupy spaces once reserved for human activity. A clear example of this shift can be seen in the proliferation of applications we install on our smartphones, which now perform mental calculations—ranging from simple to more complex—that we previously carried out in our daily lives. Our cell phones now provide these calculations by pressing a few buttons on a touchscreen. It is not only that we are surrounded by situations where numbers, their properties, relationships, uses, algorithms, and the reasoning associated with them are ever-present—this has been the case many times. What is new is that "intelligent" devices are now performing the calculations and making decisions that we once made ourselves after scrutinising and utilising the numbers or mathematical data presented to us.

In this context, *numeracy* is garnering significant attention. Data from the first cycle of PIAAC (Programme for the International Assessment of Adult Competencies) (2011–2012) revealed that a significant proportion of the population, ranging from 30–60% in low-income countries and 10–40% in high-income countries, scored below Level 1 on PIAAC's five-level scale[1]. But what does it mean to have a low level of numeracy in our current World?

[1] PIAAC uses a five-level scale: below level 1 (below 176 points, which means that respondents carry out simple processes such as counting, sorting, performing basic arithmetic operations, etc.), level 1 (176-less than 226 points, which means that respondents are able to carry out basic mathematical processes in common, concrete contexts where the mathematical content is explicit), level 2 (226-less than 276 points, which means that respondents identify and act on mathematical information and ideas embedded in common contexts with few distractors), level 3 (276-less than 326 points, which means that respondents understand mathematical information less explicit, embedded in contexts that are not always familiar), level 4 (326-less than 376, which mean that respondents understand a broad range of mathematical information

As we anticipate the release of the results from PIAAC Cycle 2, it appears evident that numeracy will assume an increasingly prominent role in the educational policy agendas of nations globally. The challenges we encounter are numerous, many of which diverge from those explored in recent decades concerning numeracy.

Therefore, one of the imminent challenges in adult learning research may be revisiting the concept of "numeracy" itself in this "new *technified* context".

In this paper, we explore the notion of "numeracy" by confronting two points of view: the *scholar's* definition of numeracy and the definition provided by adult learners, which are usually not included in the academic literature.

Theoretical Framework

To improve adult numeracy in contemporary society, we must first establish a shared understanding of what numeracy entails, providing a common framework for action. In PIAAC Cycle 2, numeracy is defined as "accessing, using and reasoning critically with mathematical content, information and ideas represented in multiple ways in order to engage in and manage the mathematical demands of a range of situations in adult life" (Tout et al., 2021, p. 93). This definition represents the most recent evolution of a concept that initially focused on the purely instrumental "ability" to work with numbers—referred to in the 1959 Crowther Report as the "mere ability to manipulate the rule of three" (p. 270)—and has since expanded to incorporate the broader application of numbers and mathematics to solve practical, everyday problems (Baker, 1998; Benn, 1997; Coben et al., 2003; Condelli et al., 2006; Cockcroft, 1982; Díez-Palomar, Ramis-Salas, Močnik, Simonič, & Hoogland, 2023; Gal et al., 2005; Gal, 2000, 2024; Ginsburg, Manly, & Schmitt, 2006; Hoogland, 2023; Hoogland, Díez-Palomar, & O'Meara, 2021; Hoyles et al., 2002; Maguire & O'Donoghue, 2003; Tout, 2020; Tout & Gal, 2015; Yasukawa et al., 2018).

As this concept has evolved, numeracy has become increasingly complex and multifaceted, continually adding new dimensions. The most recent definition of numeracy adopted by the EU (CENF – Common European Numeracy Framework) presents it as a multi-dimensional construct encompassing four key dimensions: context, knowledge and skills, higher-order thinking skills, and dispositions. Numeracy can be observed across various contexts, including everyday situations, work environments, civic engagement, financial management, health and care, recreation, and the acquisition of new learning opportunities.

Moreover, numeracy extends beyond basic arithmetic operations, including knowledge and skills related to dimensions and shapes, patterns, relationships and change, quantity and numbers, data and probability, and digital competencies such as the use of calculators and spreadsheets. Numeracy also involves cognitive processes—manifesting when we analyse situations, process information, reason, mathematise, solve problems, or engage in critical thinking. Lastly, the CENF framework includes dispositions, recognising that factors such as self-confidence, emotions, beliefs, collaboration,

---

that may be complex, abstract or embedded in unfamiliar contexts), and level 5 (equal or higher than 376 points, which means that respondents understand complex representations and abstract and formal mathematical and statistical ideas).

flexibility, and maths anxiety significantly influence how individuals engage with and apply numeracy in their daily lives.

Thus, numeracy has emerged as a complex, multi-dimensional concept. All these aspects must be considered when designing training programmes, analysing learning scenarios, or evaluating the specific responses of adult learners to educational activities.

Methods

The study presented here pertains to the case study conducted in Spain within the European *Numeracy in Practice* (NiP) project (2021-1-NL01-KA220-ADU-000 026 292). The primary aim of this project is to promote the definition of numeracy developed in the *Common European Numeracy Framework* (CENF) project (2018-1-NL01-KA204-038913) and to engage in dialogue with potential end-users.

A survey was conducted in the participating countries (Slovenia, Poland, Spain, Italy, Greece, France, Ireland, the Netherlands, and Austria) to explore how they define "numeracy" and what attitudes they have towards it. This paper focuses on the data collected in Spain around the first aspect: participants' definition of numeracy. The research question we discuss in this paper is: How do adult learners who participated in the NiP Project survey define numeracy? The aim is to compare this definition with previous work in the scientific literature, especially with the definition in the PIAAC framework (Tout et al., 2021).

A total of 20 adult learners (8.85% of the sample) responded to the survey, of whom 65% were women and 35% were men. The age distribution of the participants is outlined in the following table (four persons didn't provide their ages):

Table 1: Distribution of the Spanish sample

Age group	Absolute values
From 18 to 30 years old	1
From 31 to 50 years old	6
From 51 to 65 years old	3
From 66 to 75 years old	0
Over 76 years old	6

The survey was carried out through a questionnaire administered online. The link to the questionnaire was sent to various adult schools in Spain (Catalonia) by email and by phone, and the data was collected in a data matrix. Items were translated into Spanish. Since there is no direct translation of the word "numeracy" in Spanish, the term "*alfabetización numérica*" was used. The adult learners who participated in the survey answered the questions through the online questionnaire. The following table contains the items from the data collection instrument used in this paper:

Table 2: Selected survey items

Item 1. Gender // Item 2. Age

Item 3. Experience in the area of mathematics?

- I studied mathematics throughout primary school
- I studied mathematics at lower secondary school
- I studied mathematics at upper secondary school
- I studied mathematics as part of an undergraduate degree
- I studied mathematics as part of a vocational programme or trade qualification
- I studied mathematics in postgraduate studies
- Other (please describe)

Item 4. In what country are you enrolled as an adult learner?

Item 5. As an adult learner, what type of numeracy courses have you engaged with? Please select all that apply.

- Standalone numeracy courses i.e. sole focus of the programme was on numeracy and/or mathematics
- Integrated numeracy courses i.e. numeracy was incorporated into a programme with a different focus such as horticulture, cookery etc.
- I have never engaged in a numeracy course as an adult learner.

Item 6. Explain, in as much detail as possible, what the word "numeracy" means to you. Note: Numeracy can also be referred to as numeracy, mathematical literacy, arithmetic in your country.

Item 7. Do you think numeracy and mathematics are the same thing?

Item 8. Point out most important differences between numeracy and mathematics.

Item 9. Why do you believe numeracy and mathematics to be the same?

EXCEL was used to analyse the survey data. Open-ended questions were categorised and tabulated, with codes generated based on the thematic analysis of responses, following established procedures for the qualitative analysis of open-ended questionnaire data. The discussion in this paper uses the answers to items 1 to 9. First, the responses given by the survey participants to the survey questions (especially items 6, 7, and 8) were collected verbatim. A comprehensive list was compiled of all responses for each item. These responses were then grouped based on the presence of repetitions or similarities. Codes were subsequently developed by clustering participants' responses according to similar themes (see Table 3 for details), ensuring alignment with their original definitions and adhering to the discussion objective outlined in this paper.

Results

Most survey respondents indicated that they had studied mathematics at the primary or lower secondary level (with five adult learners reporting lower secondary education and another five saying

primary education). This suggests that for half of the participants, their formal study of mathematics spanned no more than eight years, with their mathematical knowledge limited to the primary or, at most, lower secondary level.

When asked about the types of courses in which they had studied numeracy, nearly half reported that they had learned numeracy in an integrated manner within courses not focused explicitly on numeracy. Only two respondents indicated they had taken dedicated numeracy courses, highlighting that most participants had yet to engage in specialised numeracy education.

From the profile of survey respondents, it becomes evident that the majority conceptualise numeracy as "basic mathematics." When asked to define numeracy, their responses were as follows (see Table 3):

Table 3: Responses to item 6

Responses
Numeracy is about numbers // To me, numeracy means to have knowledge about numbers // Introduction to the concept of number and its use // Learn about numbers // Any kind of calculations – problems // Different kinds of calculations // Learn different kinds of calculations // Learn to make calculations (arithmetic) // Learn calculations because you need them for the everyday life // Mathematics for beginners // Start studying mathematics // To start to learn mathematics // Yes, it is the beginning of mathematics // Understand deeply what the numbers are for.

The responses to item 6 reveal at least three distinct categories of definitions. Firstly, some respondents associate numeracy with "numbers," interpreting it as "knowledge of numbers" or "everything related to numbers."

Secondly, another group links numeracy to performing calculations, which could be "arithmetic." These individuals associate numeracy with operations such as addition, subtraction, multiplication, and division, with one respondent also including problem-solving in their definition.

Lastly, a further definition of numeracy emerges as "mathematics for beginners," where numeracy is seen as primary, elementary mathematics, serving as the starting point for more advanced mathematical study. Only one respondent referred to numeracy as involving a deeper understanding of the purpose of numbers.

When asked whether numeracy is the same as mathematics, the participants were divided: nearly half (nine of them) believe they are distinct, while the other half (eight of them) view them as synonymous. When asked to explain the differences, the results from item 6 were reinforced: most respondents associate mathematics with more advanced content, while numeracy is understood as "basic mathematics."

Table 4: Responses to item 8. What are the differences between mathematics and numeracy?

Responses
I do not know // In mathematics there are many things like equations, problems. Numeracy is like the alphabet but with numbers, for example, symbols // Numeracy is more basic than mathematics // Numeracy is to start mathematics // Numeracy is to start studying mathematics // The first one is beginners, and the second one is getting more advanced.

Discussion

The scientific community has adopted several definitions of numeracy. One prominent example is found in *The Assessment Frameworks for Cycle 2 of the Programme for the International Assessment of Adult Competencies* (OECD, 2021), where the Numeracy Expert Group (Tout et al., 2021) offers a pragmatic definition, emphasising numeracy's use in responding to real-life adult situations. This definition builds on previous OECD definitions (PIAAC Expert Numeracy Group, 2009). Hoogland and his collaborators (2021) present an alternative definition, highlighting numeracy's complex and multifaceted nature. Additionally, Yasukawa and colleagues define numeracy in sociological terms, framing it as a social practice (Yasukawa et al., 2018).

Across these definitions, one common theme emerges: the complexity of numeracy. This understanding goes beyond the earlier, more limited conception of numeracy as simply "basic mathematics," a definition prevalent in official documents of the mid-1950s (Crowther, 1959).

However, when adults are asked, "What do you understand by numeracy?" their responses tend to reflect a concept more aligned with how numeracy was understood in the mid-20th century rather than the contemporary definitions used by experts in the field.

An analysis of the responses provided (Table 3) reveals that "numeracy" is most frequently associated with concepts such as "numbers," "learning about numbers," "performing calculations," "any kind of calculations," or "mathematics for beginners." These responses suggest that adult learners perceive numeracy primarily as a basic mathematical concept, equating it with the ability to use numbers and carry out fundamental operations. This interpretation is further corroborated by the responses to item 8 (Table 4), where participants differentiate between "numeracy" and "mathematics," characterising the former as basic mathematics and the latter as encompassing "more advanced" topics, such as "equations" and "problems." Additionally, numeracy is metaphorically described as being "like the alphabet but with numbers."

It would be valuable to explore why the participants in this study hold such a view of numeracy. What factors contribute to their association of numeracy with "basic mathematics"? A possible hypothesis for further discussion is that the complexity of numeracy is often "invisible" and instead what we refer to as "mathematics" is "that which is visible." If that is so, then one challenge emerging from this discussion is the need to design training programmes that make the mathematics present in everyday contexts more visible, especially those forms of mathematics that are often not "recognised" as such. It is important to demonstrate that mathematics extends beyond what might be classified as

"advanced mathematics" (such as calculus, topology, differential geometry, vector calculus, numerical analysis, game theory, cryptography, etc.). Everyday mathematics, too, constitutes legitimate mathematical knowledge. These forms of mathematics have their representations (symbols, formulas), connections, rules, properties, and functions. They are used in reasoning and problem-solving processes.

Therefore, a key challenge for the near future is to highlight and make visible these aspects of mathematics, which are increasingly rendered invisible by technologies, artificial intelligence, and other factors. The goal is to raise awareness among adults so that they can use mathematics critically and effectively in various everyday situations.

Mathematics and vocational disciplines: A co-disciplinary perspective to reduce early school leaving

Michele Giuliano Fiorentino and Antonella Montone

University of Bari Aldo Moro, Italy; michele.fiorentino@uniba.it

The main aim of the research presented in this paper is to address the problem of early school leaving in vocational schools. For this aim we encourage the designing of co-disciplinary training courses, co-designed and co-led in the classroom by mathematics teachers and teachers of vocational subjects to bring out the existing link between the vocational subject and Mathematics. The link between the subjects is based on some vocational artefacts following the Theory of Semiotic Mediation and used as Boundary Artefacts. In this paper we analyse their semiotic potential and how their use has been fundamental in a co-disciplinary intervention which involved Mathematics and Fashion.

Keywords: Co-disciplinarity, early school leaving, boundary artefact, vocational school, theory of semiotic mediation.

Introduction

The main aim of the research presented is to address the problem of school dropout in vocational schools, designing co-disciplinary training courses, co-designed and co-led in the classroom by mathematics teachers and teachers of vocational subjects to bring out the existing link between the vocational subject and Mathematics. To involve students most at risk of dropping out of school, we propose a "meaningful" Mathematics (Wake, 2014) with respect to the vocational subject and vice versa we want to give meaning to the vocational subject through Mathematics. The Research aims to demonstrate how the integration between disciplinary contents and vocational disciplines is essential, which allows us to grasp the importance of the study of disciplines apparently distant from professions, such as for example Mathematics and the Italian Language, aimed at acquiring vocational skills and to improve the quality of vocational development. Often the students in these schools, especially in the first two years, testify to their academic and training difficulties which put the entire structure of institutional vocational training in crisis. Further support for this aim is highlighted by the contradiction that emerges from the national official documents (M.I.M., 2019). It therefore seems necessary to involve teachers of Mathematics and other disciplines in an innovative training course, because it is assumed that on the one hand, mathematics teachers do not know which specific mathematical contents are useful for vocational disciplines, on the other, teachers of vocational subjects need specific training in Mathematics, which is necessary to address some topics of their discipline. The theoretical framework that supported the research starts from the Theory of Semiotic Mediation (TSM) and is enriched by the introduction of Boundary Artefacts (BA), artefacts specially designed with the function of integration between Mathematics and vocational subjects. This article presents the analyses of the semiotic potentials of artefacts and some preliminary results relating to their use in a co-disciplinary intervention which involved Mathematics and Fashion. In this article we present the results of a first pilot study in which, through the voices of the students, the first evidence emerges on the usefulness of the co-disciplinary approach in reference to the phenomenon of school dropout.

Conceptual background

Drawing from the emerging understanding of mathematical activities in work contexts is fundamental to provide new insights into the role of Mathematics and its dual nature both as an area of study and as an increasingly diverse tool with application in and across many aspects of human life (Wake, 2014). In these cases, learning can be mediated by specifically created BA, inspired by the meaning supported by the seminal idea of a boundary object described by Akkerman & Bakker (2011). In addition, our idea of BA has the function to coordinate the different disciplines involved, even if the vocational practices that use them are different. They are suitable enough to maintain their meaning in the disciplines involved, but also flexible enough to be used effectively in each of them (Star, 1995). The BA, for us intended as an artefact in TSM, is any device created and realized by human beings for any objective. The notion of BA, which we refer, enrich the artefact's notion in TSM, in the sense that while using it, it evokes vocational meanings in addition to mathematical concepts. The notion of BA and that of schema of utilization (Rabardel, 1995) refers to the main focus of the TSM's construct of semiotic potential, that is the twofold relationship that the artefact has with the personal meanings emerging from its use, the mathematical meanings that might be evoked by such use and the vocational procedures emerging from its use. These BAs are, in this new scenario, operational tools to implement decisions, to make decisions and to represent a teaching situation intended as a "reference situation" for particular senses of the concepts in play (Vergnaud, 1994). Vergnaud's conceptual field theory, indeed, constitutes a reference theory, in which the proposed problem situations act to give meaning to the concepts in play. To identify such BAs, it seems necessary to bring together members of different disciplines with the aim of realizing a common object/task. Moving in this direction requires a co-learning inquiry approach, where the teachers involved learn together through inquiry, where inquiry is a mediating tool. Sharing Wagner's (1997, p. 16) thinking, in a co-learning agreement,

> Researchers and practitioners both participate to educational processes and school systems. Both are engaged in action and reflection. By working together, each could learn something about the other's world. Of equal importance, however, everyone can learn more about their own world and its connections to institutions and school. (Wagner, 1997, p. 16)

One of the aims of this approach is for researchers and teachers to work together to explore and develop the learning and teaching of mathematics. In our case, using a BA deriving from the vocational world, we aim to deepen and give meaning to mathematical concepts with the help of the other discipline involved and vice versa. BAs, the analysis of their semiotic potential and the activities connected to it, were designed within the TSM (Bartolini Bussi & Mariotti, 2008). TSM has its roots in Vygotskian socio-constructivism, according to which students are guided by their teacher to build mathematical knowledge by solving tasks designed with reference to the use of appropriately chosen artefacts. The use of artefacts and the deployment of their semiotic potential leads students to produce personal knowledge, which through mathematical discussions, orchestrated by the teacher, is gradually transformed into shared knowledge. The notion of semiotic potential expresses the relationship between the personal meanings emerging from the experience of acting with the artefact and the mathematical meanings recognizable by the expert in such actions; its strict dependence on the task, which must be carried out by the students, makes the artefact a key tool for designing

appropriate tasks. The TSM was used both by teachers during the co-planning of the training courses and in the analysis of the semiotic potential of the artefacts, and by researchers to analyse the results of the experimental activity in reference to Mathematics and the vocational discipline. Specifically, in the research proposed here, the tasks are appropriately designed to ensure that during the use of BAs they can bring out their semiotic potential in the same way both in relation to Mathematics and in relation to the vocational discipline involved. Their use and their dual semiotic potential are then made explicit in collective discussions (Bartolini Bussi, 1998) orchestrated by the teachers. In collective discussions it is also fundamental to analyse language, which especially in mathematics sees the use of mathematical registers as extreme forms of evolved registers (Ferrari, 2021). Moreover, from the literature, different approaches emerge in reference to the interactions between different disciplines, for the study presented in this article, it seems necessary to support the co-disciplinary approach. According to Blanchard-Laville (2000) co-disciplinarity is the way in which multiple researchers cooperate generatively on a specific project. In the common work there is the aim of co-thinking, that is designing a space in which different researchers do not have the same idea about something, but something allows them to co-think and bring out ideas to provide solutions. The interaction between the disciplines starts from planning and then materializes in observation, monitoring and reflection on specific training paths. This approach seems appropriate since the dialogue in this study occurs between teachers from different disciplines, in a co-disciplinary way.

The research methods and experimental design

In this article we present the results of a study based on design-based research (Swan, 2020). In particular, the operational phases of the project involved the identification of some problems, the solutions of which are the place where the co-disciplinarity between vocational subject and Mathematics takes place through a BA. The overall aim of the research study is to give meaning to Mathematics in relation to vocational subjects and vice versa, give meaning to vocational subjects through Mathematics. Indeed, our main assumption is that mathematical knowledge is relevant for the fulfilment of professional requirements (Winther, 2016). According with Lave & Wenger-Trayner (2008), we believe that basic skills such as Mathematics are the breeding ground for skills in the vocational field. This concept is based on the theory of situated learning. The specific aim of this research is to discover how the proposal of co-disciplinary educational paths, co-designed and co-led in the classroom by both the mathematics teacher and the vocational teacher, can bring out the existing link between vocational training and Mathematics, with the involvement of students, most at risk of dropping out of school.

We hypothesize that through this connection students give meaning to Mathematics as well as to the theories of vocational disciplines useful to the profession. Furthermore, our research hypothesis is that, by improving learning in the disciplines involved, students are motivated and find school learning useful for their future work. Therefore, the research questions we ask ourselves are:

- Does the co-disciplinary approach, through the use of BA, favor the evolution of signs and therefore learning?
- Can the involvement of students in such designed activities, and the evolution of their learning, motivate them to believe in the usefulness of school in professional development?

In Italy, vocational school is a secondary school (Grade 9 to Grade 13), which permits students both, continue with academic study and vocational career. The following experimentations were conducted in a second class, it means Grade 10, aged 15. Usually in these schools the drop-out rate is very high, quite near to 25%, in the first two years.

The organization of the teaching intervention includes various preparatory design phases before starting the classroom experimentation. Phase 1: Implementation of co-disciplinary work. Vocational and Mathematics teachers discussed the potential of synergistic work between Mathematics and vocational disciplines. Phase 2: Identification of BAs usually used in the vocational field, and analysis of their semiotic potential from both a mathematical and vocational point of view. Several BAs specific to the vocational subject were identified and analysed: the paper model, the quartometer, the flask with balls of different colours. The teachers explored the semiotic potential of the identified BAs. Phase 3: Structuring of educational paths to be tested in the classrooms. The analysis of the "dual" semiotic potential, that linked to the mathematical concepts evoked and that linked to the vocational discipline, allowed the structuring of a co-disciplinary didactic intervention. (Fiorentino et al., 2021). Phase 4: The educational intervention. A class of approximately 20 students was involved in this study and a co-disciplinary teaching path was conducted which involved Mathematics and fashion.

In the teaching paths, an initial problem situation linked to the use of the BA was proposed, the subsequent collective discussion on the first resolutions, subsequent problems to reinforce the evolution of mathematical concepts, and the final discussion. The mathematics teacher and the teacher of the vocational disciplines involved in the experimentation co-designed the activities (the initial and subsequent problems and the collective discussion questions) with the researchers. They co-led the experimental activity and mathematical discussions in class, while the researchers observed, filmed and analysed it. In the classes, approximately five to seven students were at risk of dropping out of school and had negative evaluations in both subjects.

Furthermore, unjustified absences from school were recorded at a rate of 70% in three months. To address our research aim, we analysed the transcripts of the Mathematical Discussions relating to the solution of the proposed problems and the use of BAs. To validate the teaching paths, a qualitative analysis of the transcripts was carried out, according to the criteria of credibility, reliability, transferability and confirmability (Guba, 1981). This study is part of a general project which involved 5 vocational institutes, 15 in-service teachers and around 300 students in the first two years of the schools involved. In the following we will analyse in detail only one of the experimentations, more details about the Chemistry and Mathematics experimentation are on Fiorentino et al. (2023).

"Vocational" artefacts: the case of the paper pattern and the quartometer

The experimentation regarding Fashion and Mathematics was conducted in a second class of the Industry and Crafts for Made in Italy address of a vocational school in the South of Italy. The Fashion teacher had already used a paper pattern to reproduce trousers, the mathematics teacher had addressed the concept of proportion and symmetry. In the first activity, students were asked to carry out the following problem: "Reproduce the pattern for making a bodice on a paper pattern". Students were provided with the artefact and worked in groups of 2 students. At the end of the activity, a collective

discussion was carried out by both teachers, with the aim of bringing out the mathematical concepts of proportion and symmetry linked to the concepts of the vocational discipline. The artefact used allows the modelling and creation of garments considering the algebraic and geometric relationships to create them, providing a flat representation of the garment that will subsequently be created. The identification of a part of the garment to be reproduced evokes the mathematical idea of the axis of symmetry which allows the symmetrical model of a quarter of the garment to be reproduced exactly; from the point of view of vocational discipline, however, it evokes the idea of folding fabric. The identification of specific positions in relation to each other on the paper pattern evokes the mathematical idea of proportion between two measurements; from the point of view of vocational discipline, we recognize the lengths of the circumferences relating to the waistline and the pelvis which are in proportion to each other. Finally, when switching from one size to another, the mathematical idea of proportion between measurements is evoked; from the point of view of vocational discipline, the proportions necessary to move from one size to another are highlighted. The second part of the proposed activity involved the reproduction of the garment created first at 1:4 scale, in the original format, to reproduce it in real size. This step is done using a further artefact: the "quartometer". This artefact is a real ruler built with a 1:4 ratio. The 1:4 ratio is not random, but is necessary, because it is linked to the two axial symmetries of the body. In fact, for example, to create trousers, the axis of symmetry that passes through the center of the crotch and the lateral axis of symmetry that divides the front from the back are considered. This ratio is also transferred to all trouser measurements to create a perfectly proportional model.

Data collection and analysis criteria

The analysis concerns the co-disciplinary discussion carried out in the following phase 4 to group work in which different problem solutions emerged. According to the specific hypothesis of this study, the following analysis attempts to highlight how the co-disciplinary training path has given meaning to the mathematical concepts compared to the concepts of the vocational disciplines and vice versa gives meaning to the vocational concept through the mathematical concepts in play. The analysis of some extracts from the experimentation concerning Mathematics and Fashion is given. In particular, here, the vocational discipline teacher suggests making a bodice with the help of the BA pattern. In doing this the students begin to draw one of the four parts of the bodice and place marks in particular positions. At this point the mathematics teacher intervenes by starting the collective discussion:

Mathematics Teacher: What are you tracking?
Giulia: the flank line
Mathematics Teacher: And why are you drawing it right there?
Giulia: it is central, there is a calculation to define its position.... from F we find G, then divided by two and we get the position… it is not central to everything, but only to this point F. This straight line represents the front and back of the dress…
Fashion Teacher: but are you only doing one side?
Vanessa: yes, I'm only doing the back side, because there is a front part and a back part... but then there is a "roundabout" here.... and then this part overlaps because they are symmetrical. Then the different elements are added, here is the shoulder and here is the neck (point with their finger to the lines on the paper pattern relating to the parts of the dress that correspond to the parts of the body).

Marzia: they are obviously not the same, but there are some symmetrical parts, once they overlap the body from here to here... (and indicates the position on your body of where the dress will be placed)... it is the half circumference bust... divided by the waist circumference and with this calculation we have the recovery... clearly based on the sizes... in 52, it is half of 104... 42 is half of 84 which is valid for size 50. Making (52-42): 4 ... because there are 4 thoughts, because we have four thoughts. It comes out 2.5. This 2.5 represents the gap.

Mathematics Teacher: Why the semi-circumference?

Marzia: it's done half the circumference why we are doing it half of the body... because when we let's go and place (the paper pattern) we place it double… because this is one half of the bodice

Arianna: Why it is reproduced on the double fabric... because the two parts are one front and one rear and then they come together... so the dress is divided into four parts... it is placed on the double fabric, that is, a large, folded fabric... We only make one, because when it is then placed on the fabric two parts come out...

In this extract, it seems clear how much the BA paper model manages to make students dialogue both by providing justifications relating to Mathematics and to the vocational discipline. In the discussion, in fact, in the underlined parts there are explicit references to the mathematical meanings of "symmetrical parts" and circumference, just as the references to the meanings of the discipline relating to what they are representing represents in the body appear to be clear. The discussion continues and the teacher, with the aim of moving on to the second BA, the quartometer, to bring out the concepts of ratio and proportions asks:

Mathematics teacher: how do I go from a small drawing to having a natural drawing?

Giulia: because we make the small drawing which is a quarter of the natural size... we have a particular ruler... for example, 1 cm stands for 4 cm… every centimeter corresponds to 4. Then we use a table with the measurements relating to the sizes… the pattern respects the proportions, everything is magnified 4 times… ¼ is a fundamental fraction for making clothes... starting from the drawing on a small sheet of paper, to move on to the creation of the actual size paper pattern, to finish with the cutting of the fabric and the composition of the dress with these wing the 4 symmetrical parts.

Arianna: I finally understand why we use the symbol ¼ for the ratio! It seems to me like something is getting clearer…

Marzia: I agree with Arianna, by really understanding what I'm doing, I prefer to stay here in class, so that I could better work with paper pattern on my own

In the response reported here, the reference made to the mathematical meaning of the 1:4 reduction scale with which the BA quartometer is made seems evident, indeed Giulia expressly says, "1 cm stands for 4 cm... every centimetre corresponds to 4". Furthermore, the non-randomness of the ¼ ratio also emerges, as it is expressly stated that "¼ is a fundamental fraction for the creation of clothes", referring to the "sewing of the 4…symmetrical parts". Moreover, Arianna highlights how the signs used are useful for her personal understanding of ratio concept. This seems giving an additional value to the mathematics learning. Finally in the last sentences by Marzia it seems to us evident how the involvement of students in such activities, could improve their learning and, above all, believe in the usefulness of school in their personal professional development.

Preliminary results and concluding remarks

Throughout the activity it was possible to observe the presence and interventions of the students most at risk of early school leaving, such as Marzia and Giulia. Furthermore, all of them participated in the

activities, actively intervening in the discussions. These students are often absent from school and, even when they are present, do not participate in class activities. Inspired by some intervention in the discussion, like the Marzia's one, we think that, by involving students in co-disciplinary activities aimed at giving meaning to the theoretical concepts of the disciplines, we can contribute to reducing school dropout. Students seem to demonstrate that they are rediscovering the meaning of symmetry when they encounter the difficulty to explain the position on their body. Furthermore, the reference to mathematical concepts to interpret the vocational concept itself and to the vocational concept to explain the mathematical concepts appears evident in the students' synthesis proposals. These connections seem to emerge thanks to the use of BAs and allow students at risk of early leaving school to achieve the aims set by teachers. In our study, the evolution of signs and learning through co-disciplinarity became evident in how students interacted with the BAs. The semiotic potential is reflected in the process of constructing knowledge, where students reinterpreted the mathematical meaning of proportions and symmetry through the use of BAs. The collective discussion made the dual meaning of the BAs explicit: mathematical concepts emerged alongside vocational reasoning. This process facilitated the transformation of initial student-generated signs into structured mathematical ideas, directly connected to fashion practices.

Theorizing how citizens and vocational workers interact in co-productivity chains with professional mathematicians

Peter Frejd[1] and Pauline Vos[2]

[1]Linköping University, Department of Mathematics, Linköping, Sweden; peter.frejd@liu.se

[2]Western Norway University of Applied Sciences, Bergen, Norway

Not all students need to master advanced mathematics (e.g., calculus) in their later lives. However, citizens and vocational workers may interact with advanced mathematics in, respectively, daily life and workplaces. To analyse such situations, we introduce the concept of "mathematical co-productivity chain", which connects work by (1) professional mathematicians and (2) citizens and vocational workers. We analysed three examples to characterize the concept. Our analysis shows that the mathematical co-productivity chain exists in various situations and be communicated through face-to-face dialogue or boundary objects. The citizens' and vocational workers' co-productivity involves interpreting and handling data, evaluating diagrams, identifying errors, and acting upon these. We discuss how mathematical competences revealed by the mathematical co-productivity chain can inform education for workplace mathematics and mathematical literacy.

Keywords: Mathematical co-productivity chain, mathematical literacy, mathematical models, mathematics education, workplace mathematics.

Introduction and theoretical backgrounds

Advanced mathematics plays an important role in society, such as in engineering and research. Therefore, curricula for general mathematics education often aim at guiding students to advance to the higher levels of mathematics (Mullis et al., 2020). However, many students do not advance to these levels, and when workers in industries are asked what mathematics they use, their answer often points only at primary school mathematics (Andreassen et al., submitted). In this theoretical paper we challenge the notion of separate worlds for advanced and basic mathematics and aim to analyse how people, who did not graduate in advanced mathematics, nevertheless may interact with it.

When mathematics is used in everyday life or at vocational workplaces, there is a network of people involved. For instance, a citizen's evaluation of shopping costs is framed by retailers' prices, the family's income, the landlord's rent, and so forth. Similarly, an administrator's creation of a timetable is framed by schedules and deadlines of others. From this relational perspective, citizens and vocational workers may engage in partial aspects of more advanced mathematical processes (Skovsmose, 2005). Also, they may productively engage and adapt their behaviour in accordance with advanced mathematics in various ways (Niss & Jablonka, 2020).

Skovsmose (2005) distinguishes three roles that people in society can have regarding mathematics. These are *creators*, *operators* and *citizens*. Creators are professional mathematicians employed by civil or industrial institutions (Frejd & Bergsten, 2016). They have a background in advanced mathematics and use data, theory, and existing mathematics to create new mathematics, such as mathematical or statistical models and algorithms. Often, these are hidden in technology but can materialise in spreadsheets, apps or graphs. The models, algorithms and data are used, applied or

adapted to specific contexts by *operators* (vocational workers). For example, a company that produces traffic lights will ask a *creator* to design generic software so a certain brand of traffic light can be used in various situations. An *operator* then installs such a traffic light at a crossroad. There, (s)he follows guidelines adjusting settings for the specific location. The safety provided by the light then impacts *citizens*. But the story does not end there. After installation, the citizens' behaviour is probably monitored and fed back to the creator to adjust the mathematical model and update the traffic system. In such situations, operators and citizens need neither knowledge of the advanced mathematics in the traffic system nor of the statistical analysis of user behaviour data. Hence, we see three groups of people (creators, operators, and citizens) interacting productively with each other in processes where advanced mathematics plays a role. This paper aims to characterise such interactions.

Inspired by Engeström (2001), we perceive the interactions between people in society as multifaceted. When a person engages in a goal-directed activity, this activity is mediated by tools (physical, digital, etc.), by the environment (other people, enterprises, etc.), the division of labour, and rules, norms and ethical issues in that environment. The installation of the traffic light already illustrated a division of labour between creators and operators. Between them, a manual served as a boundary object for their communication (Bakker & Akkerman, 2014). To engage in such an interactivity, each group will have their own benefits. The citizens gain a safe passage through busy traffic, whilst the creator and operator benefit financially through their salary for the work done. To study the interactions between creators, operators and citizens, we define a new concept named *mathematical co-productivity chain*:

> A mathematical co-productivity chain is a sequence of mathematical activities (shackles), in which two or more actors from different groups of people interact (links) in order to facilitate mathematical outcomes that drive social processes (co-productivity).

The rationale for developing this concept is to shed light on advanced mathematical activities in society as a series of interrelated activities divided among people with different mathematical backgrounds. This view goes beyond a perception of mathematical activities as being isolated and carried out from start to finish by individuals who all should have sound mathematical competences. Our study is guided by the following research question: *how can activities within a mathematical co-productivity chain between creators, operators and citizens be characterized?*

The background for our research is the fostering of mathematics, in particular for those who will not need advanced mathematics, which connects to research on mathematical literacy (Niss & Jablonka, 2020) and workplace mathematics (Williams & Wake, 2007). This begs for a description and discussion of operators' use of mathematics in vocational work, and of citizens' use of mathematics in daily life. An analysis of differences across the roles of citizens, operators, and creators in mathematical co-productivity chains can be a means to rethink mathematics education, in particular for those who do not want, need or can learn advanced pure mathematics.

Setting for the analysis

To answer our research question, we selected three authentic cases that we judged as fitting the definition of a mathematical co-productivity chain between creators, operators and citizens. These provided empirical data to characterize mathematical co-productivity chains. The cases were chosen

to represent each of the three perspectives, namely that of a creator, a citizen and an operator. The first case of the mathematical co-productivity chain concerned *the perspective of the creator*. We reanalysed interview data from an earlier study (Frejd & Bergsten, 2016). The study focused on how professional mathematical modellers worked. For the present study, we analysed in detail how one creator communicated with the people who were to use his models for planning their work shifts. The second case concerned the *citizen's perspective* and was based on reports from a family using an app to reduce their electricity bill. The third case concerned the *operator's perspective* and was based on the use of certain charts to monitor safety in laboratories. Using our definition for mathematical co-productivity chains, our analysis was to scrutinise each case and formulate characteristics of (i) the activities involved, (ii) the interactions taking place, (iii) ethical issues, and (iv) boundary objects in the co-productivity chains.

Results

The perspective of a creator

We describe the first case of a mathematical co-productivity from the perspective of a creator, namely an expert in mathematical optimization. He was interviewed to describe how he developed a work schedule in an organisation for health and social care (Frejd & Bergsten, 2016).

> Creator: When you have a problem… and you want to make it better... it's rare that the problem is fixed, packaged and ready to go. Usually there is a fairly long dialogue with the owners of the problem to try to understand the problem, to understand their language, to find out what kind of data they have. That dialogue can be incredibly difficult because there are usually conditions that are …, so obvious that they don't even say them .... Right now, when we're looking at planning in health and social care, these conditions are coming up all the time... We delivered a schedule where someone worked six or seven days in a row. Of course! They hadn't said a word about it, but it was so obvious to them that you can't work more than five days in a row, because then you start to get tired and that can be dangerous... Things like that come up all the time, ... it's an iterative process, you almost always have to do some kind of experiment first to see if you've got it all... You collect their requirements and then you do the test and then the misunderstandings come up. The misunderstandings are a step in the process.

Here, the creator explained that a dialogical interaction was needed for creating his scheduling mathematics. What he called “the owners of the problem” were the health workers and managers who were to use his planning model. The dialogue was complex, because the creator was insufficiently familiar with the operators’ workplace culture and regulations. He missed constraints that were obvious to the operators. This led him to develop a schedule that did not satisfy the operators. Communication back and forth was essential in this mathematical co-productivity chain. The creator described the interaction as an iterative process, whereby the first schedule model was tested by the operators, rejected and revised. In this way, the operators affected the creator’s mathematical process. The prototype mathematical model served as boundary object to mediate this communication.

Below, the creator explains aspects in the dialogue between creator and operators.

> Creator: First of all, you have to leave your own language behind to a very large extent, ... you make mistakes with mathematical terms, you absolutely mustn't do that, but you have to adapt as far as possible to the person who owns the problem... You have to have some kind of mutual respect for each other's competences and realise

> that you don't speak the same language, but you have to try to connect anyway. And you can't look down on people, you have to communicate in their language at that level as much as possible, otherwise it won't work.

For co-productivity, the creator had to show respect, avoid complex mathematical terms and adapt his language to the operators. He also emphasizes that co-productivity is based on trust. Yet, the co-productive process can also raise ethical issues, as mentioned in the following excerpt.

> Creator: Scheduling in health and social care is quite often done by the staff themselves or by managers. If you come in and do it for them, then people lose power... Because all of a sudden, you are taking away the power from people who have had the power... to set good working hours for themselves... You may need good managers to do that. But there are also ... those who have been given bad working hours in this working environment precisely because they are not so strong and good at speaking up for themselves. Suddenly, when we arrive ... without taking into account who they are and what their names are, it becomes somehow objective, and they are so grateful that they avoid these conflicts.

This excerpt reveals that the co-productivity chain can change the reality of operators; a new working schedule affects not just their own, but also their families' lives. Daily commitments, such as picking up children at school, may be disrupted by a new schedule. Also, power structures at the work floor can change, for instance, when decision making is transferred to others. When an outsider creates schedules without considering existing norms and conventions, some may lose privileges, while others may gain benefits. Then, ethics comes into play in the co-productivity chain.

The perspective of a citizen

For the second case of a mathematical co-productivity chain describes how the second author's family reduced electricity costs by reading mathematical information in an *app*. During three weeks in June 2023, the family logged their hourly electricity consumption (in kWh) and their use of electrical appliances. The electricity company applied hourly pricing, which means their electricity (in kWh) was cheaper at some hours, and more expensive at others. The hourly prices were announced one day in advance through a mobile phone app. A graph from the app screen on 14 June 2023 (see Figure 1) shows the electricity prices for the next day, 15 June 2023, expressed in øre/kWh (an *øre* is Norwegian currency). There is a price peak at 8-9 am, when households and industries compete for electricity, and a slightly lower peak in the late afternoon. By setting higher prices, electricity companies try to encourage a lower consumption when the network is extremely busy. Through the graph, the family could plan and adapt their electricity consumption for the next 24 hours.

Another graph in the app showed electricity consumption for the past days. The bar graph in Figure 2 shows the citizen's electricity consumption on Wednesday 14 June 2023 (in kWh). The citizen's family had increased their consumption and lowered it again before the 8-9 am price peak; according to their logbook, they had programmed their dishwasher and washing machine to run during these hours. Figure 2 also shows a moment in the afternoon with higher electricity consumption that avoided the second price peak. In the logbook, they reported some cooking and vacuuming between 4-5 pm. In this way, the citizens interpreted the price diagrams and adapted their behaviour to reduce the energy bill and simultaneously, contribute to reducing peaks in the electricity network.

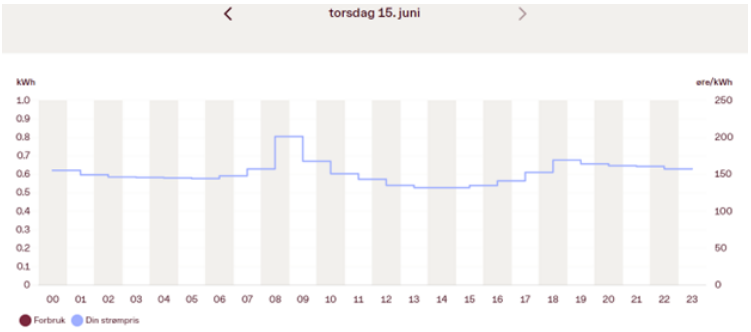

Figure 1: Blue line graph of hourly prices (in øre/kWh) for tomorrow 15 June 2023, diagram captured on 14 June 2023

Figure 2: Red bar chart of the family's energy consumption (in kWh) for yesterday 14 June 2023, diagram captured on 15 June 2023

In analysing interactions between citizens and the company, we assumed the company had a unit with mathematical professionals. These mathematicians used the data on citizens' electricity consumption to analyse how their pricing worked out. With their analysis, they could iteratively create new pricing encouragements to further change citizens' behaviour. The underlying mathematics (data, models, algorithms) remained hidden but materialised in a boundary object, namely, the graphs in the smartphone app. The app allowed citizens to collect data (about prices and their own behaviour) and decrease their bill. In this way, citizens and creators interacted in a mathematical co-productivity chain. Unlike the previous case, they did this without meeting directly. And again, there was an ethical aspect, namely, whether companies should be able to spy into citizens' behaviour on an hourly basis.

The perspective of an operator

The third case of a mathematical co-productivity chain relates to operators in laboratories, who use Levey-Jenning charts to monitor and control the quality of chemical and pharmaceutical test results. In clinical laboratories, this type of work can be critical for matters of life and death.

In the 1950s, industries with large laboratories started to hire statisticians to assist in quality control (Karkalousos & Evangelopoulos, 2015). Rather than testing every product, costs could be lower when taking samples, measuring critical characteristics thereof and comparing these to a certain range. The question was how operators (laboratory workers) could contribute to the statistical quality control. Generally, it was believed that operator's mathematical abilities would be low and lead to errors

(Smith III, 2002). To avoid these, pathologists Levey and Jennings designed the Levey-Jennings chart ("Laboratory Quality Control," 2023), see Figure 3. Based on earlier data and quality criteria, experts (creators) determined a mean and standard deviation. These were used to make seven lines in a chart, with the middle line representing the mean, and dotted lines above and below representing distances by one and two standard deviations. The outer lines, which are three standard deviations from the mean, were not to be crossed. In a Levey-Jennings chart, the centre line is usually coloured green (meaning "accurate") and the outer lines are coloured red (meaning "danger"). A laboratory operator was handed an empty chart. At regular time intervals, (s)he was to measure a sample item and plot the result into the chart. They were instructed to alert a supervisor if the measurement approached the outer limits.

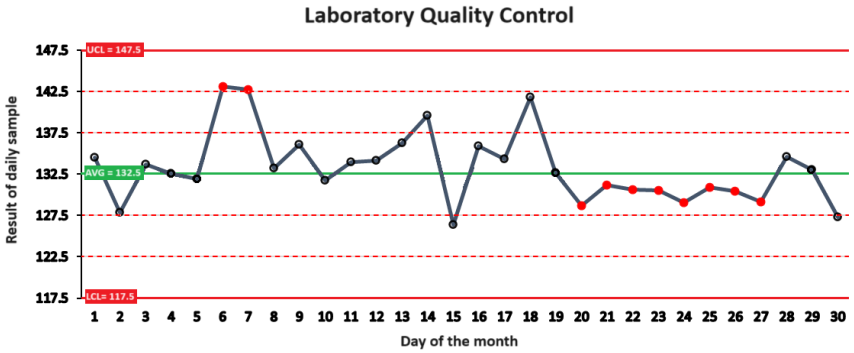

Figure 3: Example of a Levey-Jennings chart

Levey-Jenning charts are still in use today, but now digitally with automated alerts to further reduce errors. In Figure 3, days 6 and 7 are coloured red because two consecutive readings were above two standard deviations; this can indicate a handling problem. Also, on days 20 to 27, there is a sequence of several below-average readings, which can indicate a contamination or equipment failure.

The activities of laboratory operators involved taking measurements, plotting these into the chart, interpreting the chart, identifying points or trends that could indicate quality problems, and alerting experts (creators). The interactions between the operator and the creator takes two directions. On the one hand, a creator determines the values on the y-axis and the criteria for the alerts, which are sent to the operators. On the other hand, the operators take measurements, plot these into the chart, and sends these back to the creator for analysis and further statistical calculations. The interaction between creator and operator is facilitated by a boundary object, namely the data visualisation in the chart, which reduces the need to meet face-to-face. However, an operator may be able to interact with the creator if accuracy needs to be further improved, for example if the Levey-Jennings chart needs to be re-coded to display other alerts. As for the ethical aspects, we observed that this co-productivity chain is based on mistrust in operators' mathematical abilities.

Conclusion and discussion

Based on our analysis of (i) the activities involved, (ii) the interactions between operators/citizens and creators (mathematicians), (iii) ethical issues, and (iv) boundary objects, we identified characteristics of the theoretical concept of mathematical co-productivity chains. See Table 1.

Table 1: Characteristics of activities within a mathematical co-productivity chain

Case	Activities involved	Interactions, Gains	Ethics	Boundary object
Creator's perspective	Collecting data, eliciting information, adapting language, creating, testing and evaluating mathematical models	Two-way, face-to-face, long dialogues, iterative process, mutual respect Creator gains salary, operators get a better planning	Transfer of power over planning	Prototype scheduling model
Citizen's perspective	Interpreting statistics, evaluating and adapting own behaviour, feeding back behaviour data	Two-way, do not meet in person. Citizens gain a lower bill, creators reduce power peaks	Loss of citizens' privacy	Data visualizations (in app)
Operator's perspective	Measuring, plotting, interpreting chart, identifying errors, alerting creators	One way, rarely meet in person. Operator and creator gain salary, employer gains higher quality products	Mistrust in operators' skills	Data visualization (digital/paper)

In this paper, we contend that not all students will become creators of mathematical models. Thus, mathematics education cannot only emphasise the perspective of creators. Jablonka and Gellert (2007) argued that citizens and operators engage productively and adapt their behaviour in different ways according to mathematical models. Our results complement their findings by showing that advanced mathematics appears in society in a variety of ways. Advanced mathematics is complex, and with reference to Engström's (2001) notions of division of labour, environment and norms, we conclude from our cases that advanced mathematical activities take place across environments between people. The new theoretical concept of mathematical co-productivity chains provides new input for discussing aims and content of advanced mathematics education. The concept explains that in society, advanced mathematical activities are part of human collaboration and reveals ethical issues of decision making, privacy or mistrust. Also, it puts an issue on the agenda for research on mathematics education regarding those students who will not become professional mathematicians but study more practical mathematics, such as in vocational tracks. Of course, there are drawbacks to the concept, as a mathematical co-productivity depends on perspectives and contexts, such as the cases selected for this paper. We do not claim that all advanced mathematical activities are the same, but we want to point at the variations when considering the different roles that students will have in their adult lives. Based on the results of the three cases, aspects such as interpreting and applying different types of visualisations and diagrams in various technological tools used in workplace situations and in private life for making personal decisions and acting upon these, could be highlighted more in mathematics education. Such visualisations serve as boundary objects (Bakker & Akkerman, 2014) to translate the mathematics across different environments (Williams & Wake, 2007). The first case showed that the creator (a professional mathematician) adapted his language of

communication and showed respect to his partners (operators) when discussing a prototype of the schedule model. It is a goal of mathematical education to provide students with societal situations connected to vocational mathematics and mathematical literacy, and to show that mathematics is human, social and a tool to reflectively act upon and solve problems in society.

Mathematics workshops in prison: Design and practice

Sofia Galli[1], Giulia Bernardi[1], Domenico Brunetto[1], Helena Dell'Anna[1] and Francesco Nappo[1]

[1]Politecnico di Milano, Mathematics Department, Milan, Italy; sofia.galli@polimi.it

This paper presents the design and results of an informal mathematics education project for young adults in an Italian prison. The workshops were designed to emphasize problem-solving with the aim to provide inmates with skills transferable from mathematics to daily life. To overcome language barriers and different levels of schooling, a learning-by-doing approach was adopted. Participants' feedback indicate success in fostering mathematical and psychological empowerment: inmates reported increased patience, greater self-esteem, and improved mental engagement. Furthermore, the workshops promoted social inclusion by encouraging collaborative problem-solving among inmates, prison officers, and staff, highlighting the potential of mathematics to empower marginalized individuals and strengthen social bonds in fragile communities.

Keywords: Informal mathematics education, empowerment, problem solving, experiential learning, adult education.

Introduction

Prison education plays an important role in the successful integration of incarcerated individuals and in their social inclusion upon release (Manger et al., 2010; Ferrarello & Mammana, 2022). Mathematics education can be a powerful agency in these contexts due to its capacity to bridge educational gaps and empower marginalized individuals. In this regard, Byrne and Carr (2015) highlight the connection between perceived competencies in mathematics and improved social status. Andrà and Brunetto (2020) discuss how mathematics can trigger psychological empowerment. Here, we refer to it as longitudinal dynamic of development and attainment of a set of insights, and abilities best characterized as participatory competence (Kieffer, 1984). Roughly speaking, psychological empowerment is the process which turns a person from an object (passive and powerless) to a subject who acts on the world (Andrà & Brunetto, 2020). Moreover, as noted by Brunetto et al. (2021), developing problem-solving skills in the "safe space" of mathematics can be useful to gain confidence in daily life problem resolution, fostering mathematical empowerment. Mathematical empowerment is the development of mathematical skills and the ability of applying them both within formal context (e.g. school) and informal one (Andrà & Brunetto, 2020).

However, implementing a mathematics education experience in prison poses immense practical challenges (Byrne & Carr, 2015; Byrne & Harrison, 2022). Inmates typically have different levels of education and speak different languages, and attendance can be sporadic. Learning may also be interrupted because prison officers recall inmates during activities for various reasons, such as meeting with attorneys or communicating with other officers.

Last year, a collaboration between Politecnico di Milano (henceforth: PoliMi) and Casa Circondariale San Vittore di Milano (henceforth: San Vittore) gave our research group the opportunity to design and test an informal mathematics education program in a high-turnover prison context. The aim of our research was to identify suitable designs and practices that would make the program accessible to everyone, despite the aforementioned obstacles, and trigger empowerment. Moreover, we

wondered how mathematics could be used to foster a wider network of social relations within the prison context, reaching not only inmates, but also prison workers.

In this paper, we present design and findings from our workshops, highlighting the potential of mathematics education to enhance inmates' empowerment and promote socialization and collaboration, overcoming social barriers, in the prison context as a starting point for a social inclusion upon release. In this paper, we mean social inclusion as the equitable participation of individuals in social, economic, and political aspects of life (Rawal, 2008).

Methods

Research context

The collaboration between PoliMi and San Vittore started in 2021. The people housed in San Vittore are awaiting trial, after which they are either released or transferred to a permanent prison. The jail section we worked at hosts male adults between 18 and 30 years of age. Due to current policies, inmates remain locked in their cells for most of the day. This condition leads to a strong sense of powerlessness and self-deprecation among inmates (Brown, 2020). Since 2021, San Vittore hosts a PoliMi office (called "Off Campus") inside its premises, where researchers and students involved in prison projects can stay and work during working days. The PoliMi Departments that have so far been involved in this collaboration with San Vittore are Architecture, Design, ICT and Mathematics. Last year, all four of them jointly contributed to a project named "METHEXIS: Mathematics, narratives and generative spaces for extremely fragile contexts", funded by the 2023 Polisocial Award, whose overarching objective was to foster greater participation of inmates and workers in the young adult section in forms of social life and mutual support. As part of the METHEXIS project, an informal mathematics experience was designed to provide a neutral space where people with different backgrounds and with different roles in prison (e.g. inmates and officers) could work together to solve puzzles, setting aside the role barriers of prison life.

Conceptual framework

The research was conducted in accordance with the principles of Design-Based Research (DBR), defined by Wang and Hannafin (2005) as a methodology aimed to improve educational practices through systematic and iterative processes of analysis, design, development and implementation. Findings are based upon collaboration among researchers and practitioners in real-world settings, leading to the formulation of principles or theories. Based on this methodology, we designed a workshop, implemented it (May-June 2024), and collected data that served our analysis. Our subsequent evaluation led to a refinement of the initial workshop design, the implementation of a second version (July-August 2024), and a new analysis of the results.

The initial workshop design was based on previous experiences of mathematical instruction in immigrant communities (Brunetto et al., 2021) as well as existing literature about the teaching of mathematics in prison (Byrne & Carr, 2015; Maffia & Decembrotto, 2022). Furthermore, we considered experiential learning theory and informal mathematics education, where student learning is attained through personal experience and involvement (Kolb, 1984) also out-of-school (Kuş, 2024). In line with Manger (2010) we conjectured that experiential learning activities assume an even more

important role in prison. Indeed, convicted people are often relieved of any work responsibilities. Therefore, having a space where they can learn by doing can be an important incentive. We were also inspired by Maffia and Decembrotto's (2022) recent work, where the utility of assigning tasks with multiple levels of difficulty is highlighted. Finally, both in the way of conducting the meetings and in some of the proposed contents we took some hints from Liljedahl's (2021) thinking classroom.

Design and first implementation

Considering the above-mentioned studies as a conceptual framework, we proposed an informal mathematics workshop based on learning-by-doing principles (Kolb, 1984), with a focus on problem-solving. Our purpose was both offering stimuli to be active thinking about and doing mathematics and opportunities to cooperate regardless of culture, nationality, religion and so on. High turnover, sporadic attendance and differences in languages and mathematical knowledge (average schooling age being around 13) led us to design a short-length workshop consisting of six meetings that were not preparatory to one another and did not require fluency in Italian or previous mathematical instruction. The maximum number of participants was 15 and at least two tutors were always present.

Each meeting was structured into three parts. The first one served as an introduction to buy some time while waiting for all the people to arrive. We proposed intriguing challenges, preferably preparatory or at least related to the next parts. The second part was the core of the workshop: a problem-solving activity, possibly with several steps of increasing difficulty, according with the "flow" theorized by Liljedahl (2021), and following experiential learning principles (Kolb, 1984). In accordance with the experiential learning cycle, the main activity presented a problem in a concrete way (concrete experience) and allowed ample time for participants to reflect on the problem (reflective observation) and to devise solution strategies (abstract conceptualization); once the solution strategy had been identified, participants were presented with further instances of the problem to test their full grasp of the solution strategy (active experimentation). Both in the first and in the second part we invited participants to work in pairs or small groups standing in front of a vertical blackboard, as suggested in the "thinking classroom" by Liljedahl (2021). In Table 1, introductory quizzes and core activities of the first workshop are summarized. The third part was dedicated to a metacognition activity: we will return to this in the section about data gathering. During the final greetings, attendants were given a take-away puzzle that they could try to solve on their own over the following days. We handed over the puzzles also to the prison officers, hoping to create a connection between them and the prisoners.

Table 1: The activities proposed in the 1st edition of the workshop

Day	Introduction	Main activity
Day 1: The desk calendar	Some matches are displayed to form a number as in a digital screen. Moving only 2 matches, what is the highest/lowest number you can get?	Which digits must you write on each face of the cubes to build one of those desk calendars where the date is displayed on the faces of 2 cubes?
Day 2: Symmetry puzzles	Having several cutouts of shapes consisting of 6 squares joined together, identify which of these are developments of the cube and which are not.	Given a square sheet with some dots on it, you can fold it, as many times as you like, so that if you make only one hole, it is at all and only the dots.

Day 3: Points of view	Two players have the same number and type of cubes. One makes a construction, then gives instructions to the other to reproduce it without looking at it.	Solve different skyscrapers grids.
Day 4: Eulerian Graphs	Draw a small house without ever taking the pen off the paper and without going over an already drawn line.	Analyze several graphs to find the criterion for which it does or does not admit a Eulerian path.
Day 5: Eulerian Graphs	Explanation of the historical background of graph theory and the Seven Bridges of Königsberg problem.	Same as in Day 4.
Day 6: Strategy games	Play tic-tac-toe in one of the grids attached to the wall.	Find a winning strategy for the *nim game* starting with 7 bricks, in which players, in turn, can take 1 or 2 bricks. The winner is the last player to move.

Data gathering

In the third part of each meeting, we asked participants a metacognition effort: to fill out a journal answering the questions "What I did and what I learnt" and "What I liked and what I did not like". The purpose was twofold: help them fix ideas in a context where everything is transient and collect feedback. Moreover, at the end of the whole workshop, they filled in a questionnaire where we asked if they liked it, which meeting they liked the most, how they found the level of problems (both in terms of understanding the task and in solving it) and their preferred mode of work (individually, in pairs or in groups). For ease of access, we wrote it in both Italian and Arabic. The Likert scale ranged from 1 to 4, to avoid the medium value, and we opted for a graphical visualization of it, using "stars" as in reviews. After each meeting, the tutors also filled in a journal with observations about the classroom setting, how the activity was conducted, participants' attitudes, difficulties (both logistical and content-related) and interventions. These three data served us for the analysis of the first workshop, as required by the DBR.

The open-ended questions of the journals were analyzed according to the conceptual framework. In particular, the empowerment lens allows us to figure out if and what elements of the workshop trigger the empowerment, namely the participants manifest an experience of control on mathematics, on relationships, or on the future. Examples of such analysis are provided in the next sections.

Second cycle of DBR

We report here the most relevant findings from the analysis of tutors' journals of the workshop's first edition and changes in light of our evaluations. In line with Liljedahl (2021), we confirm that encouraging participants to work by standing in front of a vertical blackboard was very successful both in making them feel involved and in reshuffling working groups, to encourage collaboration between all; hence, we decided to improve this working method in view of the second edition. As

indicated in the literature (Maffia & Decembrotto, 2022), it is useful to give tasks that can be tackled step by step (e.g. the skyscrapers' grids and the Eulerian graphs). We noted that when someone understands the game strategy or the solution, they are enticed to seek challengers; this being a symptom of proactivity, we took care, in the second edition, to stimulate competitiveness to an appropriate and positive extent. We also observed that participants were often not autonomous in grabbing the materials to work on and tutor guidance was necessary. Thus, in the second edition, we looked into ways to encourage participants to be more proactive (e.g. leave the material on a table so that they stand up to get it instead of us distributing it desk by desk). To encourage participants to take better care of the material and to enable them to keep track of the path they would be taking, we planned to provide participants with a cardboard folder to collect all their materials in the second edition. Moreover, since in the previous edition some inmates came to us asking for the solution of the take-away riddle, we decided to put more emphasis on them by asking, at the beginning of each meeting, if anyone has solved the riddle provided the previous time. The metacognition activity of journals turned out to be too difficult for some of them, so in the new edition we decided to ask them just to write on a sticky note a free comment about the meeting at the end of it. Regarding questionnaires, using stars in the Likert scale turned out not to be a good idea both because the language of the reviews was not familiar to everyone and because in Arabic you read from right to left. We thus kept the same questions and same answers' range from 1 to 4 but changed the answers' format into multiple choice.

Considering the findings above, we implemented a second edition of the workshop, whose introductory challenges and core problems are described in Table 2. We made only a few adjustments to the schedule after the first edition, changing the order of the activities and adding a new activity (Day 4) devoted to solving logic puzzles similar to the matches' puzzle provided at the beginning of Day 1 in the first edition, which had proved intriguing for all participants: it seemed appropriate that this activity should not only be introductory but main. We designed this with the aim of supporting a challenge dynamic among participants, that we had noticed as positive, and to stimulate their proactivity, leaving them free to engage in the puzzles that they perceived as most appealing.

Among the changes we introduced in the second edition, having people standing in front of a vertical blackboard worked well, whereas asking them to take good care of the material in the cardboard folder failed almost completely. Referring to the solution strategy of the take-away puzzles at the beginning of each new meeting highlighted continuity throughout the six meetings.

Table 2: The activities proposed in the 2nd edition of the workshop

Day	Introduction	Main activity
Day 1: The desk calendar	Enter the numbers 1 to 8 in a specific grid, satisfying some constraints.	As in the 1st edition, Day 1.
Day 2: Strategy games	As in the 1st edition, Day 6.	As in the 1st edition, Day 6.

Day 3: Eulerian Graphs	As in the 1st edition, Day 4.	As in the 1st edition, Day 4.
Day 4: Mixed puzzles	Card tricks played by tutors.	Six different puzzles on the wall of the room and participants had a study card to mark their solution.
Day 5: Symmetry puzzles	Counting the numbers of triangles in symmetric figures.	As in the 1st edition, Day 2.
Day 6: Points of view	How to fold a sheet into a square and then the square into an equilateral triangle.	As in the 1st edition, Day 3.

Results

According to the student log, the average number of participants and the number of them attending at least 66% of the workshop were respectively 10 and 4 in the first one, 8 and 7 in the second one.

In the final questionnaires the most highly ranked meeting in the first edition was the one about Eulerian graphs, while in the second edition was that on skyscrapers grids. One participant reported the following motivation for enjoying the workshop on graphs the most: “because now I know the street rule”, referring to his having found the criterion for a graph to be Eulerian in his own words. Such a statement is evidence of perceived control on mathematics, at least temporarily. Considering the answers to the second questionnaire only (being it more reliable), the level of problems was judged fair (not too easy nor too difficult) by 87%, and 74% of participants always understood the task (37% at the very beginning, 37% after a while).

The qualitative data collected via journals and sticky notes highlight some notable findings. The role of patience in facing problems (“I confronted my patience and myself by doing these exercises”), participants’ perception of using mind and time well (“I enjoyed pushing myself more and more into more difficult exercises and challenging myself”; “It was stimulating for the mind”), increasing self-esteem (“I found out that I am smarter than I thought”). Such statements refer to controlling themselves: patience, challenging, and feeling smarter. There were also some comments on the opportunity that mathematics gives you in escaping from the vicious circle of everyday thoughts (“There was less noise and more concentration”; “I detached my mind a little, re-entering my logical world”) and some others on purely mathematical topics (“I saw new geometric shapes”; “Mathematical tricks. I learnt the binary system, winning at tic-tac-toe, winning at cubes”). Those are evidence of acting on mathematics, either thinking about or doing. Finally, some wrote about mathematical skills that can be transferred to daily life, such as “I learnt that to everything there is a reason and to everything there is a solution”; “I have learnt not to take anything for granted”; “I learnt to look outside the box” and the utility of mathematical instruction for their future, noting a link between the activities completed in the workshop and problems encountered in real life (“They are useful for our future, even outside [prison]”). Those manifest the control of using mathematics outside the specific context.

As mentioned before, one of the aims of our project METHEXIS was to offer opportunities for social life and mutual support. In this regard, we report the following comments: “I met new people”; “[I spent] a beautiful afternoon with a beautiful family”. Moreover, in both the final questionnaires, all participants indicated they preferred to work in pairs or in groups. Other feedback we had concerns the involvement of other prison stakeholders. As mentioned earlier, the take-away riddles had a twofold purpose: firstly, to give prisoners something to think about to kill time in the cells and, secondly, by also distributing them to prison officers, educators and healthcare staff, to create an invisible network of connections among minds all thinking about the same mathematical riddle. At first, we expected them to maintain a form of detachment and to not put themselves on the same level as the inmates. Over time, however, by making ourselves known as “the mathematicians of PoliMi” and establishing a riddle delivery as a ritual, their attitude changed. Seeing their growing interest, we started hanging a weekly riddle outside our office and left copies in small format to be taken freely by anyone interested. To our surprise, soon after that we observed inmates and police officers solving riddles together. This is evidence of the large potential of mathematics to create a neutral space where to free one’s mind and get involved and it seems to indicate very interesting possibilities.

Discussion and conclusion

In this paper, we presented an experience of informal mathematics education designed for young adults in a high-turnover jail in Italy. Different linguistic and mathematical backgrounds and discontinuous participation have represented crucial challenges for designing a successful workshop and, indeed, have had a strong impact on the way the meetings were conducted. Recalling the aim of our research to find an appropriate design and practice for an informal mathematics educational experience in prison, tutors’ observations and participants’ feedback suggest that, even in extreme conditions of low literacy and high turnover of inmates, there is considerable potential for mathematics activities based on problem solving and learning-by-doing principles to be empowering for them. We observe an important interplay between mathematical and psychological empowerment mediated by experiential learning activities: the comment “I learnt to draw possible and impossible roads, like life” is symptomatic of this. In drawing graphical patterns and identifying rules behind them, the inmate was appropriating a theorem. This could be an indicator of mathematical empowerment. This research indicates that psychological empowerment came from exploiting mathematics, reflecting upon roads which are not only graphical patterns but signify real life.

Researchers’ observation on the dynamics between inmates, prison officers, health workers and educators indicate that mathematics can offer a neutral ground for overall networking within the prison. This was made possible by devising take-away riddles that were accessible to anyone, but at the same time engaging. Further studies on mathematics education through experiential learning can help support its important role in creating a positive and inclusive social fabric in socially marginal and difficult contexts.

Teachers' perceptions of educationally significant vocational mathematics knowing

Hanna Knutson and Angelika Kullberg

University of Gothenburg, Sweden; hanna.knutson@gu.se

In construction work vocations, geometry evidently plays a significant role. However, the question of how geometry should be understood and used within vocational activities, and consequently how the topic should be treated in vocational education remains an important question of debate. In this study phenomenographic interviews were conducted with the aim to describe vocational and mathematics teachers' various ways of perceiving the core characteristics of "educationally significant vocational mathematics" knowing in geometry. The result shows a set of categories, which describe qualitatively different perceptions of this phenomenon. Taking all of these perspectives into account the study encourages a view of "vocational mathematics knowing" that goes beyond simplified procedures, specific concepts and context bound reasoning, and acknowledges mathematics understanding as an essential component of students' holistic vocational "bildung".

Keywords: Geometric concepts, vocational education, phenomenography.

Introduction

Vocational mathematics teaching and learning is a sub field of mathematics education research in which the context by definition plays a crucial role. Mathematics utilized in workplace activities is often embedded in vocational practice, making it an elusive component of vocational proficiency (Christidis, et al. 2024; Hoyles, 2010). Such tacit knowing, which could be difficult to identify and articulate, naturally poses significant challenges for teaching, and is therefore a critical area of educational research. However, the area has received rather scant attention, partly due to this complexity. Furthermore, there are significant differences in the use of mathematics across various vocations and between vocational education systems in different countries (Bakker, 2014). This study is carried out in upper secondary vocational education in Sweden, where a general mathematics course with a clear intended focus on vocational applications, have been mandatory at the vocational programmes since 2011. Previous research has highlighted both the significance of mathematics as a key component of vocational competence (Christidis et al., 2024; Muhrman, 2016) and the role of vocational relevance in enhancing students' motivation to learn mathematics (Muhrman, 2016; Dalby et al., 2016). Moreover, vocational mathematics knowing has been described as a complex learning objective, involving mathematical as well as vocational aspects, and within both of these areas, theoretical aspects as well as practical. The connection between those aspects, is also referred to as an intricate field of knowledge, which should be in the focus of attention when planning vocational mathematics teaching (FitzSimons & Boistrup, 2017). Furthermore, the fluctuating role of mathematics in vocational education has been highlighted, for example by Dalby and Noyes (2022), who exemplify a variety of requested mathematics qualifications for vocational students, which have been established and later discarded. Vocational mathematics thus seems to be an educational content for which the objectives are not clearly agreed and defined. Therefore, it is urgent to further

investigate, not only the teaching of vocational mathematics, but also perceptions of the very nature of the knowledge to be taught.

Geometry is both one of the main pillars of mathematics and an area of certain interest in construction work vocations. However, addressing real-world spatial problems requires partly different geometrical properties than those typically studied in mathematics, and is therefore a challenge in vocational education (Bessot, 2000). Boistrup et al. (2018) describe geometrical knowledge within a construction work context as an intersection between mathematics and vocational subjects, and pinpoint that mathematical knowledge is used both for application in practical problems, and to explain aspects of the vocational context. Also, Bessot (2000) conclude that geometry could be used both for solving practical tasks, and as a part of the discourse, which enables theoretical justifications of the practices taught. The concept of similarity is a fundamental geometric idea, which is important for further studies in mathematics (e.g., trigonometry and calculus) as well as for vocational practice (e.g., scale drawings and slope of e.g. roof or drainage). Starting from the concept of similarity and its applications in a construction work context, this study aims to provide a multifaceted description of vocational and mathematics teachers' perceptions of *educationally significant vocational mathematics knowing*. This is explored using a phenomenographic approach, which focuses on variation in peoples' perceptions of phenomena. In this way several facets of a phenomenon could be exposed, taking its' complexity, nuances, and contradictions, into account. The research question is: In what ways do teachers perceive *educationally significant vocational mathematics knowing*?

Theoretical framework and method

Phenomenography is an empirical and exploratory research approach, which aims to describe qualitative differences in peoples' perceptions of phenomena (Marton & Booth, 1997). Like phenomenology, phenomenography is based on the assumption that a meaningful phenomenon is constituted in the relation between the experiencer and what is experienced. The phenomenon is thus not a pre-existing entity but is perceived and constituted in this relation. According to phenomenography, a phenomenon can be perceived in a limited number of qualitatively distinct ways. Each individual perception contributes to the understanding of the phenomenon as a whole. That is, the aim of phenomenographic research is not to find a single "truth" about the phenomenon, but to describe the variation of perceptions (also called conceptions or ways of experiencing) that can be observed within a group of people. A phenomenographic result is typically presented as an outcome space of categories, which are often hierarchically related where higher-level categories reflect more inclusive or complex perceptions (Marton & Booth, 1997). A common type of phenomena studied within the phenomenographic tradition, are those that correspond to a specific subject content, e.g. how children perceive number. The study described in this paper, concerns a partly different phenomenon. Here teachers' perceptions of students' appropriate knowing, is considered. The outcome space, thus represent different perceptions of the knowing of a content, rather than different ways of knowing (or understanding) a content. That is, this study does not aim to articulate peoples' actual vocational mathematics knowing, which according to previous studies, is often embedded in vocational practices, but to investigate the ways in which this knowing is perceived at a meta level. The term *knowing* is used here in accordance with, for example, Carlgren et al. (2023) indicating a form of knowledge that goes beyond facts and concepts, encompassing a

disposition for action in real-world contexts. However, *knowing* should rather be seen as a mere labelling of the phenomenon than a pre-determined definition. In a similar way, the term *bildung* serves as a conceptual label for category 6, referring to a process of transformative professional development that encompasses values such as reflection, independence, and active engagement (e.g., Klafki & MacPherson, 2000). For this study, the phenomenographic research process was considered particularly appropriate, since it enables a categorization, which derives directly from the empirical material, and which highlights both important features and significant differences in teachers' perceptions. To suit a phenomenographic analysis, the empirical data should be focused and well constrained, and at the same time exhibit a richness of perspectives (Marton & Booth, 1997).

To this end, the empirical data was generated through in-depth semi-structured interviews. Eight vocational teachers (labelled V) and eight mathematics teachers (labelled M) from seven different schools were interviewed. The selection was based on a combination of purposive and convenience sampling. To ensure a consistent focus, all interviews started from a common set of tasks. Four mathematical textbook-type tasks were designed, aiming to cover different aspects of the similarity concept and at the same time relate to a construction work context. The first task concerned scale drawings. The second task dealt with the slope of a drainage, expressed as a ratio (1:200) and as a percentage (0.5%). In the third task the SSS similarity theorem was applied to enlarge the 3:4:5 triangle and thereby get a right angle. The fourth task involved constructing a porch roof, matching the slope angle of an existing house roof. To achieve this, the SAS similarity theorem, the concept of slope**,** or scaling, could be applied. The intention was that the group of tasks together should involve theoretical understanding of a constrained geometric topic (similarity), as well as potential relations to a broader area of mathematics and to a vocational context. By giving rich opportunities to make connections both within mathematics and within the vocation, the tasks were considered to constitute an appropriate starting point for the interviews. Open ended questions, regarding students intended learning, were asked in relation to the tasks. The interviewees' answers to the questions were assumed to reflect how they made sense of the phenomenon. The interviews lasted about 1h and were audio-recorded and transcribed verbatim.

Drawing on Åkerlind (2005) the analysis process proceeded as follows: To begin with the transcripts were read several times in order to identify a common phenomenon. Then, the sections of the interviews, which were significant for, and maintained a specific focus, in relation to the studied phenomenon, were selected as unit of analysis. The entire interviews and the selected quotes were read in detail to grasp the meaning conveyed in each quote, and to detect distinctive differences in meaning between quotes. Categories were formed based on the reading, and then reformulated, during a process of reading, analysing and comparing interview extracts and category descriptions. To enhance reliability, both authors, together with other researchers were involved at different stages of this process. In several phenomenographic studies it has been observed that the same person can express different or even contradictory perceptions of a phenomenon. The quotes were, thus, not seen as expressions of individual perceptions, but rather as making up a "pool of meaning" (Marton & Booth, 1997). Within the phenomenographic tradition a few different ways of analysing data have been described, all of them aiming to provide a set of categories of description, empirically grounded, clearly distinguished, logically interrelated, and being as few as possible (Åkerlind, 2005). The

current analysis was carried out focusing alternately on the "what" and "how" aspect of the voiced experience, in order to capture key features of the categories. Phenomenography, like gestalt theory, assume that people tend to experience phenomena as meaningful wholes, and that the way they attend to specific parts, reflects how they make sense of the whole. That is, by noticing "what" teachers chose to focus on, and the ways in which these parts are discussed, conclusions could be made about "how" the phenomenon is understood.

Result

As a result of the analysis an outcome space of six categories of description emerged. The categories should not be seen as mutually ranked in relation to a preconceived view of the phenomenon, but rather as complementary perceptions, representing different facets of the phenomenon. *Educationally significant vocational mathematics knowing* is perceived as:

Category 1: Procedural retention of isolated facts and methods

In this category, the phenomenon is perceived as a toolbox of useful, memorized procedures, facts and rules, which could be utilized to perform a specific task. This perception is characterized by reference to isolated skills, number series or techniques which could be used, without necessarily understanding the mathematical rationale behind them. Typical for this perspective is also that mathematical competence, needed in vocational practice, is described as mainly "basic arithmetic skills" (V1, M7). When describing what students need to understand the focus is on knowing how to do, and students learning is discussed in terms of "it's something you have to imprint" (M1) and as "it should become second nature" (V1).

M3: They can learn, maybe, **certain procedures and things like that** (…) if they see 6.5 cm on a drawing and they know the scale, then they can remember to multiply by 50 or multiply by 100, for instance.

V1: You take the height measurements in cm, and then the difference, and then you get, in this table, the roof slope (…) **They ought to be able to learn this:** If you know that you should have one meter in level, like that, and a height there and a height there [pointing]. **That's how you get the roof slope**.

These quotations indicate that, handling the task, is in the foreground. In contrast to the next categories, this category focuses on retention rather than comprehension, and it relates the phenomenon mainly to vocational practice rather than to vocational experience and education.

Category 2: Practice based grasp of specific vocational tasks

Here *educationally significant vocational mathematics knowing* is perceived as context bound understanding, a vocational skill, to be learned by hand and used in a specific vocational situation. The vocational task is in the foreground, perceived as an integrated whole, in which the mathematical part is not discerned from the context. In contrast to category 1, however, students intended knowing is not only referred to as remembering what/how to do but rather as understanding in practice, by grasping it with the hands. This perception is expressed in the interviews through a focus on practice-based knowing, developed in specific situations, using concrete tools and materials.

V3: They learn quite easily to calculate the meter. So, if the pipe is 6 meters, how much should it be from that end to this end then? Then they divide it into meter segments.

(…) They usually work with **6-m long pipes, and 1m parts**. We have made it like that, so that it should become pretty easy for them. (…) When they come out to the workshop, (…) **they can do it with their hands**. Then they get a **completely different understanding**. (…) You need to work with it there and then, like, now we're working with this, and explain it.

That is, when discussing how the concept of slope might be explained, reference is made to specific pipes of certain dimensions, and it is pinpointed that students get a completely different understanding when they might work with their hands and learn in a concrete situation.

Category 3: Conceptual understanding of vocationally relevant mathematics

In this category, generalized understanding of geometric concepts, is in the foreground. This perception is, for example, indicated through an emphasis on the importance to "grasp the essence" (V2) and "explain the connections" in contrast to just "learn things routinely" (M2). Students intended knowing is referred to as "understanding why" rather than just "how to do" (V2), and as "truly understanding concepts theoretically" rather than "understanding in a context" (M6).
